It is an ambitious project to cover the nutrition of pigs and poultry in a single volume. The *Proceedings* cover four main aspects: (1) general physiology and principles of nutrition; (2) environmental physiology; (3) nutrition of poultry and (4) nutrition of pigs, and in terms of page space these subjects are dealt with in the ratios of 1 : 1 : 1 : 2. Section 1 serves as an introduction and is mainly a re-examination of fairly well established knowledge. Section 2 brings home the fact that the scientific study and evaluation of the environmental physiology of both pigs and poultry is a comparatively new field, demanding far more intensive investigation than so far has been given to it. Although these studies are still largely academic the practical importance of this work will mount steadily over the next few years. It is now becoming recognized that much of the older nutritional work with these species completely disregarded the all-pervading influence of environmental factors, which assume an ever-increasing importance in the practical translation of laboratory findings to the field of economic animal husbandry.

Section 3 is concerned with poultry nutrition, and it is well accepted that the nutrient requirements of poultry generally are better understood than those of any other economically important class of livestock. The main trend to-day is to work out a more complete understanding of the optimum relationships between energy, proteins, minerals and vitamins and to translate these into terms of practical dietary formulation. Section 4 covers the nutrition of the pig in all aspects from the nutrition of the fœtus, the pregnant and lactating sow, and the piglet through the normal phases of growth and fattening. In this major section of the *Proceedings* most contributors were able happily to marry fundamental scientific concepts to practical implementations and thus give sustained interest to the mixed audience of fundamental and applied scientists, advisers and commercial interests. In consequence these published *Proceedings* will no doubt have a strong appeal to a reading public of very diverse outlooks connected with animal nutrition.

One cannot pay too high a tribute to the skill of the editors, who have managed to weld some twenty separate contributions and associated discussions into a coherent and masterly volume that should serve as a valuable reference work for several years to come. As they state in the preface " . . . the objectives of precision in nutrition can only be built upon a more complete knowledge of the basic biochemistry and physiology" of pigs and poultry. Although these objectives have not yet been reached and our basic biochemical and physiological knowledge is far from complete, this volume admirably indicates how far we have advanced, and as such it is to be commended to all with interests in the nutrition of pigs and poultry.

A. Eden

DOMESTICATION AND BEHAVIOUR OF ANIMALS

The Behaviour of Domestic Animals

Edited by Prof. E. S. E. Hafez. Pp. xiv + 619 + 21 plates. (London : Baillière, Tindall and Cox, Ltd., 1962.) 75*s*. net.

THE origin and adaptiveness of the races of domestic animals is a topic of wide interest, for it is a field in which the zoologist, the comparative anatomist, the ethologist, the physiologist, the farmer, the animal trainer, the psychologist, the anthropologist and the archæologist all have a stake. The production, therefore of a massive book on the subject raises high hopes and this book is indeed a considerable achievement. It is divided into four parts: (1) behaviour and domestication, (2) fundamentals of behaviour, (3) behaviour of mammals, (4) behaviour of birds; together with an epilogue entitled "Comparative Behaviour." Such a large book by so many authors is, however, bound to be very uneven and there is plenty to criticize in individual contributions; moreover, the editors have not succeeded in making any real unity out of a diverse series of topics covered by a diverse collection of authors.

Of the two chapters in Part 1, Scott's introductory essay is too vague and too limited to help the book on very much. E. B. Hale's chapter, on the other hand, entitled "Domestication and the Evolution of Behaviour," contains a good deal of interest; but even he misses out some of the most important points—due, I think, to being insufficiently at home with the modern ethological approach. Thus there is no satisfactory discussion as to the evidence bearing on the nature and evolution of innate or instinctive behaviour from a study of the characteristics of this behaviour in domesticated species. Again, it is well known that, among domestic animals, improperly directed sexual behaviour is particularly common—so common as to be almost a characteristic of domestication. In this connexion it has been argued that those animals most likely to have been domesticated are those which could learn most readily to transfer their responses from individuals of their own species to individuals of the human species. That is to say, species which could be readily imprinted, and so psychologically modified, would be those which would be most likely to respond successfully to attempts at domestication. But a contrary thesis has also been maintained: namely, that under domestication the probability or possibility of imprinting on to biologically inappropriate objects is so much greater than in the wild that there would tend to be selection against the ability to be imprinted during domestication; for if it were not so, imprinting would almost certainly interfere with normal reproduction. Here is an issue of fundamental importance and interest which seems to be almost entirely ignored.

Part 2 commences with J. L. Fuller's chapter on the genetics of behaviour. It is scarcely the author's fault that this is not so interesting as the title might lead one to expect; behavioural genetics is in fact an extremely difficult subject and—in the higher animals at least—the inheritance seems always to be polygenic. It will be a long time yet before there is enough material to write a satisfactory summary of this subject. Some of the chapters show too exclusive a dependence on the American literature and, in particular, a neglect of the European continental contribution. This is specially evident in what should otherwise have been a valuable chapter, that on physiological mechanisms and behaviour patterns. On the other hand, the chapter on behavioural pharmacology is both unusual and extremely useful. Denenberg in Chapter 6 contributes a valuable discussion on the effects of early experience.

Coming to Part 3, we find chapters written much more from the point of view of the student of animal husbandry. They are interesting, valuable and competent in their way; but they tend too often to be a collection of isolated facts unrelated to the ethological principles underlying the subject. Thus it is almost unbelievable that anyone should set out to write a chapter on the behaviour of dogs and make no mention of the classic work of Schenkel on wolves, or even of the excellent though popular account of the Cryslers on the same species, or of Murie on the coyote. Some of Lorenz's work in this field is unjustly neglected, and throughout the whole book the contributions of Hediger on the behaviour of animals in zoos and circuses seems to have been entirely forgotten. Of the mammalian chapters, those on the horse and the cat are perhaps the most thorough and widely based. Part 4, which deals with bird behaviour, contains valuable and original work by Hale and Schein on turkeys, and Collias on ducks. To summarize, the book is in many respects an achievement to be welcomed; but large though it is, its faults are chiefly those of omission and sometimes of too restricted an outlook.

W. H. Thorpe

THE REALM OF FISHES

A History of Fishes

By J. R. Norman. Second edition revised by P. H. Greenwood. Pp. xxxi + 398. (London : Ernest Benn, Ltd., 1963.) 21*s*. paperback.

THIS is an extremely interesting and informed book, a revision of a work first published in 1931. Comparison with the original edition reveals that much of the text remains unchanged, as does the general plan of the book; the chapter headings and many of the text figures are the same. Thus, at first glance, the new edition is closely similar to the old, and this gives some idea of the reason for the success of the book (which went through no less than four impressions after the Second World War). Norman's book was a remarkably original one in its emphasis on the study of fishes as living animals, not as museum specimens, and his approach being essentially modern, few alterations have been necessary to the basic plan of the book.

There have, of course, been many advances in our knowledge of fish in the past thirty years, particularly in so far as their physiology and behaviour are concerned, and in the study of fossil forms. Many new fishes have been discovered, some, like the cœlocanth, of first importance. On closer inspection, it is evident that the new edition has been very carefully revised to include the results of recent work, and although a few pages shorter than the old, it contains a great deal more information. A number of new text figures have been drawn by the artist who illustrated the first edition, most of these are of fossil forms such as *Jamoytius*, but other new figures are of *Latimeria*, of different forms of the jaws and their articulations, and so on. Although Dr. Greenwood apologizes in his preface for the possible appearance of a dogmatic tone due to the demands of compression, in

fact it seems that great care has been taken to give both sides of controversial problems. It is, for example, pleasant to find clearly stated the alternative hypotheses required if that of continental drift be not accepted, or again, to see a discussion of Dr. Tucker's views on the breeding of eels after the classical account is given.

In general, all the interpolations and additions in this revision are judicious and valuable, and few topics which have arisen since Norman's day, or have increased in importance since he wrote, are not to be found in this new edition. It is a pity that space could not be found for a discussion of the effects of the land-locked sea lampreys of the Great Lakes on the commercial fisheries there, perhaps the most striking example to be found of the direct competition of men and fishes for the same food source (particularly as the statement about the value of these fisheries on p. 335 is scarcely true to-day); but in less than 400 pages there must be some omissions.

Very few errors or ambiguities were detected by me but three may be mentioned. It is difficult to understand the distinctions drawn in this edition between true and virtual parasitism, both terms being applied to the special case of the dwarf males of certain angler fishes (pp. 211; 244) which live attached to the females.

One error in the first edition which has not been remedied is that the female ray of Fig. 101 (Fig. 107 of the first edition) is in fact an immature male, and this is unfortunate, since the figure purports to show the difference between the male and the female. Finally, it is something of a surprise to find that Dr. Greenwood has placed the lancelet, *Branchiostoma*, among the Hemichordates (p. 258).

These are minor defects, and Dr. Greenwood is to be congratulated on a very successful revision of one of the best popular books on fish. It would be difficult to find so much information so well presented in any other book of comparable size and price, and this new edition well deserves the success of its predecessor. Q. BONE

CLASSIFICATION OF NEMATODES

Soil and Freshwater Nematodes

By Dr. T. Goodey. Second edition, revised and rewritten by Dr. J. B. Goodey. Pp. xvi + 544. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1963.) 100*s*. net.

NEMATOLOGISTS have looked forward to a new edition of this outstanding work on the classification of the soil- and fresh-water inhabiting and plant-parasitic nematode genera for quite some time already. The first edition has been out of print for many years now. Moreover, large sections of the book were becoming more and more out of date. To incorporate the large amount of new information which has become available since the first edition was published this new edition has been entirely rewritten, and expanded from about 400 to more than 600 pages. The number of illustrations has increased from 190 to 298 and a larger format has been chosen. Several illustrations have benefited from the better-quality paper than that used for the first edition. However, the reviser has justifiably maintained the original plan of the book.

Contrary to other more or less similar works (for example, Meyl's *Freilebende Nematoden* in *Die Tierwelt Mitteleuropas* 1, 5*a*, 1960) which are compilations of extremely abbreviated descriptions of species, the new edition of *Soil and Freshwater Nematodes*, like the first, concentrates on the definition of genera and their classification in higher categories. The definition of each genus is followed by an illustrated description of the type species or of another characteristic species if this serves the purpose better: to make the genus definition more than an abstraction and therefore much easier to use.

It is this judicious combination of definitions of higher systematic categories with full descriptions and illustrations of a limited number of species which makes the book so usable also to non-taxonomists. The species belonging to a genus are listed alphabetically with author, date and synonyms after the description of the type or representative species and the section on each genus closes with a paragraph on the bionomics of its members. An improvement compared to the first edition is the insertion of tabular keys at the beginning of each systematic category. They are not the usual dichotomous keys but tables which list in columns the members of the category with, under appropriate headings (cuticle, stoma, œsophagus, etc.), their taxonomically important features. The tables are intended to enable the reader to determine the order, family and genus to which specimens actually belong, but they also make a comparison of the members of the category possible, thereby providing a quick insight in the concepts the classification has been based on.

In adapting the classification to the present state of knowledge the reviser has not only made a choice from the various concepts found in the literature but has also expressed his own, hitherto unpublished, views. He has reduced the status of the nematodes from that of a phylum to that of a class with the name Nematodea and abandoned the division into Phasmidia (Secernentes) and Aphasmidia (Adenophori). On the other hand, several lower categories have been raised in rank and a division of the genera under consideration in ten orders instead of the four of the first edition has been adopted, resulting in a higher degree of uniformity within most of them.

The orders Tylenchida and Rhabditida were maintained virtually unchanged apart from placing *Teratocephalus* and *Euteratocephalus* (formerly in Rhabditida) in a new order *Teratocephalida*. Within these orders considerable changes in classification were made. The Chromadorida and the Enoplida of the first edition are now divided into four and two orders respectively : Araeolaimida, Desmoscolecida, Monhysterida, Chromadorida, Enoplida and Dorylaimida.

One could scarcely expect systematists not to disagree with the classification of the original author and of the reviser on several points. For example, I question the inconsistency in the evaluation of the structure of the œsophagus in the Tylenchoidea, allowing it to prevail over all other characters in one case (Neotylenchidae) and giving it only secondary importance in others. I must admit, however, that it will not be easy to find entirely satisfactory alternatives in this and other cases unless new material and a better knowledge of nematode anatomy, for example of the topography of the œsophageal glands in Tylenchoidea, give us a better insight in systematic relationships.

Neither queries nor differences of opinion, however, suggest that the new edition of *Soil and Freshwater Nematodes* is not an excellent work and of great importance to all those who study nematodes as taxonomists, plant pathologists or while engaged in faunistic studies.

J. W. SEINHORST

INDIAN WATER PLANTS

Aquatic Angiosperms

A Systematic Account of Common Indian Aquatic Angiosperms. By K. Subramanyam. (Botanical Monograph No. 3). Pp. viii + 190 (illustrations). (New Delhi: Council of Scientific and Industrial Research, 1962.) Rs. 20.00; 40*s*.; 6.00 dollars.

THIS book is the third in a series of botanical monographs published by the Council of Scientific and Industrial Research, New Delhi, with the aim of collecting together the scattered results of researches published in

India and elsewhere. It is hoped that these monographs will eventually provide a source of material to be used in the preparation of Indian botanical text-books.

The present volume deals systematically with the numerous common aquatic flowering plants of India, and in addition to descriptive matter provides keys for their identification at family, generic and species levels. The characteristics of the Indian climate are such that many plants which grow during the monsoon season could well be classed as aquatic plants, since the soil in which they grow is often immersed in some depth of water; however, in the interests of brevity the author has excluded both monsoon and mangrove plants from his treatise.

Although they contain much interesting information, on the whole the descriptions of the various species are somewhat dull; however, the book will no doubt be used principally as a work of reference. The text is sprinkled with numerous botanical terms, some of which are not in common usage, and the provision of a glossary might have been helpful. In providing morphological, anatomical and especially embryological information about the species described, where this is available, the author has drawn largely from Indian literature. The pharmaceutical and other economic uses of the plants are also given, where appropriate, and this information is interesting and sometimes surprising; aquatic plants are utilized in numerous ways, both as medicaments and in the manufacture of articles such as sun hats. A useful appendix supplies the chromosome numbers of many of the plants described.

This well-produced book is illustrated with many clear line-drawings and a few photographs; the latter are of rather indifferent quality and add little to the value of the text. The usefulness of the line drawings would probably have been increased by the provision of scales of magnification, which are supplied in only some instances. With a few exceptions, the text seems to be largely free from errors.

As a systematic work, the present volume appears to fulfil its purpose admirably; it will provide a very useful addition to Indian botanical literature, and to the literature of aquatic plants in general. No description of a Flora which can claim several representatives of such fascinating families as the Podostemaceae could fail to interest the morphologist as well as the systematist; it is to be hoped that this book will stimulate the further investigation of aquatic angiosperms in all their aspects.

Elizabeth G. Cutter

THE ROYAL ARMY VETERINARY CORPS

The History of The Royal Army Veterinary Corps 1919–1961. By Brigadier J. Clabby. Pp. 244+56 photographs. (London: J. and A. Allen and Co., 1963.) 50*s*.

THE history of the British Army Veterinary Services in the First World War (*History of the Great War: Veterinary Services*, by Blenkinsop and Rainey, London; H.M.S.O., 1925) is now succeeded by a history bringing the story up to 1961.

It is of interest to compare the outlook and methods in the two Wars, one before the mechanized age had got into its stride and the other after the general public had ceased to regard animals as of importance for military purposes except for food. Again, it is of interest to consider the recently issued history of the U.S. Army veterinary services (*Nature*, 198, 822; 1963.) It could be said that the British histories follow a rather typical, amateur-sounding trend, very enterprising and perhaps rather personal, and with some hankering after the old days of the horse and even the camel. On the other hand, the American account is very impersonal, efficient, bustling and very well planned. The achievements of both countries in military veterinary service in the First World War were outstandingly good.

By 1939 cavalry had disappeared as such and the artillery services and most of the former pack transport had been mechanized; army veterinary officers had seen the red light and found civilian careers on a large scale. Actually horses and mules found a place in operations to a much greater extent than could be anticipated and were of much importance in certain spheres in Italy, Africa and Asia. Considerable numbers were captured from the Italians in Africa and taken over in the ensuing operations.

Bizarre new problems had to be met. Mules were dropped from aeroplanes by parachute. In Wingate's Chindit force mules were a serious handicap to his troops when penetrating enemy country because of their braying, which warned the enemy and was a danger to morale. At relatively short notice mules were 'devoiced' and dispatched as replacements. This involved a surgical operation on the vocal cords and a special scheme for the procedure on a large scale had to be devised hurriedly and without previous experience of what surgical interference was required to achieve the desired results.

Most of the book is devoted to detailed accounts of the work done and systems followed in the five widely separated theatres of war.

This is an arresting book which will be of interest to all concerned with riding, draft and pack animals in particular and with all aspects of animal life. In war, animals have, unfortunately, increased dangers from many sources, and cruelty and even pain not related to cruelty. The army veterinary services are very active in measures to prevent unnecessary suffering. A hazard to the animal that has always accompanied war is when persons unaccustomed to animals are drafted to animal units; in the Second World War this was a very common occurrence because, by then, so few persons had experience with horses. Many loved the job and did it well, but others were probably disappointed in a non-mechanical duty and not very efficient. Mules reported to be vicious were found on occasion to be underworked and overfed: in any event for a tyro to be placed in charge of an army mule could be described as an experience.

A surprise was that the Japanese did not understand surra in horses; it is not serious in cattle, but they are carriers of the trypanosome concerned, and they thought that it could be ignored in the horses. From their known interest in Burma before the War it would not have been expected that their observers had slipped up in such a fashion.

War dogs really came into their own in the Second World War. It is a serious failure that their value was not recognized in earlier days. There was plenty of evidence of the reliability, after the right training and in the right hands, of suitable dogs for certain very intricate work. Survival of a medieval outlook may have tempered the judgment of war lords. As infantry patrol aids, guards, messengers in certain types of country, for finding casualties and even for finding buried *caches* of arms and for mine detection they have value. An illustration shows a dog with a rifle that it had found in a concealed position.

In modern war there is important linkage with civil services, air raid and bomb precautions, Animals of all kinds require service, as hazards to the human population, as well as for veterinary attention. With the importance of war gases, missile damage, fall-out, etc. the animal side requires special attention and the army veterinary services are trained accordingly.

The book is full of interesting illustrations and is well written and produced.

W. A. Pool

European Brewery Convention

Report of the Barley Committee: Trials, 1961. Pp. 136. (London: Institute of Brewing, 1963.)

THIS twelfth report of the series compares the agricultural and malting performances of various new barley varieties in fifteen European countries. In addition to details of sowing, ripeness, yields, quality characteristics such as nitrogen-content, grain size and dormancy, the volume contains a wealth of tabulated data on the lay-out of the individual trials, their location, soil analysis, fertilizer treatment, field observations such as those relating to disease resistance, meteorological data and statistical evaluation of yields. Moreover, samples of the barleys were converted into malts by small-scale methods and, here also, the newcomer to this field will perhaps be surprised both by the variation in the results and by the multitude of malt properties which have to be brought into view to provide an adequate comparison.

It will be clear that this is a specialized publication of particular importance to those concerned to see that with this quantitatively and economically outstanding crop the varieties grown shall best meet the rather different needs of the farmer and the maltster. It has, however, a wider lesson to teach by revealing how complex a problem is posed by this seemingly simple objective. Thus not only are the barleys subject to almost unavoidable variations in methods of cultivation and uncontrollable differences of weather, the malts also vary widely. The latter circumstance is in part due to the fact that different regions often prefer malts of quite different character, but is also the result of malting plants apparently giving different qualities of product even when much care is taken to standardize the procedure employed. These considerations are additional to more familiar ones such as the adequate botanical description, identification and stability of the new varieties. The present volume, therefore, both summarizes clearly the results of a phenomenal number of hours of endeavour and provides a valuable guide to those who may be concerned with similar evaluations of other crops on a wide geographical basis. A. H. Cook

Advances in Astronautical Propulsion

Proceedings of a Seminar held in Milan by Istituto Lombardo Accademia di Scienze e Lettere in collaboration with the Advisory Group for Aeronautical Research and Development of Nato, 8–12 September 1960. Edited by Corrado Casci. (International Series of Monographs in Aeronautics and Astronautics. Division 9: Symposia, Vol. 11.) Pp. xxvii+366. (London and New York: Pergamon Press; Milan: Editrice Politecnica Tamburini, 1962.) 100*s*.

THE papers which compose this volume are concerned with most aspects of astronautical propulsion and a few other closely related subjects. The book begins with a useful introduction to the various methods of electrical propulsion, by the late Theodore von Kármán. Then comes a fine survey of the mechanics of space propulsion by L. Crocco (in Italian), covering the dynamics of high- and low-thrust systems and the properties of transfer orbits. There follow four contributions on conventional rocket propulsion, including a passionate plea for solid fuels from J. Buchanan, and a pleasing discourse on liquid-fuel rockets by A. O. Tischler. Nuclear rockets form the subject of two papers, a practical survey of fission rockets by R. W. Bussard, and a forward-looking review by E. Sänger, covering such topics as photonic fission rockets and intermittent water plasma fusion rockets. Other papers deal with magnetohydrodynamics and power generation in space. The dynamical and heating problems of atmospheric re-entry are admirably discussed in three papers by A. Ferri, L. Broglio and P. A. Libby. Finally, H. L. Dryden outlines some of the future United States plans and also "dips into the future far as human eye can see".

The papers (though not all well written) together constitute an excellent review of the subject. But the book is marred by printing errors so numerous and glaring that they often distract the reader's attention and sometimes obscure the meaning. D. G. King-Hele

Thermodynamic Properties of Helium to 50,000° K

By Wilbert J. Lick and Howard W. Emmons. Pp. 122 (including charts). (Cambridge, Mass: Harvard University Press; London: Oxford University Press, 1962.) 24*s*.; 2.95 dollars.

THE authors give an excellent and precise account of the methods used in the preparation of these tables, although the preceding introduction is a discouragingly vague attempt to justify their existence. In contrast to many other similar compilations, it is indeed welcome to find an extremely graphic physical discussion of the type of atomic model and particle interactions assumed in the analysis. The partition functions for electronic excitation and ionization are based on Unsölds treatment, and thus allow for a density-dependent cut-off of levels and reduction in ionization potential due to particle interactions. The justification and validity of this approach is discussed clearly and at length. There are 108 pages of thermodynamic data—including sound speed—for equilibrium mixtures from 8,000° to 49,800° K and from 10^{-4} to 10^{3} atm., listed in steps of 200° K for each ten-fold pressure increment. The chemical species considered are He, He^{+}, He^{++}, and e; the molar constituents of these are similarly tabulated. The data is also conveniently presented in the form of two splendidly large and clear Mollier charts. This will be welcome to those concerned with the use of helium in high-enthalpy electrically driven shock tubes, although an order extension in pressure would be useful in this respect. The extreme range covered will be more than adequate for those interested in its use in plasma-arc and space propulsion facilities.

Ian R. Hurle

Plant Hairs

By Prof. J. C. Th. Uphof. Die Verbreitung der Haartypen in den Natürlichen Verwandtschaftsgruppen. Von Dr. Karl Hummel und Karin Staesche. (Handbuch der Pflanzenanatomie, Band IV, Teil 5). Pp. xi+292+5 plates. (Berlin-Nikolassee: Gebrüder Borntraeger, 1962.) 96 D.M.

THE long article by Uphof looks like a general essay on hairs and emergences, but is really a pure compilation. The author, on the evidence of his own bibliography, has not been personally active in this field of research, and does not deal with the plants themselves, but only with the literature concerning them. Furthermore, his scale of values is antiquarian rather than botanical. Nothing can disguise the intrinsic sterility of such a treatment. The botany expounded here is one in which iodine is the principal histological stain, and in which the electron microscopy of the cotton fibre is firmly subordinated to the "faint reticulation" which appeared on staining with Congo red in 1925.

The shorter contribution by Hummel and Staesche is a statement of the distribution of the principal hair-types (unicellular, uniseriate, stellate, etc.) among the angiosperms. The only conceivable objection to it is that the material might just as well have been tabulated in a fraction of the space.

At this price the purchaser is entitled to a professional standard of book-production. He does not get it. The English text reads like a bad translation, misprints abound, and Hummel repeats both his own statements and Uphof's to an extent which borders on the farcical. In all, this is a serviceable classified guide to a scattered literature, giving enough detail to obviate in many cases all need for reference to the originals. From every other point of view, it represents a lost opportunity.

K. J. Dormer

STUDIES OF RADIOACTIVE FALL-OUT FOLLOWING 1961 U.S.S.R. TESTS

By Dr. ALAN WALTON, Dr. MICAH W. M. LEO and PHILIP W. KREY

Isotopes, Incorporated, Westwood, New Jersey

ON September 1, 1961, it was announced that the testing of nuclear weapons in the atmosphere had been resumed by the U.S.S.R.[1]. Thus, the voluntary moratorium which commenced in Autumn 1958 and which had been officially maintained by the United Kingdom, the U.S. and the U.S.S.R. was ended abruptly. Afterwards, between September 1961 and November 1961, the U.S.S.R. conducted about fifty such atmospheric tests. Most of these were detonated in the Arctic regions. Following a series of underground tests in late 1961 and early 1962 the U.S. resumed atmospheric testing in April 1962, most of which occurred in the Pacific on Christmas Island. As a result of the time delay between the respective resumptions of atmospheric testing by the U.S.S.R. and the U.S., it is clear that the dominant source of nuclear debris at Westwood, New Jersey, during late 1961 and early 1962 was the U.S.S.R. tests.

In this article we discuss several aspects of the U.S.S.R. radioactive debris, including the overall deposition, the rate of fall-out and the comparison of 1962 and 1959 situations. Of special importance is the total yield of the U.S.S.R. series at 120 megatons and the relatively small fission yield of 25 megatons[2]. Also the fate of the nuclear debris from the two high-yield weapons 25 and 55–60 megatons is particularly worthy of discussion.

Fall-out Prior To Renewal Tests

In a detailed investigation of the recent tests it is instructive to examine the deposition of fall-out prior to September 1961. When testing was suspended in 1958 the rainwater sampling programme of our laboratories at Westwood was curtailed after the short-lived nuclides from the earlier tests decayed. Through the early part of 1959 many short-lived isotopes such as barium-140 and strontium-89 were measurable with ease and their behaviour during this period was extremely useful in ascertaining the age and origin of the debris[3]. As time progressed, however, and their concentrations decreased, the importance of monitoring some longer-lived nuclides increased. Thus during 1960 and 1961 attention was given to the determination of cerium-144, ruthenium-106, rhodium-102, etc. Cerium-144 and rhodium-102 were considered most valuable in determining the age and source of the debris in precipitation at these times. Throughout the period the variability of the deposition of strontium-90 was examined as a reference nuclide and because of its importance in radiation hazards.

In Fig. 1 the monthly concentrations of strontium-90 in precipitation at Westwood, New Jersey, are plotted as a function of time. The strontium-90 concentrations show pronounced peaks in spring in both 1960 and 1961 as they did in the previous years. It is interesting to note that the peak concentrations are attained in different months—April, May and June—a phenomenon which is governed by at least four factors: (*a*) schedule of testing; (*b*) magnitude and types of tests; (*c*) frequency and types of precipitation; (*d*) mechanisms of release of nuclear debris from the stratosphere for high-yield bursts.

One of the most important conclusions to be reached from these data is that, in spite of the moratorium on atmospheric testing, the spring maximum in 1961 was almost as high as that in 1960. Table 1 will reveal this fact a little more clearly.

Table 1. Deposition of Strontium-90 at Westwood, New Jersey (January–June 1959–62)

Year	Precipitation (in.)	Sr-90 (mc./mi.²)	Sr-90 Average concentrations (mc./mi.²/in.)	(μμc./l.)
1959	18·45	20·28	1·10	16·7
1960	18·35	3·36	0·18	2·78
1961	22·61	3·96	0·18	2·66
1962	22·88	19·57	0·85	13·0

The average concentrations of strontium-90 for the first six-month periods in 1960 and 1961 were almost equal, but the actual deposition in 1961 was slightly higher than that in 1960 chiefly due to increased precipitation. Such data tend to indicate a similarity in the magnitude at the source region of the stratosphere in 1960 and 1961 and hence some method of replenishment of debris lost in 1960. Replacement of the material deposited in 1960 must have occurred therefore in the latter part of the year. Some confirmation of this suggestion can be seen in the rhodium-102 results which were reported elsewhere[4] and in the cerium-144 results.

Our cerium-144 results are presented in Fig. 2. Here the average monthly cerium-144/strontium-90 ratios for two types of samples are presented. One series of results

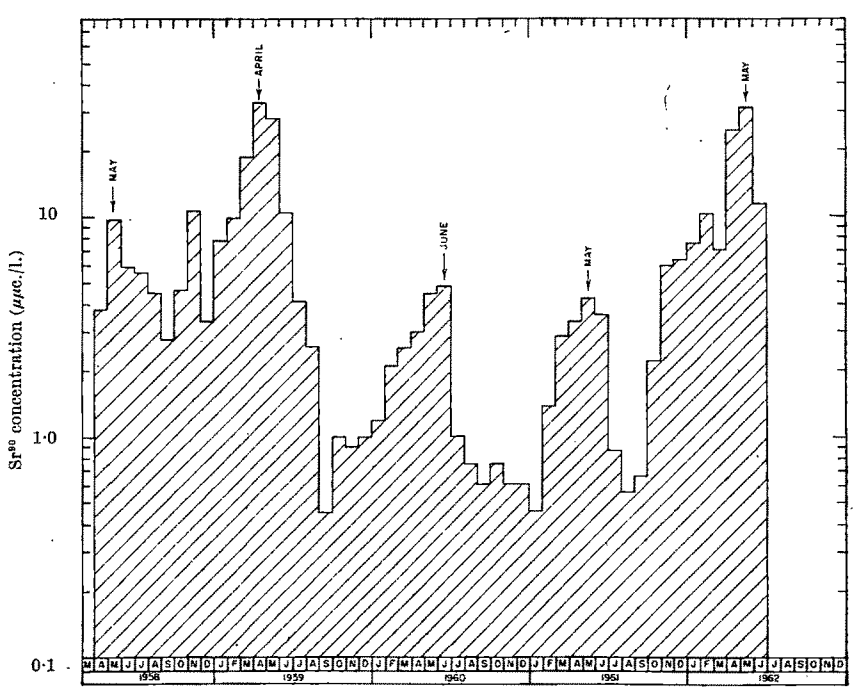

Fig. 1. Average monthly concentrations of strontium-90 in precipitation at Westwood, New Jersey (1958–62)

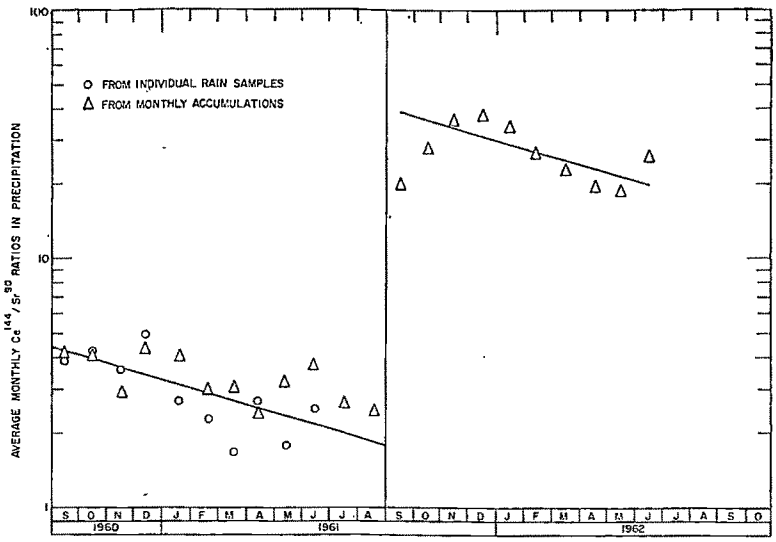

Fig. 2. Cerium-144/strontium-90 ratios in precipitation (1961–62)

was derived from the analysis of single monthly accumulations of precipitation while the second series was obtained from monthly averages of individual rainstorm measurements. Prior to September 1961, the results showed an apparent shot date of approximately May 1958 (assuming an initial ratio at shot date of about 39). The French tests in early 1960 were low yield and did not produce sufficient debris to cause any appreciable increases in the cerium-144/strontium-90 ratios in precipitation at Westwood, New Jersey[5]. The majority of the nuclear debris being deposited during the first half of 1961 can probably be assigned, therefore, to detonations occurring in mid-1958. The majority of the debris from the U.S.S.R. detonations of the autumn of 1958 had deposited in 1959. It is concluded the U.S. test series of mid-1958, with some contribution from United Kingdom tests, are the major source of the radioactivity deposited at Westwood in the January–June period of 1961. These findings are substantiated by studies of cerium-144/strontium-90 ratios in stratospheric air-filter samples[6]. Here the results suggest that most of the debris in the lower stratosphere in 1961 had originated in the rocket shots *Teak* and *Orange*, detonated in the summer of 1958. In fact it was calculated by the same authors[6] that about 68 per cent of the debris in the lower stratosphere between 10° N. and 50° N. latitude during June–September 1961 was produced by the rocket shots. This situation is to be compared with the previous year, 1960, when the material in the lower stratosphere did not contain as high a quantity of rocket shot debris but was primarily attributable to lower altitude bursts occurring in the equatorial regions of the Pacific in 1958.

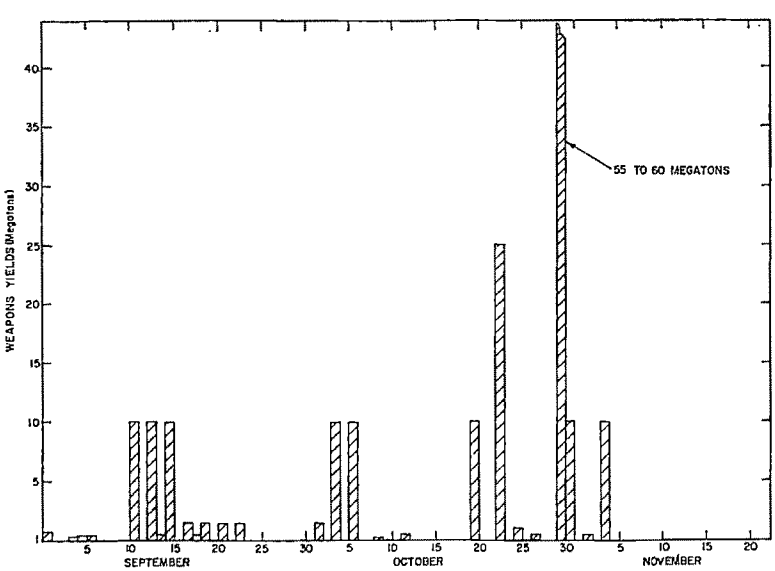

Fig. 3. U.S.S.R. atmospheric nuclear detonations in 1961

Two approaches are possible in determining what the fall-out deposition at Westwood would have been in the absence of further atmospheric testing. The first approach is dependent on a knowledge of previous year's fall-out and some information on the changes in radioactivity concentration in the source regions, that is, the lower stratosphere in the northern polar regions. A second method is to use the acquired information on nuclide ratios of short-lived isotopes to assess the fraction of strontium-90 attributable to the relatively 'old' debris.

Comparison of 1961 and Older Debris

It has already been mentioned that the major sources of debris for the deposition occurring in the first half of 1961 were the rocket shots *Teak* and *Orange* of 1958. In Table 1 it can be seen that the precipitation in 1961 and 1962 was quite similar. Thus if the frequency and types of rainfall and quantity of nuclear material in the source regions were the same in both years the total deposit of strontium-90 at Westwood in the first six months of each year would have been similar. According to Friend and Feely[6], the strontium-90 burden in the northern hemisphere stratosphere up to an altitude equivalent to 40 mb was 0·40 megacurie in early 1960 and 0·21 megacurie in June–September 1961. Approximately 0·27 megacurie of the 0·40 megacurie in the lower stratosphere was deposited in early 1961. Applying the same ratios to 1962 it would appear that we could have expected approximately 0·14 megacurie of the 0·21 megacurie strontium-90 lost from the northern hemisphere stratosphere. In other words, the fall-out in 1962 could have amounted to about 50 per cent of that experienced in 1961. Thus on a crude semi-quantitative basis, using the foregoing information and the results given in Table 1, a strontium-90 deposit of about 2 mc./mi.^{2} could have been expected in January–June 1962 in the absence of testing. As also can be seen in Table 1 the actual deposit was 19·6 mc./mi.^{2} and thus about 10 per cent of this should be relatively old debris.

In order to interpret the data on nuclear debris in precipitation at Westwood, particularly during the first five months of 1962, Fig. 3 has been plotted to show the extent of atmospheric nuclear testing in late 1961. Other testing conducted in 1961 and early 1962 was underground and should not have contributed to the radioactivity found in precipitation at Westwood during this period. The data for this plot were taken from the details announced by the Atomic Energy Commission and compiled by the U.S. Public Health Service in several reports[7]. (The U.S. Atomic Energy Commission has later advised that approximately 50 tests were conducted by the U.S.S.R. during September 1–November 4, 1961, but only 31 specific U.S.S.R. tests were announced during that period.) It has been arbitrarily

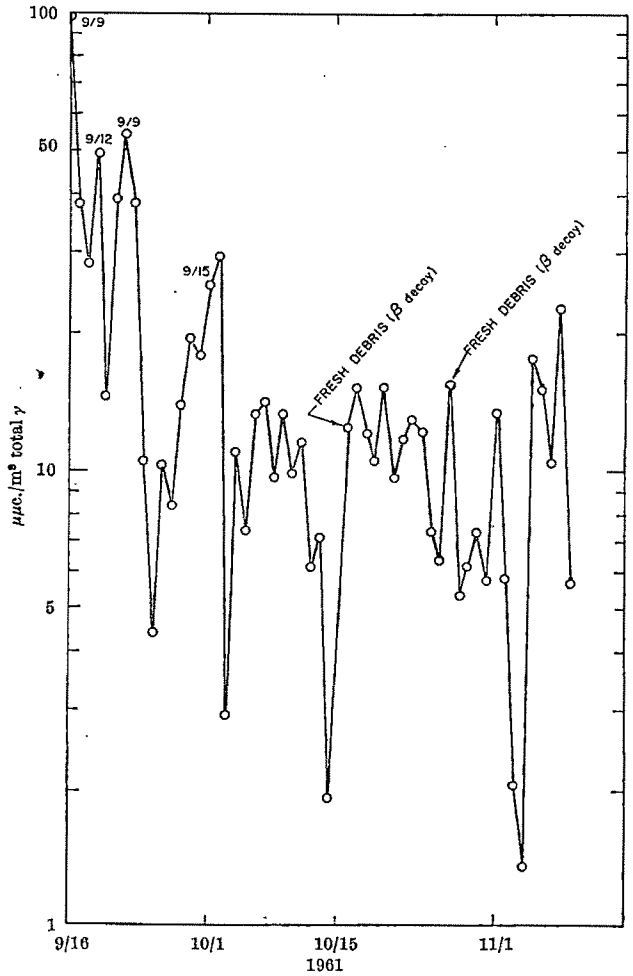

Fig. 4. Concentrations of radioactivity in air during September–November 1961

assumed that those detonations reported as possessing a yield of 'several megatons' actually had a yield of about 10 megatons.

The object of this plot was to obtain a view of the extent of the testing series and determine a date which could be taken as an average shot date for this particular series. It can be seen that the U.S.S.R. testing for larger weapons was distributed over the period September 10–November 5, 1961. The mid-point of this time span is about October 8, 1961. From the pictorial presentation this appears to be quite reasonable. Other estimates will be made from isotope ratio data.

Following the announcement of renewal of nuclear testing an air sampling programme was instituted in our laboratories at Westwood. Daily samples were collected during the period September 1–November 15, 1961, and analysed primarily by γ-ray spectrometry for barium-140, zirconium-95, ruthenium-103, iodine-131 and molybdenum-99. Various combinations of activity ratios give good indications of the date of origin for the debris.

In Fig. 4 the total γ-results on air filter samples are plotted as a function of time, and identification of shot dates has been made using molybdenum-99/barium-140 ratios. These dates are given for some samples.

The first significant quantities of activity to be detected at Westwood occurred on September 16, 17, 1961. Other sampling stations throughout the U.S. observed similar increases in air activities on or about the same time[8]. Radioactive debris layers over Flin Flon, Manitoba, Canada[9], were detected by balloon flights on September 14 and 15, 1961. Isotope ratios indicated that the material originated around September 9, 10, 1961. Reference to a compilation of tests shows the nearest detonations to have taken place on September 10, 1961, when two devices were exploded near Novaya Zemlya. The meteorological conditions leading to the arrival of this debris in the U.S. have been discussed fully elsewhere[8].

Subsequent analyses of filter samples during October 1961 gave ages varying from September 9 to September 15, 1961.

Isotope Ratios in Rain at Westwood

According to our results of activity measurements in precipitation the first rain to exhibit measurable quantities of 'fresh debris' occurred on September 14, 1961. This was a day or so earlier than our ground-level air measurements indicated for the arrival of U.S.S.R. material. Our best estimates of shot dates for this type of sample are obtained from barium-140/strontium-89 data. In this particular sample the isotope ratio had a value of 3·84 and assuming an initial ratio of 6·49 a shot date close to September 1, 1961, was calculated. This result is several days older than was indicated by molybdenum-99/barium-140 ratio in the air filter sample collected later.

In view of these observations it is felt that neither measurements of radioactivity in ground-level air nor in precipitation is a guaranteed method for monitoring the first arrival of debris. Movement of radioactivity in the upper troposphere may pass undetected in the absence of any precipitation.

Several nuclides had been analysed in individual rains during the period September 1961–June 1962. Here our discussion will be limited to three nuclides, strontium-90, strontium-89 and barium-140, where isotopic fractionation is less of a problem than with others such as cerium-141, cerium-144 and zirconium-95.

In Fig. 5 the barium-140/strontium-89 results from the analyses of individual rains are plotted as a function of time. Since neither of these nuclides was present in

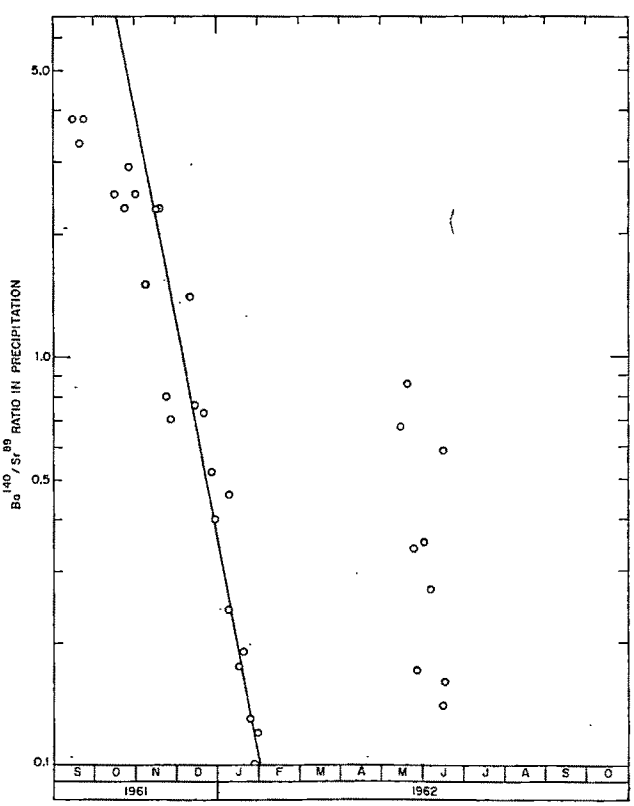

Fig. 5. Barium-140/strontium-89 ratios in precipitation (September 1961–June 1962)

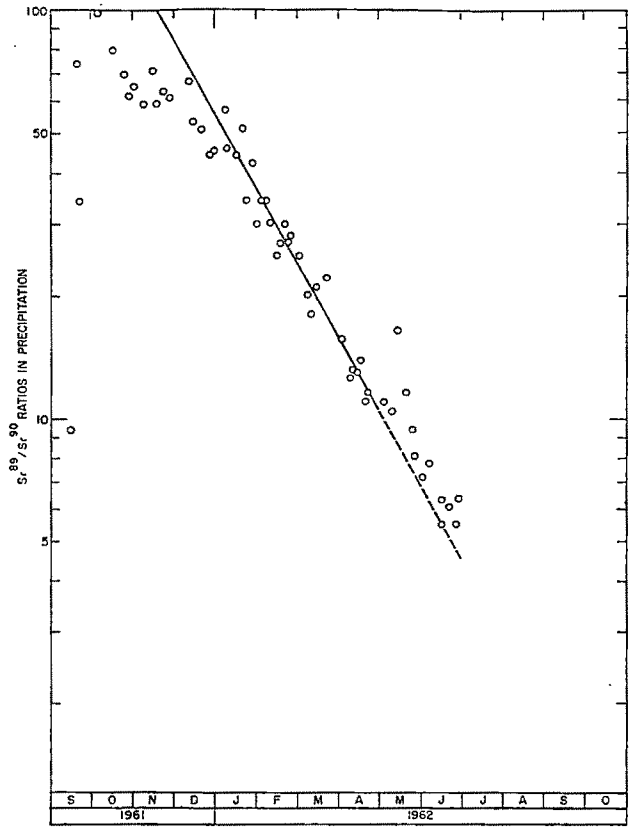

Fig. 6. Strontium-89/strontium-90 ratios in precipitation (September 1961–June 1962)

measurable quantities in precipitation prior to September 1961 and U.S. atmospheric testing did not commence until the end of April 1962, the results during this period are indicative of the behaviour of U.S.S.R. debris. In May 1962 evidence of debris originating at a source apparently different from that of the preceding months is clear in the results of this nuclide ratio (Fig. 5).

Following the two-month period September–October 1961 when the barium-140/strontium-89 ratios were somewhat variable, the results indicate a progressive decay with a half-life which is close to the theoretical decay of a well-mixed source of these nuclides (~17 days) (ref. 10). Such behaviour has been observed on several previous occasions[3,10]. Extrapolation of the smooth decay section of the curve to an initial ratio of about 6·7 yields a date close to the middle of October 1961. A very crude estimate of a mean shot date from the schedule of testing gave a date of about October 8, 1961, which is in quite good agreement with that obtained from the isotope ratio data. For the practical purposes of calculations a mean date of October 15, 1961, has been adopted in ensuing sections.

Fig. 6 shows the variability of the strontium-89/strontium-90 ratio in precipitation at Westwood from September 1961–June 1962. Features similar to those in the preceding curve for barium-140/strontium-89 are clearly visible in that a smooth decay in the ratio, close to the theoretical rate of decay, follows an initial disturbed period. There is a suggestion that the smooth decay commences a little later in time for the strontium-89/strontium-90 ratios than for the barium-140/strontium-89 ratios.

If the strontium-89/strontium-90 ratio decay curve is extrapolated to the mean shot date as previously determined a ratio of about 155 is obtained. Assuming, therefore, an initial ratio[10] at shot date of 176 the observed value of 155 on October 15, 1961, could result from the inclusion of close to 10 per cent of 'old' material. In other words, 10 per cent of the strontium-90 deposited at Westwood during the period December 1961–May 1962 was derived from debris pre-dating the 1961 U.S.S.R. tests.

The graph of barium-140/strontium-90 ratios shown in Fig. 7 can be used in the same manner as above. In this instance the theoretical ratio at shot date is 1,185 and the observed value on October 15, 1961, obtained from extrapolation of the straight line portion in Fig. 7, is about 1,000. Therefore, the percentage contribution of old material to the total deposit at these times is approximately 15 per cent.

It appears from independent estimates that the extent of old debris present in fall-out during the late winter of 1961 and early spring of 1962 is about 10–15 per cent of the total deposit. This estimate is expressed pictorially in Fig. 8.

Total Fall-out from 1961 U.S.S.R. Tests

One of the most interesting features of the 1961 U.S.S.R. test series is the total yield of the weapons detonated. It has been estimated by the U.S. Atomic Energy Commission that the yield was about 120 megatons with a fission yield of close to 25 megatons[2]. Using the generally agreed ratio 1 megaton of fission equivalent to 0·1 megacurie of strontium-90 the strontium-90 yield should be 2·5 megacuries. The rather slow rate of fall-out of this 2·5 megacuries is of special interest in view of the 25 and 55–60 megaton detonations which occurred during the series.

Kuroda and Nix[11] reported that the 1961 weapons were 'cleaner' on the average by a factor of five than those exploded in 1957 and 1958. However, no explanation of the fact was given. Machta, List and Telegadas[8] pointed out that the clouds from both the 25 and 55–60 megaton tests may have injected fission products to an altitude of 30–45 km.

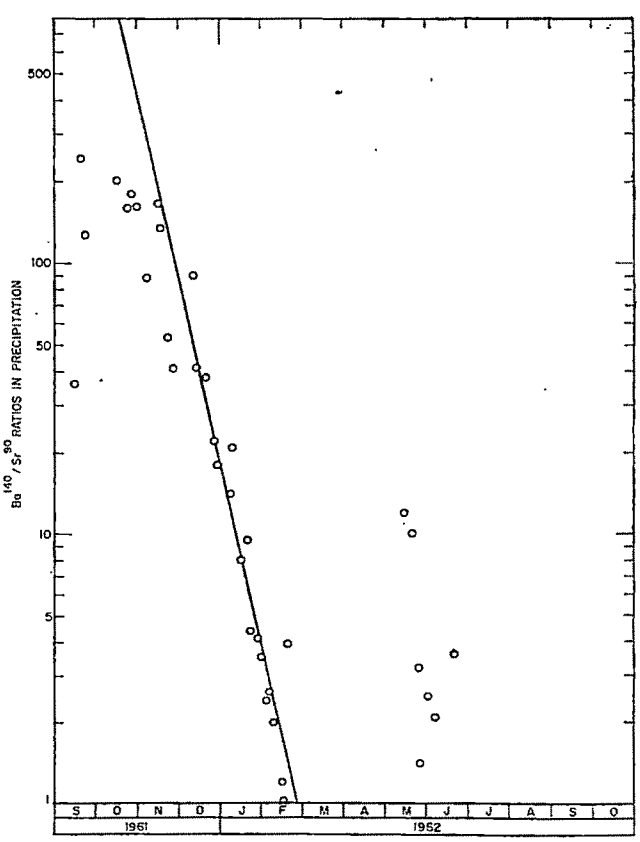

Fig. 7. Barium-140/strontium-90 ratios in precipitation (September 1961–June 1962)

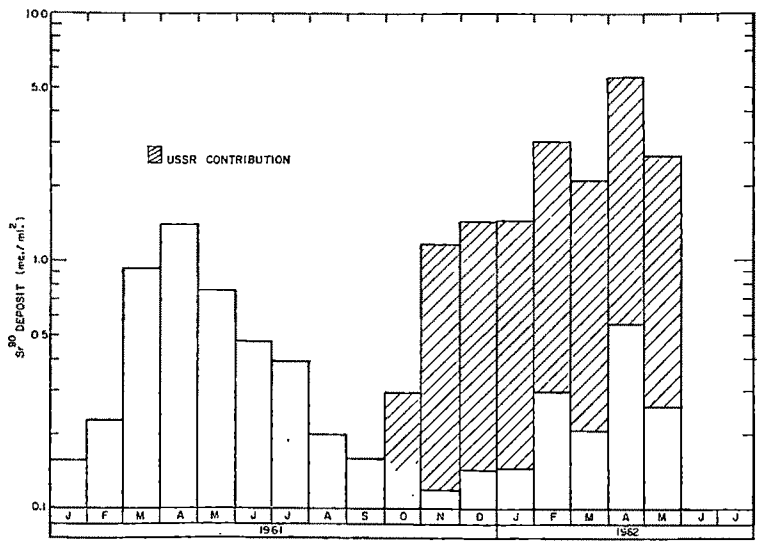

Fig. 8. Contribution of U.S.S.R. (1961) and 'old' debris to the total fall-out of strontium-90 in 1961–62

At this point in time two facts are needed to allow estimates of the rate of deposition of the U.S.S.R. strontium-90 to be made. The amount of strontium-90 deposited to date must be known together with the quantity remaining in the stratosphere. Pending the examination of world-wide fall-out collections some initial estimates of the former quantity may be made from the results already secured at our Westwood, New Jersey, laboratories. Preliminary estimates of the stratospheric inventory of U.S.S.R. material are available at this time.

Table 1 presents the quantity of strontium-90 deposited at Westwood in the first six months of the years 1959–1962. From strontium-89/strontium-90 ratios and an initial ratio of 176 at shot date a contribution in 1959 of 65 per cent 1958 U.S.S.R. debris was calculated. Based on this figure, the U.S.S.R. tests of 1958 would have contributed about 13 mc./mi.² out of a total of 20 mc./mi.² strontium-90 deposited at Westwood in the first half of 1959.

In 1962, on the other hand, the total fall-out of 19·6 mc./mi.² strontium-90 in the corresponding six-month period was shown to have been between 85 and 90 per cent from U.S.S.R. 1961 debris. If the lower value is used, to allow for some contribution from U.S. atmospheric tests from April 1962 onwards, the quantity of strontium-90 from the U.S.S.R. detonation would be about 16·6 mc./mi.².

The total fission yield of the 1958 U.S.S.R. series was given as 10–15 megatons with a resulting yield of 1·0–1·5 megacuries of strontium-90. Most of the debris from these tests was brought down in the spring of 1959 [3,6,11,12]. If we equate this yield, say, 1 megacurie, with the fall-out experienced at Westwood in 1959, 12 mc./mi.², and assume similar fall-out conditions in this area in 1961–62 it follows that the amount of U.S.S.R. debris brought down in 1962 is in the region of 1·4 megacuries.

Study of world-wide isotope ratios by Telegadas and Murayama[12] demonstrates that the fission yield in 1958 is closer to 0·6–0·9 megacurie of strontium-90. Using a mean value of 0·75 megacurie, it follows again that the U.S.S.R. tests of 1961 would contribute a total deposit of strontium-90 of close to 1·0 megacurie during 1962. A summary of these results is given in Table 2.

Table 2. Behaviour of U.S.S.R. Debris from 1958 and 1961 Test Series

Test series	Energy yield (megaton)	Estimated data Fission yield (megaton)	Sr-90 yield (megacurie)	Sr-90 deposits (megacurie)
1958	20–30	10–15	1·0–1·5	0·6–0·9*
1961	120	25	2·5	1·0†

* Total yield of 1958 U.S.S.R. Sr-90 on Earth's surface calculated from Sr-89/Sr-90 ratio in world-wide precipitation.

† Yield to date of 1961 U.S.S.R. Sr-90 on Earth's surface calculated from comparison of 1959 and 1962 depositions at Westwood, N.J.

In order to compare these results with the reported yield of 25 megatons of fission, or 2·5 megacuries of strontium-90, one must have some knowledge of the stratospheric inventory. It would be preferable to have this information for a given point in time, but unfortunately only a mean value of an inventory over a few months is available. Machta[13] has reported that during January–April 1962 the estimated amount of strontium-90 present in the stratosphere (up to 70,000 ft.) was 1·3 megacuries and even after the "Spring peak" of 1962 perhaps 1·0 megacurie of strontium-90 from the U.S.S.R. tests remained in the stratosphere. Coupled with a deposit of 1·0 megacurie of strontium-90 on the Earth's surface this gives for the 1961 tests a total yield of about 2·0 megacuries. This value, together with some possible undetected portion in the higher stratosphere above the ceiling of *U*-2 aircraft, is to be compared favourably with the reported yield of 2·5 megacuries of strontium-90.

Conclusions

An investigation has been made of the deposition of radioactive fall-out at Westwood, New Jersey, immediately prior to and immediately following the atmospheric Soviet tests of 1961. Before September 1961 the major source of radioactivity appeared to be the Pacific tests of 1958 while in the first six months of 1962 these same detonations seemed to have contributed about one-tenth of the deposition of strontium-90 at Westwood, New Jersey. The U.S.S.R. tests series of late 1961 would seem to be responsible for 90 per cent of the debris in 1962. The total deposits of strontium-90 during the first six months of 1962 and 1959 were almost equal at 20 mc./mi.². Knowing the contributions of U.S.S.R. debris to the total fall-out in 1959 and 1962, and the world-wide deposition of U.S.S.R. material from 1958 tests it is estimated that about 1 Mc. of 1961 U.S.S.R. strontium-90 has been deposited over the Earth's surface to date. It is also suggested that the total yield of 2·5 Mc. estimated by the U.S. Atomic Energy Commission is in reasonable agreement with our inventory.

Results from our rainfall studies indicate that nuclear debris from the 1961 U.S.S.R. test series is behaving somewhat differently from similar but earlier detonations. Other autumn test series conducted in Arctic regions had resulted in rapid deposition of the majority of the radioactivity in the northern hemisphere in the following spring. On this occasion it appears that only half the total yield would be released from the stratosphere in 1962, with the majority of the remainder most likely being deposited in spring 1963. It is probably a direct result of these high-yield weapons that the average 'residence time' for the debris from the 1961 series is longer than previously determined values for other test series. This strongly suggests that the early concepts of residence time is too elementary for an adequate description of the fate of nuclear weapons' debris.

The distinguishing of 1961 U.S.S.R. debris from the material originating in U.S. and later U.S.S.R. series, at some future time, presents a problem. Careful consideration will have to be given to the use of suitable isotope ratios and, in addition, the measurement of cadmium-109, a unique tracer, added to the U.S. high altitude detonation on July 8, 1962, may be used in similar ways as was tungsten-185 (refs. 14 and 15) and rhodium-102 (refs. 4 and 16).

This work was supported by the U.S. Atomic Energy Commission under contract *AT*(30–1)–2415. We thank

Drs. H. W. Feely and J. P. Friend for helpful discussions. We also appreciate the air filter and rainfall sampling, radiochemical separation and radiometric assay made by the staff of the Analytical Division, Isotopes, Inc. Finally, we thank Joshua Z. Holland, Division of Biology and Medicine, U.S. Atomic Energy Commission, for his continuous interest and practical encouragement of this work.

MINERALIZATION OF KERATIN AND ITS COMPARISON WITH THE ENAMEL MATRIX

By Dr. F. G. E. PAUTARD
Astbury Department of Biophysics, University of Leeds

ALTHOUGH it has long been known (for example, ref. 1) that keratins of varying degrees of hardness are responsible for the shape and function of claws and nails by the differential wear of the tissue during use, the structural classification of these organs has been limited to the general description of a 'harder' unguis and a 'softer' sub-unguis. It is customary to regard the hardness of keratin as being due to the compactness of its cells, its fibrils, microfibrils and other protein units and to the presence of abundant cystine residues. The purpose of this article is to present evidence in support of the hypothesis that a principal factor in determining the form and function of hairs, hoofs, claws, beaks and enamel is the pattern of hardening of keratins with calcium and other salts. The broad picture of an exoskeleton of keratin, mineralized according to its position and use is in conformity with the situation in other epidermal structures; there is a parallel case in the crustacean cuticle, for example, where calcium carbonate and phosphate and other salts are laid down to strengthen the tissue.

A biophysical, biochemical and cytological survey (some aspects of which will be reported elsewhere) has been carried out on a wide variety of natural and calcined mammalian, avian and reptilian keratins, and the results suggest that all keratins contain insoluble calcium and other salts which are deposited by, and usually within, the epidermal cells in selected parts of each tissue. In the case of enamel, the X-ray diffraction evidence points to some affinity of the mature enamel proteins with the keratins, and enamel may be regarded as the most highly calcified but least keratinized member of the group.

It is well known that X-ray diffraction patterns of some keratins contain 'salt' reflexions, and it has been shown that in baleen the inorganic pattern is given by bone salts[2] laid down in an oriented partnership with keratin instead of collagen[3]. Recently, similar 'apatite' reflexions have been reported by Earland, Blakey and Stell in Indian rhinoceros horn[4] and in platypus hair, lion whiskers, goose feather calamus and in some human fingernails[5]. In the survey presented here, the nature and extent of mineralization varied widely, ranging from sparse deposits rich in calcium and phosphorus giving clear X-ray diffraction patterns of hydroxyapatite to dense deposits poor in phosphorus giving no inorganic pattern. In the air-dried native tissues, the calcium salt varied in composition, concentration, crystallinity, location and orientation. Those keratins which did not give an X-ray diffraction pattern of inorganic salt were calcined at 900° C for 2 h; with a few exceptions (some hairs) the diffraction patterns of the water-insoluble part of the ash contained reflexions characteristic of one or more of the hydroxyapatite/CaO/$Ca_3(PO_4)_2$ lattices described by Carlström[6] for calcined bone and enamel; added reflexions suggesting other salts were frequently present. The analyses of a representative selection of specimens is set out in Table 1.

For convenience, the keratins have been divided broadly into three groups according to the nature of the mineral which is deposited.

Group I : Hairs, Quills, Feathers, Horns

The feature common to all members of this group was the lack of histological identification of the inorganic deposits, even though the gross calcium concentration was found to be as high as 1 per cent and the total mineral content often exceeded 2 per cent. The X-ray diffraction evidence was inconclusive. Several specimens of hairs gave 'salt' reflexions which coincided with the strongest reflexions from the specimens of powdered bovine enamel used for comparison, but the details of the fainter wide-angle spacings were obscured by scatter from the sample. One batch of hairs from the sole of the feet of the polar bear (*Thalarctos maritimus*), however, gave a more readily identifiable pattern of bone salts, with the *c*-axis of the crystallites oriented parallel to the fibre axis. Nevertheless, not more than 0·1 per cent calcium phosphate (calculated as $Ca_{10}(PO)_4(OH)_2$) could be present in most of the hairs, where the proportion of the salt was usually not more than 25 per cent of the ash. In spite of the low proportion of calcium and phosphorus, however, the water-insoluble fraction of the ash gave X-ray diffraction patterns with many reflexions closely resembling those from calcined bone (Fig. 1*a*, for example). On the other hand, the diffraction patterns from powdered calamus of some flight feathers gave a clearer indication of hydroxyapatite and the proportion of calcium phosphate present in the ash was usually in the region of 60 per cent.

Differences were observed in the amount of calcium and phosphorus in similar keratinous structures in the same animal; for example, mature flight feathers were more heavily mineralized than down feathers. In horse tail hairs, however, differences were found not only in the ash, calcium and phosphorus content of medullated hairs as compared with non-medullated hairs, but also in the distribution of mineral within each type of hair. Medullated and non-medullated hairs were removed from several white horse tail switches and analyses for ash, calcium and phosphorus were carried out on bundles of fibres cut into 5-cm sections from the tips of the hairs backwards. The results, which are expressed in graph form in Fig. 2, show clearly that while the percentage of calcium is much the same for both medullated and non-

HA = Equivalent spacings of powdered bovine enamel. Calcium estimation by the method of Weatherell[21], phosphate estimation by the method of Gomori[22]. The percentage $Ca_{10}(PO_4)_6(OH)_2$ is calculated from maxima Ca^{++} or PO_4^{---} available.

medullated hairs, non-medullated hairs contain appreciable amounts of phosphate and both the ash content and the calculated amount of calcium phosphate rise steeply in the thin worn tips of the fibres. It would appear that the non-medullated hairs have a denser core of amorphous calcium, and other salts, than the medullated hairs, perhaps related to the function of the fibres in the switch.

Group II : Hoofs, Nails and Claws

In this group, which might be called the 'digit keratins', the proportion of calcium in the ash was generally higher than that present in the subjects in Group I and the mineral deposits were clearly visible under the optical microscope as clusters and layers of particles, which were distributed in various patterns in each tissue. A number of specimens gave X-ray diffraction diagrams which only suggested that hydroxyapatite might be present. In most cases (hoof unguis, for example) the reflexions were faint and difficult to measure, but some samples (a few claws) gave 'salt' patterns which were sharp and distinct. On the other hand, many well-calcified hoofs and claws gave no indications of crystalline substances, judging from their X-ray diffraction patterns.

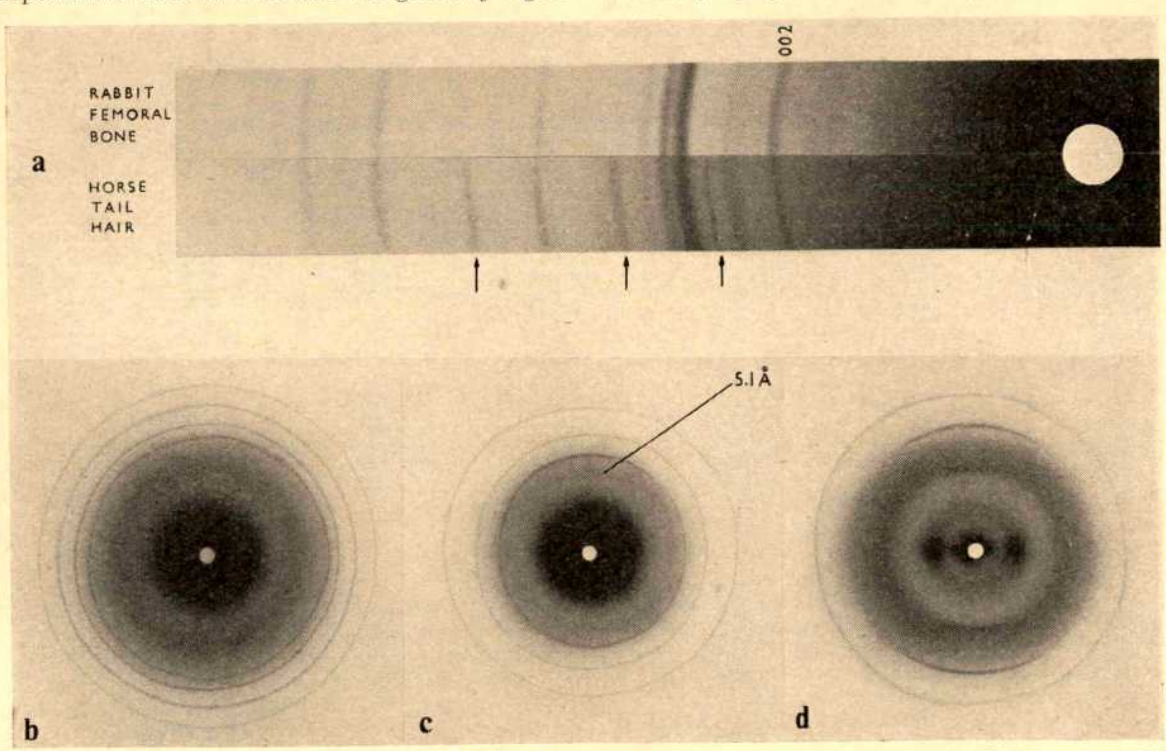

Fig. 1. X-ray diffraction patterns from keratins and enamel matrix. All specimens were examined by copper *Kα* radiation, collimated by glass capillary, using a flat-film camera with a 4-cm specimen-to-film distance
(*a*) Comparison of patterns from specimens of rabbit femoral bone and horse tail hair, both calcined at 900° C for 2 h and rinsed briefly with ion-free water. The 002 reflexion is marked for reference; added reflexions from the horse tail hair are indicated by arrows. (*b*) Calcified region of bear (*Ursa ferox*) claw, beam perpendicular to the claw axis. (*c*) Stretched and dried fibres drawn from partially decalcified films of enamel matrix from the erupted incisor teeth of new-born calves, fibre axis vertical. The equatorial spacing at about 10 Å has been obliterated by the exposure necessary to demonstrate clearly the reflexion at 5·1 Å, which is marked for reference. (*d*) Fringe fibres from the baleen of the fin whale (*Balaenoptera physalis*), fibre axis vertical

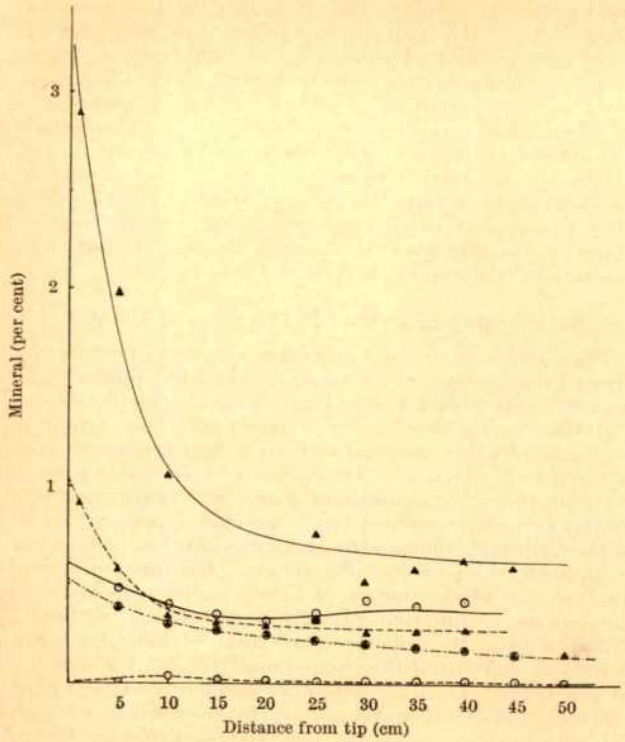

Fig. 2. Distribution of mineral salts in horse tail hairs. ▲, Non-medullated hairs; ○, medullated hairs. —, total mineral (ash); —·—, Ca^{++}; — — —, calcium phosphate calculated as $Ca_{10}(PO_4)_6(OH)_2$

In some instances, the phosphate concentrations were so low that less than 10 per cent of the calcium salt could be accounted for as $Ca_{10}(PO_4)_6(OH)_2$. No carbonate was detected in these phosphate-deficient specimens; the insoluble portion of the ash gave characteristic 'calcined bone' X-ray diffraction diagrams (similar to the pattern from horse tail hair shown in Fig. 1*a*).

In the hoofs that were examined, the calcification zone was always visible to the eye as a white line or patch confined to the least worn (middle) region of the hard wall (unguis). In cattle from the Leeds area the proportion of salt in the centre of the wall keratin was not high, but in many wild ungulates, such as the Klipspringer (*Oreotragus oreotragus saltratrix*), the very hard hoof tips were heavily mineralized. Under the optical microscope, the particles of calcium salt were usually observed grouped around the horn tubules. A typical pattern of mineralization in bovine hoofs is illustrated in Fig. 3*a*. In detail, shown in higher magnification in Fig. 3*b*, the particles showed up in various forms, mostly within the cells, which were sometimes filled completely with salt. In other areas, the deposits were elongated, flattened and irregular in shape; or scattered as a fine dust round the perimeter of the cells. All these structures (and often the whole cells) stained strongly for calcium. Treatment with 0·1 N hydrochloric acid or 0·2 M ethylenediamine tetraacetic acid (sodium salt *p*H 7·4) removed the particles completely, leaving only the small, easily identified melanin granules in those parts which happened to contain pigment.

In human finger- and thumb-nails, the calcified structures present appeared to be similar to those found in hoofs, except that the pattern of calcification varied considerably, often changing from thin 'woven' layers of sparsely distributed, mineralized cells to sheets and patches of dense salt in the space of a hundred microns or so of tissue (Fig. 3*c*).

A most striking example of a functional pattern of intracellular calcium deposits was found in leopard claws, where the mineralized zone is clearly visible as an opaque band narrowing in an arc to the tip of the claw (Fig. 3*d*). In transverse section (Fig. 3*e*) the mineralized cells are arranged into a T-shaped pattern, with the long

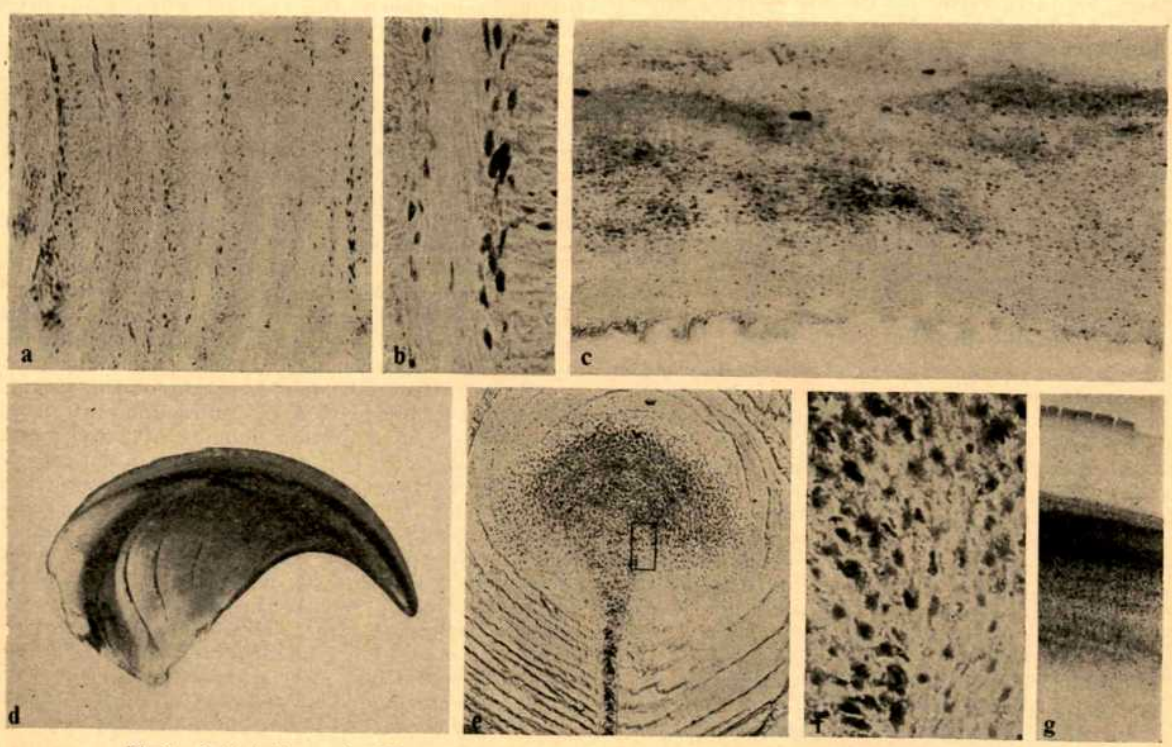

Fig. 3. Optical micrographs of Group II keratins. Each specimen has been cleared by immersion in clove oil (*a*) Longitudinal section of tubules in the calcified zone of the unguis of domestic cattle hoofs (× *c.* 55). (*b*) Enlarged detail of particle arrangement from (*a*) showing general shape of the deposits (× *c.* 300). (*c*) Transverse section of human thumbnail showing variations in density and distribution of the calcium deposits (× *c.* 50). (*d*) Leopard claw, bisected and viewed by transmitted light (× *c.* 1·5). (*e*) Transverse section tip of leopard claw. The annular fracture lines have been produced by the knife during sectioning (× *c.* 60). (*f*) Detail of mineralized cells outlined in (*e*) (× *c.* 420). (*g*) Longitudinal section of bear claw showing dense calcification zone (× *c.* 20)

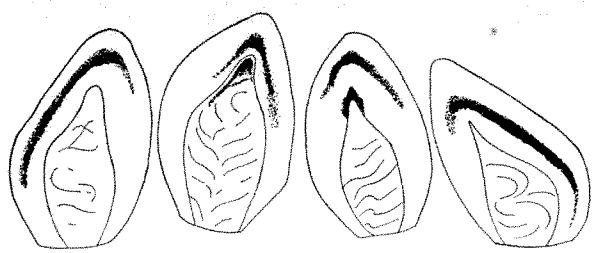

Fig. 4. Distribution of calcified deposits in rabbit claws. Right hind-foot viewed from below, sections cut about 5 mm from the claw tips. The keratin wears down to the outer edge of the mineral deposits. Note that in the outer central digit the anterior part of the 'soft' sub-unguis is hardened with salts also

limb of the T forming a rigid keel or strut to the concave (ventral) surface of the claw. The calcium salts appear to be laid down within the cells in positions corresponding to nuclei. In detail, these dense 'nuclear' particles are often surrounded by numerous smaller granules (Fig. 3*f*). Judging from the disposition of the calcified zone in the claw and from the fracture lines shown in Fig. 3*e*, it is clear that, as the cat sharpens its claws, the outer sheets of softer, less-mineralized keratin are flaked away, exposing the hardened core, which then maintains the hook-like shape of the organ by the resistance to wear of the projecting strut on the concave surface. In spite of the heavy impregnation of the central cells with salts and the hundred-fold increase in calcium content from the 'soft' to the 'hard' parts of the claw (Table 1), no reflexions suggesting crystalline inorganic substances have been found in the X-ray diffraction diagrams of any specimen of this or related types of claw. The relatively low phosphate concentrations suggest that other calcium salts or complexes may play a part in hardening the tissue.

In claws of the bear, on the other hand, a similar dense calcified zone (Fig. 3*g*) was found to give sharp 'salt' reflexions in the X-ray diffraction diagram (shown in Fig. 1*b*) indicating crystallites of similar, or larger, size than those found in enamel. In this subject, mineral particles were observed so closely packed together that in places the local concentration of salt was estimated to be about 50 per cent.

In other claws, several zones of calcification were traced in each specimen. The rabbit, for example, appears to possess a highly complex calcification pattern in its claws, each of which contains a different arrangement of salts. In the hind feet, the densest deposits were found dorsally on the two central digits but they extended down the outer sides of the claws on the two outer digits; the overall effect on the closed paw is an effective 'scoop' of salt-hardened keratin (Fig. 4).

Group III : Bird Beaks and Baleen

The distinguishing characteristic of this group was that most of, or all, the mineral fraction was in the form of calcium phosphate; where X-ray diffraction patterns indicated a crystalline salt, it was present as hydroxyapatite and usually oriented with respect to the axis of the organ.

Baleen is the best example which has been found so far of oriented deposits of bone salts in the keratins. The whalebone plate is a complex structure composed of rows of hard fibres embedded in a softer matrix; the whole is enclosed in a thick sheath of tough covering horn. As the closely packed plates wear, the fibres fray along the lingual margin to form the curtain of bristles with which the whale strains its food. The baleens from all the rorqual whales showed evidence of oriented deposits of hydroxyapatite, although the amounts of calcium and phosphorus were found to be different in each species of whale and always greater in the fibres than in the covering horn (sei whale, Table 1). On the other hand, no crystalline inorganic salts were detected in any part of Greenland whale baleen, even though the amount of calcium and phosphorus was the same as that found in the lesser rorqual whale. As in the case of the rorqual baleens, however, more calcium and phosphorus was found in the fibres than was found in the covering horn. All the baleen fibres were found to be unevently calcified, the calcium salts being laid down in concentric layers which increased in number and density towards the central tube. The evidence suggests that irrespective of the crystallinity of the calcium phosphate, the way in which the solid baleen plate wears away into a triangular shape with a fringe of fibres on one side could be decided by the distribution of calcium salts alone (cf. Figs. 2 and 3*d*).

Relationship of Enamel to Mineralized Keratin

The exception to the apparently universal partnership of hydroxyapatite (or crystallographically similar substances) with collagen has been enamel, which contains plate-like crystallites of larger size than those found in bone and dentine, associated with a sparse matrix often referred to as 'keratin'. The nature of the enamel protein is debatable, since amino-acid analyses[7–9] of the insoluble matrix of mature enamel have included 5 per cent or so of the hydroxyproline in the assay and this has been taken to indicate the presence of collagen. Recent amino-acid analyses[10–12] of the matrix of fœtal enamel suggesting an anomalous proline-rich protein (or proteins) markedly different from the substances of mature tissue have not helped to establish if the enamel matrix is truly a member of the keratin family. Attempts to identify the enamel matrix by X-ray diffraction have been even less successful; the protein has been described as being in the β- (ref. 13) or cross-β- (refs. 14–16) configuration; or in no recognizable form[17]. The evidence is inconclusive but it could be that the mineral salts in enamel are deposited in a collagen-free matrix.

Although the enamel matrix is flimsy and difficult to prepare for X-ray diffraction examination, it is possible to remove thin membranes of (predominantly) enamel protein by the cautious decalcification of appropriate tissue, particularly the erupted incisors of new-born calves[15]. Thin, dry films of such preparations have not been found to give clear X-ray diffraction patterns; a sharp meridional reflexion at 4·2 Å (lipid) was frequently observed in films viewed with their edges parallel to the X-ray beam. Otherwise, the pattern was of non-specific protein; no continuous, or meridionally disposed, reflexion at about 4·65 Å suggesting the β- or cross-β-state was observed in any preparation. It is therefore likely that previous reports[13–16] might be the results of artefacts caused by denaturation.

On the other hand, it was found that when the wet enamel membranes were stretched in moist air, they extended easily into fibres. A few of these fibres contained reflexions suggesting collagen (presumably contaminating material from dentine), but when carefully prepared, particularly from the labial margin of the tooth, both wet and dry fibres gave X-ray diffraction patterns indicative of the α-configuration, judging from the meridional reflexion at 5·1 Å and a broader equatorial reflexion at about 10 Å. In some cases it was found possible to partially decalcify the enamel in such a way that the remaining enamel crystallites were stretched with the fibres to give an oriented pattern of hydroxyapatite superimposed on a typical α-keratin-like diagram (Fig. 1*c*), altogether closely comparable with the diffraction pattern from fin whale baleen (Fig. 1*d*). Mature enamel, therefore, may contain a small proportion of protein in the α-state which can be detected best after stretching the enamel matrix.

This result might be expected from the amino-acid analyses of the mature enamel protein. The whole enamel matrix from fœtal teeth contains too much proline to be readily compatible with a stable α-helix[18], but there is no evidence that the proline-rich protein (or proteins) persist during enamel maturation, and it is reasonable to suppose that in enamel, as in other typical 'α-keratins', there are

changes in the cell contents as the microfibrils are formed. The ameloblasts may not synthesize fibrous proteins as completely as other mammalian epidermal cells and hence the portion of protein in the α-configuration may be less.

Conclusions

The evidence presented above seems to leave little doubt that the mineralization, particularly the calcification, of keratins is a widespread and complex phenomenon associated closely with the form and function of horny tissues. It is impossible to generalize about the inorganic hardening process which controls the rate of wear of the epidermal 'skeleton'. The mechanism seems to function on a cell-to-cell basis according to local demands—the worn horse tail is the result of different mineralizations of hairs, the rabbit's claws are armoured for their collective purpose by the co-operation of many regions of calcified cells.

The gross assay of keratin for minerals is at best a pointer which gives us no clues as to the distribution of the hardening cells. The X-ray evidence, too, must be treated with caution; less than 0·2 per cent of crystalline salt can produce a distinctive pattern, often in subjects containing the major bulk of their inorganic substances in some other amorphous form.

While the X-ray diffraction patterns from most keratins containing crystalline salts suggest consistently that calcium phosphate in the form of hydroxyapatite might be present (and the similarity between the calcined keratin and bone patterns emphasizes this possibility throughout) it is only in the Group III keratins that organized deposits of bone salt alone have been demonstrated beyond doubt. In the Group I keratins, the nature of the mineral is debatable. The calcium and other salts may be present in the form of small, diffuse, sub-crystalline particles, but it is equally likely that some, or all, of the hardening ions and complexes will be cross-linked with the protein matrix.

In the Group II keratins, where there are many examples of 'anomalous' calcium salts, it is clear that the deposits are laid down inside the cells. While intracellular calcification does not normally take place in bone and most invertebrate shells and tests, it has been reported in renal disease[19] and in Protozoa[20] and may be more common than has been supposed hitherto.

The heterogeneous character of calcification in the keratins suggests that even in enamel, where the 'keratin' is replaced almost entirely by calcium phosphate, there are probably areas of different hardness depending on the function of each type of tooth. The history of wearing baleen, or sharpened claws, is doubtless repeated to some degree in every keratinous tissue; to what extent the pattern of hardening is determined by selection or by environment is a matter which requires further investigation.

Finally, the occurrence of well-oriented deposits of hydroxyapatite in the keratins raises wider issues about calcification. Calcium phosphate has been examined principally in bone (and in the analogous dentine), where the association of small inorganic crystals of specific size and composition with collagen has led to numerous theories as to the role of this protein in the initiation, growth and orientation of the mineral phase. There is a need to re-examine the present theories of calcification now that hardened vertebrate tissues other than bone and enamel have come to light. Work is in progress to this end and will be reported in due course.

I wish to thank Dr. K. M. Rudall for much valuable information, the staff of the British Museum of Natural History for specimens and useful advice, and Mr. F. B. Preston for assistance; this work is part of a programme supported by grant *DE*–01345–02 from the U.S. National Institutes of Health.

NEWS and VIEWS

Virology and Bacteriology at Birmingham : Prof. N. P. L. Wildy

Dr. N. P. L. Wildy has been appointed professor of virology and bacteriology at the University of Birmingham. He is forty-three years of age and was educated at Eastbourne College, Caius College, Cambridge, and St. Thomas's Hospital. He served for two years in the R.A.M.C., principally with the Royal West African Frontier Force, both in West Africa and India. In 1947 he was senior medical officer of Sierra Leone and of Gambia. After hospital appointments in medicine, he joined the Department of Bacteriology, St. Thomas's Hospital Medical School, first as a research fellow and during 1952–58 as lecturer and senior lecturer. At this period he spent a year as a British Memorial Fellow in virology at the Walter and Eliza Hall Institute in the University of Melbourne. Since 1959 until now he has been assistant director of the Medical Research Council Experimental Virus Research Unit in the University of Glasgow. Dr. Wildy is the author of some thirty papers, principally on the structure of viruses, particularly those of a symmetrical configuration as the icosahedral form of adenovirus. In these investigations, Dr. Wildy has developed new methods of delineation by electron microscopy. Dr. Wildy will continue this work in Birmingham, as well as directing the Department of Virology and Bacteriology in the Medical School and acting as a consultant in bacteriology to the Queen Elizabeth Hospital.

Physics at Birmingham : Dr. S. E. Hunt

Dr. S. E. Hunt has been appointed head of the Department of Physics in the College of Advanced Technology, Birmingham. Dr. Hunt was head of the Nuclear Physics Section at the Associated Electrical Industries (A.E.I.) Research Laboratory, Aldermaston. He was born in 1922 and was educated at Belle Vue Grammar School, Bradford, and then read science in the University of Liverpool. His studies were interrupted by War Service in the Royal Air Force and he graduated at Liverpool with first-class honours in physics in 1947. He joined the A.E.I. Research

Laboratory at Aldermaston in 1947, and in 1952 obtained a degree of Ph.D. at the University of Reading. He was elected Fellow of the Institute of Physics in 1957, and in 1958 was appointed visiting professor in modern physics in the University of Algiers. Dr. Hunt's main research interest has been in low-energy nuclear physics and he has a considerable list of publications in this field, and on the development of Van de Graaff accelerators. He has also published a number of papers on thermo-nuclear work and during 1960–61 acted as head of the Thermo Nuclear Section at A.E.I., Aldermaston. He was also in charge of Radiological Protection for the A.E.I. Woolwich Group of Companies.

Theoretical Physics at Bristol : Dr. J. M. Ziman

Dr. J. M. Ziman, whose appointment to the newly created chair of theoretical physics in the University of Bristol has recently been announced, studied in New Zealand and Oxford. He graduated from Victoria University College, Wellington, New Zealand, in 1945, and obtained an M.Sc. in physics there in 1946, after which he went to Balliol College, Oxford, to read mathematics. He took his Oxford B.A. in 1949, and D.Phil. in 1952, and continued as a postdoctoral research fellow in Oxford until 1954, when he moved to Cambridge to join Sir Nevill Mott, who had himself just left Bristol to become Cavendish professor in the University of Cambridge. Prof. Ziman's early work was on antiferromagnetism, on the hydrodynamics of liquid helium, and on thermal conductivity in solids. More recently his research interests have extended to cover the whole field of transport phenomena in solids, particularly metals, and to liquid metals. His book, *Electrons and Phonons*, is already a classic. He has had success as leader of a theoretical research group on these topics in Cambridge. He has also shown a wide interest in the more general academic affairs of the University, as joint editor of the *Cambridge Review*, and as author of articles in the national weeklies. His move to Bristol will strengthen the already traditional interest there in the properties of solids and liquids, pioneered by Lennard Jones and Mott. Prof. Ziman is at present on leave of absence in Australia and is expected to take up his duties in Bristol in October 1964.

Microbiology in the University of London : Prof. B. A. D. Stocker

Dr. B. A. D. Stocker has been appointed to the new Guinness chair of microbiology of the University of London at the Lister Institute of Preventive Medicine. Dr. Stocker, who is forty-six, qualified in medicine in 1940, from King's College, London, and Westminster Hospital Medical School. In 1946, after service in the R.A.F.V.R. Medical Branch, he returned to Westminster Medical School, to the Pathology Department. During 1948–53 he worked in the Department of Bacteriology in the London School of Hygiene and Tropical Medicine, spending 1951–52 as a Commonwealth (now Harkness) Fund Fellow in the Department of Microbiology at New York University College of Medicine. In 1953 he was appointed head of the Guinness–Lister Research Unit in the Lister Institute. The Institute owes the establishment and maintenance of this unit, for research in microbiology, to the generosity of the Directors of Messrs. Arthur Guinness, Son and Co., Ltd.

The work of the Unit in bacterial genetics and physiology has elucidated the phenomena of abortive transduction and somatic antigen conversion effected by phage in *Salmonella*, the genetics, physiology and biochemistry of bacterial flagella and motility, and the transmissible determinants of production of colicine; recently these determinants have been used to obtain fertility in *Salmonella*, and all of many different loci have been found to fit into a single closed-loop linkage group. The new chair, which is named to commemorate the contribution of Messrs. Arthur Guinness to microbiological research at the Institute, is the first chair of microbiology to be established in the University; Prof. Stocker will continue to direct the Unit's researches, and to teach graduate students.

Mathematics at Manchester : Prof. J. S. Griffith

The Councils of the University of Manchester and the Manchester College of Science and Technology have approved the appointment of Dr. J. S. Griffith to a newly created chair in mathematics in the Faculty of Technology. Dr. Griffith, who is thirty-four years of age, entered Trinity College, Cambridge, with an open major scholarship in natural science in 1946. He was awarded a senior scholarship at Trinity in 1948 and obtained a distinction in Part III mathematics in the following year. During 1949–51 he worked on the course for a Part II natural science in biochemistry and was awarded a research scholarship at Trinity College. In 1951 and 1952 he was engaged in research in the field of theoretical chemistry and in October 1952 was awarded a senior Royce Boyle studentship which he was permitted to use for a year of research at Oxford in Prof. C. A. Coulson's Department. In 1953 he was engaged at the Admiralty Research Laboratory, Teddington, and in 1954 was awarded the Stokes studentship by Pembroke College, Cambridge. For the next five years he was engaged in research at Cambridge on various aspects of theoretical chemistry, molecular physics and biophysics, receiving in 1956 the Berry–Ramsey fellowship in mathematics at King's College, Cambridge, which he still holds. He became professor of chemistry in the University of Pennsylvania in 1960, returning to Cambridge in 1961 to undertake further research. He was awarded the Marlow Medal of the Faraday Society in 1961 and was awarded an Sc.D. at Cambridge in the same year. He has recently completed a three-months period as professor of chemistry at Stanford University, California. Dr. Griffith is the author of two books and has published a considerable number of papers in various scientific journals. He will take up his new appointment in September.

Genetics at Canberra : Prof. D. G. Catcheside, F.R.S.

The Australian National University, Canberra, has established a chair and Department of Genetics within the John Curtin School of Medical Research, and Prof. D. G. Catcheside has been appointed as the first professor. The John Curtin School of Medical Research at present consists of Departments of Biochemistry, Experimental Pathology, Medical Chemistry, Microbiology, Physiology and Physical Biochemistry, so the addition of a Department of Genetics will add considerable strength to the research structure of the School. Prof. Catcheside, who is fifty-six, has been professor of microbiology in the University of Birmingham since 1956. During 1952–55 he was professor of genetics in the University of Adelaide. He held a visiting professorship at the California Institute of Technology in 1961. Educated at the Strand School and the University of London, Prof. Catcheside held teaching appointments in the Universities of Glasgow, London and Cambridge from 1928 until 1950. He was reader in cytogenetics at Cambridge during 1950–51, and a Fellow of Trinity College, Cambridge, during 1944–51. Until comparatively recently Prof. Catcheside carried out genetical and cytological work with flowering plants, particularly the evening primrose. During this period he made the notable discovery that the position of a gene in the chromosomes of a plant may profoundly alter its activity. His later experiments were concerned with the effect of radiations on the genetic material. For about the past ten years he has examined the genetics of the bread mould, *Neurospora*, making important discoveries regarding the interactions of gene products in the cell. He is the author of a book, *The Genetics of Micro-organisms*, and was elected a Fellow of the Royal Society in 1951 for his outstanding research. He became a Foundation Fellow of the Australian Academy of Science in 1954.

Developments in Television Services in the United Kingdom

In a written answer in the House of Commons on July 9, the Postmaster-General, Mr. J. R. Bevins, stated that he had approved, in principle, proposals by the British Broadcasting Corporation to build additional 405-line stations in Band III to serve north-east Wales, south-west Scotland, east Lancashire, mid-Lancashire and south-west Lancashire, and to proposals by the Independent Television Authority to serve the Bedford/Peterborough, Central Berkshire, east Lancashire, Scarborough, Dundee and Caithness/Orkney areas. The last-mentioned six stations would bring the programmes of independent television to nearly a million new viewers and would improve reception for 600,000 others. The north Wales station would complete the main network of stations transmitting the B.B.C.'s distinctly Welsh programmes, and the additional station to serve south-west Scotland would enable this area to receive programmes transmitted in Scotland while continuing to receive those available on the B.B.C. English network. The remaining three stations were designed to improve reception in Lincolnshire and Lancashire, which is at present spoilt by periodic interference from Continental stations operating on the same channels. The low-power Band I satellite stations to serve Grimsby and Blackpool would no longer be necessary, but the B.B.C. stations for north-east Wales and south-west Scotland and the I.T.A. station for the Bedford/Peterborough area would need to use Channel 6. The Mullard Observatory at Cambridge was conducting a sky-survey of the northern hemisphere using frequencies within Channel 6, and until this survey was completed at the end of 1967 it would be necessary to restrict transmissions from these stations on Channel 6 to the twelve-hour period noon to midnight.

Oil in Navigable Waters

The Oil in Navigable Waters Bill, which received its second reading in the House of Lords on June 28, gives effect to the amendments to the International Convention for the Prevention of Pollution of the Sea by Oil, 1954, agreed by the Convention of March–April 1962. This, as Lord Aberdare explained, was attended by 55 countries, and the amendments have already been ratified by France, Poland and Sweden, and the Bill will enable the United Kingdom Government to ratify them also. Clause 1 relates to sea areas in which the release of oil is prohibited and eliminates the distinction between tankers and other ships. One of these areas extends some 1,000 miles westward into the Atlantic from Iceland to Cape Finisterre, including the whole of the Bay of Biscay, the English Channel, the North Sea, the Irish Channel and the Baltic Sea. Clause 2 makes it an offence for any United Kingdom registered ship of 20,000 gross tons or more, for which the building contract is placed after the clause becomes effective, to discharge persistent oil anywhere at sea. The intention is that ships of this size built in future should include arrangements for retaining oil separated from water in tank washings, oily ballast water and oily residues, so that clean water only is discharged at sea and oily waste deposited on arrival at port. Discretionary discharge in special circumstances outside the prohibited areas is allowed provided the master reports the fact to the Minister of Transport. Naval vessels are still excluded, but the provisions of the Bill now apply to other Government ships such as cable-layers and weather ships. The Marquess of Willingdon warmly welcomed the Bill on behalf of the Fauna Preservation Society and the World Wild Life Fund. Lord Hurcomb referred to the difficulty caused by some authorities abroad who charged dues on the separated oil.

Seismological Computing Centre, Edinburgh

The U.S. National Science Foundation has awarded 280,700 dollars to the University of Edinburgh to assist in the establishment of a Seismological Computing Centre within the Department of Astronomy. The award will be supplemented by a grant of £10,000 capital and £6,500 recurrent from the British Treasury. It is hoped that the project will be the beginning of a continuing International Service. The awards arise from recommendations which were made by the Committee for the International Seismological Summary, which pointed out the inability of existing institutions to cope with the increasing flow of data from the seismograph stations of the world. The first objective of the new Centre will be to use the station readings to determine the positions of origin of all the earthquakes which can be detected, at present estimated at some 30,000 events per annum. This activity will provide the basis for numerous research and engineering projects, ranging from the study of the deep interior of the Earth to the investigation of local tectonics and the estimate of earthquake hazards in developing countries. The establishment of the new Centre will make Edinburgh one of the focal points of world seismology. As such, it should provide great stimulus to the existing Seismological Research Group at the Royal Observatory which is led by Dr. P. L. Willmore, and which is a joint project of the University, the Department of Scientific and Industrial Research, and of the Scottish Home and Health Department (see also *Nature*, **195**, 1250; 1962).

Graduate School of Engineering Studies at Trinity College, Dublin

A Graduate School of Engineering Studies will be inaugurated in Trinity College, Dublin, in October. It will provide a full-time course of one year in computer applications leading to the degree of master in science. The course is designed with the emphasis on the mathematical side of computers for graduates in mathematics, physics or engineering, and on the computer as a management tool for graduates in other fields. The School will also provide short courses in engineering mathematics, computers, properties of materials, aircraft structures and photogrammetry, and seminars will be organized on research topics by members of the staff or visiting teachers. Most of the research work related to industry which is being carried out in the Engineering School at present will be transferred to the new Graduate School. The director of the School will be the professor of engineering, Dr. William Wright. Giving information about the purposes of the School recently, he said that the rapid technological advance of the present day increased the need for specialization in the various branches of engineering taken at university-level. At the same time, it is becoming more and more necessary to provide advanced instruction beyond the undergraduate stage. The Engineering School at Trinity College recently has introduced new specialized undergraduate courses in civil engineering, mechanical and production engineering, and electronic engineering. A course in aerodynamics will begin in the autumn. The new Graduate School will have the two main functions of continuing the education of new graduates and providing refresher courses for older engineers with the aim of bringing them up to date in new branches of technology relevant to their fields of work.

The Volcanic Eruption on Tristan Da Cunha, 1961–62

In October 1961, after two months of earth tremors, an eruption occurred a few hundred yards from the only village situated on a low-lying coastal plain on the north-west side of the island. This resulted in the immediate evacuation to Great Britain of the entire population of nearly 300 islanders and Europeans. This eruption aroused considerable interest among volcanologists mainly because: (*a*) Tristan had previously been considered to be an extinct volcano; (*b*) the type of eruption, that is, the extrusion of a solid tholoid followed by extremely viscous blocky lava flows, had rarely been observed during growth on a truly oceanic island. The Council of

the Royal Society considered these factors warranted immediate investigation by scientists while the eruption was still proceeding, and in November 1961 formed a committee to consider the possibility of dispatching scientists to the island.

During December 1961 two geologists made a brief reconnaissance visit to Tristan da Cunha aboard H.M.S. *Jaguar* by courtesy of the Royal Navy (*Nature*, **193**, 719; 1962). This brief visit was followed in January 1962 by a twelve-man expedition which spent seven weeks on the island (*Nature*, **194**, 1119; 1962). This expedition included four geologists, one botanist and one zoologist, and the summary of their preliminary results was reported at a discussion meeting of the Royal Society in February of 1963. A film which was largely taken by the members of the Royal Society expedition shows the development and growth of the volcano from the beginning of the eruption in October 1961 until March 1962, when active growth had virtually ceased. It also indicates some of the effects of the volcano on the flora and fauna of the island. The film is of approximately 20-min duration, in colour, sound on film, and is available on hire at a charge of 25*s*. from the Executive Secretary, The Royal Society, Burlington House, W.1.

Royal College of Science and Technology, Glasgow: Biological Engineering Research

The Department of Mechanical Engineering of the Royal College of Science and Technology has received a grant of £50,000 from the Medical Research Council to support the further development of biological engineering research. 'Biological engineering' is a collective phrase used to describe the application of a wide range of specialist aspects of the physical sciences and of technology, in collaboration with the medical disciplines, to investigation of problems relating to the human body. There is already very considerable activity in biological engineering in Britain and abroad; yet the field is so wide and the problems so numerous that the present effort will have to be considerably intensified if the full potential of this collaboration is to be realized. Work in this field commenced at the Royal College of Science and Technology some six years ago with the application of refrigeration techniques in hypothermia, followed at a slightly later stage by the experimental studies of skin tensions in the human body. Since then, the College's research activity has greatly intensified in close co-operation with surgeons and physicians in Glasgow's teaching hospitals, combined teams drawn from the professions working in the College engineering laboratories, the hospital wards, the operating theatres and the medical research departments. The success of this co-operation has led to the creation of a College-based Biological Engineering Unit under the direction of Dr. R. M. Kenedi. The work will be carried out under the guidance of a Steering Committee composed of representatives of the Medical Units concerned and of the College.

British Food Manufacturing Industries Research Association

The annual report for 1962 of the British Food Manufacturing Industries Research Association has recently been published. The research programme has been largely concerned with problems which arise in factories dealing with cocoa and chocolate, sugar confectionery, meat and fish products, preserves, pickles and sauces, oils and fats and baker's prepared materials. Apart from contributions to the general literature, the Association published during the year six research reports and nineteen technical circulars. The 'analytical service' examined a total of 1,190 samples, of which 30 per cent were meat products for assessment of the proportion of meat present and 20 per cent were sugar products and chocolate for general composition. The special section dealing with extraneous materials handled 275 samples, of which 40 were rejected as failing to conform with U.S. requirements. Also 52 of the 81 samples examined for the Howard mould count failed to conform to presumptive U.S. tolerances. In addition, the 'bacteriological service' examined 978 samples, including 548 curing brines. The new library and information office came into full operation in September. The newly appointed director of research, Dr. C. L. Cutting, states in his report: "It should not escape official notice that although the largest single item amounting to between 20 and 25 per cent of the national outlay is food at £5,000 million a year, the total of about £5 million expenditure on technological research by the food manufacturing industry and Government combined is woefully inadequate compared with a number of other industries that are surely no more vital than food".

Further Education for School Leavers

A new booklet, entitled *Further Education for School Leavers*, which the Ministry of Education is sending to every secondary school in England and Wales, is intended to help teachers, and particularly careers masters and mistresses, to advise boys and girls as to the extent and variety of courses now available for those who wish to continue their education after leaving school (Pp. 40. London: Ministry of Education. 1963). The first two chapters deal with full-time courses for the sixth-form and fifth-year leaver, respectively; the third deals with other opportunities in further education, and the fourth with opportunities for girls, particularly in commerce, in science, in librarianship, management and catering, and in nursing. Enrolment, fees and grants are dealt with in a fifth chapter and lists of Colleges of Technology and of publications are appended. The booklet deals with the technical colleges as well as the universities, including also the social sciences, art, agriculture and commerce.

Science Journalism

The first Inter-American Seminar on Science Journalism was held in Santiago, Chile, during October 16–18, 1962, under the sponsorship of the Department of Scientific Affairs, Pan American Union, and of the Technical Centre of the Inter-American Press Association. The main purposes of the Seminar, the report of which is now published (Pp. iii + 30. Washington, D.C.: Department of Scientific Affairs, Pan American Union, Pan American Bldg. 1963. 35 cents), were to examine the techniques of science journalism, discuss some aspects of Latin American science, and promote better understanding among scientists and journalists. Besides abstracts of addresses given at the Seminar, the report includes the recommendation of the three committees appointed to deal with educational, information and administrative matters, respectively. The Committee on Educational Matters recommended universities to include in the programmes of schools of journalism and communications, curriculum courses in science journalism or chairs widening the traditional concepts that relate this work to humanism and philosophy. The universities and schools of journalism are also recommended to conduct seminars for professional journalists and schools of journalism in accordance with the science journalism programmes. The Committee also recommends to the Department of Scientific Affairs of the Pan American Union a programme including publication of a list of science writers, promoters and reporters in the hemisphere, publication of text-books popularizing science, translation and publication of didactic text-books on journalism, organization of an Inter-American course for professors of scientific journalism, interchange of schools of journalism curricula, establishment of awards to outstanding science journalists, and possibly the foundation of a Latin American association of science journalists.

Synthesis of Normally Dispersed Wave Trains by means of Linear System Theory

Stephan Mueller and Maurice Ewing have published a thesis with this title as contribution No. 559 of the Lamont Geological Observatory, Columbia University, Palisades, New York. Examples of natural wave propagation processes with normal dispersion are seismic surface waves and explosion sounds in shallow water. If transient signals of this kind are analysed by a new technique, it is possible to display directly the group travel time as a function of frequency. A quantitative description of this empirical dependence in the frequency domain yields an explicit system function, the inverse transform of which, for regular dispersion, has the form of an Airy function in the time domain. For inverse dispersion the solution leads to a Bessel–Clifford function, while for wave propagation processes associated with minimum group travel time the convolution integral of these two types of functions is obtained. These system transfer functions include instrumental distortion caused by the amplitude and phase characteristics of the recording system. The most important system property is the relation between the phase characteristics deduced from the group travel time and the logarithmic amplitude function of wave propagation systems with energy losses due to leakage. By means of the known transfer function the system response due to various physically plausible input functions can be synthesized. If these theoretical results are compared with actual observations, it is possible to draw certain conclusions with regard to the transient excitation at the focus of the disturbance. The deductive method described, therefore, not only permits us to make statements about the behaviour of wave propagation systems in the complex frequency domain, but also allows us to find some essential criteria concerning the little-known mechanism of the focal transient.

Small-Animal Anæsthesia

A SYMPOSIUM organized by the British Small Animals Veterinary Association (BSAVA) and UFAW (Universities Federation for Animal Welfare) at the Middlesex Hospital Medical School during July 23–24 achieved outstanding success and is likely to lead to studies, far better co-ordinated in the future than in the past, of the techniques for anæsthetizing laboratory animals and animals dealt with in veterinary practice. The Organizing Committee, comprising Mr. Oliver Jones of the Zoological Society, who acted as chairman, Mrs. Joyce Wright of the BSAVA, who acted as organizing secretary, Dr. Phyllis Croft and Miss Felicity Charig of UFAW, and Dr. Lane-Petter of the Medical Research Council, brought together a remarkable array of experts to deal with the techniques of anæsthetizing primates, reptiles, amphibians, aquatic animals including fish and porpoises, rodents and lagomorphs, birds including fowls and cage birds, the smaller ungulates, and carnivores including, among others, stoats and weasels. The proceedings were opened by Dr. S. J. Folley and closed by Prof. J. G. Wright, a historic figure in this field who directed particular attention to the risks incurred in the use of muscular paralysants as adjuncts to anæsthesia. The proceedings, which will be published by the Pergamon Press, exhibited a combination of technical expertise and unashamed humaneness which cannot fail to stimulate thought and research in the important and difficult field with which they deal.

U.S. Air Force Office of Scientific Research: Research Grants and Contracts

THIRTY-SEVEN universities and sixteen research firms in the United States and Europe were awarded research grants and contracts, amounting to more than three million dollars, during the month of May, by the U.S. Air Force Office of Scientific Research. The May grants and contracts bring the total for this fiscal year to more than twenty-eight million dollars. The primary mission of the Air Force Office of Scientific Research is "to support research through grants or contracts based on unsolicited proposals both within the United States and throughout the free world". Grants in Europe, Africa and the Near East are administered by the European Office of Aerospace Research, Brussels.

The Jane Coffin Childs Memorial Fund for Medical Research

THE Jane Coffin Childs Memorial Fund for Medical Research supports investigations in the fundamental aspects of neoplastic growth, and awards post-doctoral fellowships to candidates of outstanding potential in the same field. Applications for grants-in-aid are reviewed by the Board of Scientific Advisers and the Board of Managers of the Fund three times a year, in the fall, winter and spring. Final dates for receipt of applications are September 1, November 1 and March 1. Fellowship applications are reviewed at the winter meeting of the Fund, the final date for applications being October 1 of each year. Grants-in-aid and fellowships are not restricted to U.S. nationals. Information may be secured from the Office of the Assistant Director, 333 Cedar Street, New Haven 11, Connecticut.

Registrar General's Quarterly Return for England and Wales

THE *Registrar General's Quarterly Return for England and Wales* for the last quarter of 1962 (H.M.S.O., 1962. 2*s*. 6*d*. net) makes it possible to calculate the natural increase for that year. The total number of live births was 840,557, the largest number since 1947. There were 557,446 deaths, in absolute numbers also the largest figure since 1940. Natural increase therefore amounted to some 283,000 persons, a figure which is very considerably in excess of the average of 203,000 in the period 1952–60 and nearly 30,000 higher than the figure of 252,000 for 1961. The acceleration in rate of population growth in Britain is well brought out by these data. It has become customary to have a new record low in the infant mortality rate each year, and 1962 is no exception, though the decline was marginal from 21·6 to 21·4 per 1,000, indicating perhaps that the minimum rate likely to be achieved under present conditions is slowly being reached. Stillbirths have decreased more significantly from 19·1 to 18·1 per 1,000, but neonatal and perinatal rates have not yet become available.

Effects of Atomic Radiation

DR. C. AUERBACH has written to the Editor of *Nature* stating that, in her review of the second report of the United Nations Scientific Committee on the Effects of Atomic Radiation (*Nature*, 198, 343; 1963), she warned readers that most of the literature references in the chapters were wrongly numbered. "The Secretary of the Scientific Committee on the Effects of Atomic Radiation has pointed out to me that this warning rests on a misconception, and that the correct use of the reference numbers is explained in a note on p. ii of the report. Unfortunately, this note is not prominently displayed and has been overlooked by most readers. I, therefore, wish to draw attention to it. I should, however, like to add that the present procedure for locating literature references is very cumbersome: the reference number does not refer to a page but to a paragraph in one of the appendixes, and since there are no running headlines it takes some time and effort to find the relevant paragraph. I feel that the usefulness of this extremely useful publication would be greatly enhanced by (1) references to literature by page numbers, (2) running headlines showing appendix and paragraphs, (3) a full index. The latter is of special importance. Many items are discussed in more than one appendix, and at present location of any particular piece of information is a time-consuming job."

University News : London

The title of professor of clinical cardiology has been conferred on Dr. J. F. Goodwin in respect of his post at the Postgraduate Medical School of London. The title of professor of physics has been conferred on Dr. M. J. Seaton in respect of his post at University College. The following titles of reader have been conferred: Dr. D. E. Barton (statistics), in respect of his post at University College; Dr. A. F. Seager (mineralogy), in respect of his post at Birkbeck College; Dr. D. A. Walker (botany), in respect of his post at Queen Mary College.

The title of professor of experimental veterinary medicine has been conferred on Dr. F. R. Bell, in respect of his post at the Royal Veterinary College. The title of reader in anatomy has been conferred on Dr. R. W. Guillery, in respect of his post at University College, and that of reader in physiology on Mr. O. C. J. Lippold, in respect of his post at University College.

Announcements

Dr. F. H. K. Green is retiring from his position as scientific secretary of the Wellcome Trust on August 31. He will be succeeded by Dr. P. O. Williams, at present deputy scientific secretary.

The Robert Cormack Bequest Committee of the Royal Society of Edinburgh has awarded a Robert Cormack Fellowship to Miss Helen M. Hollingsworth, Silverwood, Sywell, Northampton, to enable her to undertake research at the University Observatory, St. Andrews, under Prof. W. N. Stibbs, on radiative transfer in stellar atmospheres and interiors. The Fellowship is tenable for three years and is the seventh award under the Bequest, which is administered by the Society for the purpose of promoting astronomy in Scotland.

The College of Physicians of Philadelphia has awarded the Alvarenga Prize for 1963 to Prof. Rupert E. Billingham, professor of zoology, Wistar Institute, University of Pennsylvania, for his outstanding work on tissue transplantation immunity and immunological tolerance. The Alvarenga Prize was established by the late Pedro Francisco DaCosta Alvarenga, of Lisbon, Portugal, an associate fellow of the College of Physicians of Philadelphia, to be awarded annually by the College on the anniversary of his death, July 14, 1883.

A symposium on "Changing Food Habits" will be held at Queen Elizabeth College, University of London, on September 24. Further information can be obtained from J. C. McKenzie, Nutrition Department, Queen Elizabeth College, Campden Hill Road, London, W.8.

A symposium on "Progress in the Biological Sciences in Relation to Dermatology" will be held in the School of Clinical Research and Postgraduate Medical Training, University of Cambridge, during September 30–October 5. Further information can be obtained from the Secretary of the Medical School, Tennis Court Road, Cambridge.

The Central Electricity Generating Board is organizing a symposium on "Environmental Monitoring", to be held at Berkeley, Gloucestershire, during October 3–4. Further information can be obtained from the Secretary, Central Electricity Generating Board, Room 728, Friars House, 157–168 Blackfriars Road, London, S.E.1.

An informal discussion on "Solvation of Molecules and Ions", arranged under the auspices of the Faraday Society, will be held at Bradford Institute of Technology during September 26–27. Further information can be obtained from Dr. W. R. Moore, Department of Chemical Technology, Bradford Institute of Technology, Bradford 7.

An international summer course on "Advances in Experimental Embryology", sponsored by the NATO Advanced Study Institutes Programme, will be held at the Zoological Station, Naples, during September 30–October 30. Further information can be obtained from Prof. G. Reverberi, Istituto di Zoologia, Università di Palermo, via Archirafi 18, Palermo.

A second regional meeting on "Particle Size Analysis", arranged by the Whiting and Industrial Powders Research Council, is to be held on October 2, 1963, at Sheffield. For further details and tickets please apply to the Director of Research, Industrial Powders Division, Whiting and Industrial Powders Research Council, The Hall, Welwyn, Hertfordshire.

A conference on "Plasma Physics", arranged by the Institute of Physics and the Physical Society, will be held at the Culham Laboratory of the U.K. Atomic Energy Authority during September 24–27. Further information can be obtained from the Administration Assistant, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

The fifth International Congress on Electro-Heat, arranged by the International Union for Electro-Heat, will be held at Wiesbaden during September 30–October 5. Further information can be obtained from the Secretary, British National Committee on Electro-Heat, c/o the British Electrical Development Association, 2 Savoy Hill, London, W.C.2.

A programme of displays and lectures on "Electronics Research and Development for Civil Aviation", organized by the Ministry of Aviation in association with the Electronic Engineering Association, will be held at the Ministry's research establishment at Farnborough and Malvern during September 23–October 1. Further information can be obtained from the Ministry of Aviation, Strand, London, W.C.2.

An international conference on "Elementary Particles" will be held in Sienna during September 30–October 5. The programme will include sessions on: weak interactions; electromagnetic interactions; particles and isobars; GeV physics; future of old and new theoretical ideas; general accelerator programme in Europe. Further information can be obtained from E.N.D. Steel, Scientific Conference Secretariat, CERN, Geneva 23.

A three-day laboratory course on "Radioactive Analysis of Water and Effluents" will be held in the Manchester College of Science and Technology during September 25–27. The course is designed to give practical experience in those radiation measurement techniques which are suitable for the monitoring of radioisotopes at low concentration-levels, and will provide an opportunity to use the latest equipment available. Further information can be obtained from the Registrar, Manchester College of Science and Technology, Sackville Street, Manchester 1.

The special series of postgraduate level courses is to be held in the Liverpool College of Technology for the fifth consecutive year. In the coming session the short full-time courses will cover topics such as radiological protection, radiobiology and radiometric analysis. The two-weeks' full-time courses in radiological protection provide an introductory survey of this increasingly important subject and are of assistance to medical officers and safety officers concerned with the new regulations under the Factories Act and the Radioactive Substances Act of 1960, which is to be implemented from December. The course in radiometric analysis is designed to be of assistance to the analytical chemist who is concerned with the public assessment of radiation hazards in the environment. The courses in radiobiology provide an up-to-date account of advances in this rapidly expanding and important subject. Opportunities for research in all these fields will also be available. Further particulars of all courses are set out in a twelve-page leaflet now available from the Principal Lecturer for Nuclear Studies, College of Technology, New Building, Byrom Street, Liverpool 3.

HUMIDITY AND MOISTURE

THE symposium on "Humidity and Moisture—Measurement and Control in Science and Industry" attracted more than 850 scientists and engineers from five continents to Washington, D.C., during May 20–23. The symposium was sponsored by the U.S. National Bureau of Standards and the U.S. Weather Bureau, both of which are agencies of the U.S. Department of Commerce, together with the Instrument Society of America, the American Meteorological Society, and the American Society of Heating, Refrigerating and Air-Conditioning Engineers. These five organizations joined in sponsoring the symposium because of their interest in humidity and moisture, ranging from the meteorologist's interest in humidity of the atmosphere to the engineer's concern with humidity in cryogenic materials.

The more than 230 papers presented in thirty-two sessions dealt with topics ranging from humidity standards and fundamentals, through means of measuring and controlling humidity and moisture, to specific applications. These applications varied from measurement of the humidity of air for meteorological purposes to determination of moisture in grain—an important factor in storage. Of particular interest were papers on applications in biology and medicine, describing the use of controlled humidity in treatment and the relationship of symptoms to humidity-level.

Moisture has always been the essential, though often invisible, ingredient in most processes of science, industry and agriculture—in fact, virtually every field of human endeavour. To-day humidity measurements are being extended in two dimensions—to include more processes, and to obtain more accurate values. It is now sometimes necessary to know to an accuracy of a fraction of 1 per cent how much moisture is included in a cryogenic material, a refrigerant or a storage enclosure.

All five of the organizations sponsoring the symposium are concerned with problems of measuring and controlling humidity and moisture. Both the Weather Bureau and the American Meteorological Society deal with humidity measurements for weather prediction, including the recording and transmission of humidity data from unattended stations. The American Society of Heating, Refrigerating and Air-Conditioning Engineers is concerned with measurement and control of humidity not only for personal comfort but also in industrial and agricultural processes and in the preservation of materials. Members of the Instrument Society of America are interested in the design and applications of hygrometers, psychrometers, and other humidity transducers. Finally, the National Bureau of Standards is faced with the need for new techniques in measurement of humidity and for more accurate and easily used standards of humidity.

The symposium was opened on May 20 with a plenary session presided over by W. A. Wildhack, associate director of the National Bureau of Standards and chairman of the general committee of the symposium. The main address was delivered by Dr. J. H. Hollomon, assistant secretary of commerce for science and technology. Dr. Hollomon noted that man's advances in science and technology now permit him to exercise control over his environment, including humidity and moisture. He saw man's own abilities as a neglected or undeveloped natural resource, noting that the number of engineers who will graduate in the United States in 1963 is the same as five years ago. The remainder of the plenary session was devoted to papers on basic concepts and of general interest in the field of humidity. A second plenary session held later consisted of papers surveying the state of the hygrometry art in selected fields.

At a banquet held on the evening of May 21 the assembly of scientists was addressed by officers of the five sponsoring groups. J. H. Fox, president of the American Society of Heating, Refrigerating and Air-Conditioning Engineers, described the activities of his Society, emphasizing the research activities it supports, such as investigations of the effect of humidity on milk production and the habitability of survival shelters. He expressed the Society's concern that the number of students reading applied sciences is decreasing, although the number of college registrants is rising.

The American Meteorological Society was represented by its vice-president, Dr. Helmut E. Landsberg, who commented briefly on personalities and instruments prominent in the history of humidity measurement. The wide variety of indicating materials used in early hygrometers was a surprise even to those well versed in hygrometry.

The activities of the Instrument Society of America were noted by its president, Nathan Cohn, who also suggested that honour is due to the only American whose name has been given to a fundamental electrical unit. Mr. Cohn described Joseph Henry's concern that scientists be able to communicate and co-operate with each other and cited the Symposium as one which would have had Henry's approval.

F. W. Reichelderfer, chief of the U.S. Weather Bureau, discussed humidity as being of widespread interest as a factor in forming the world's weather. He described the World Meteorological Organization as a particularly effective means of transmitting useful meteorological data.

Dr. A. V. Astin, director of the U.S. National Bureau of Standards, noted the necessity that measurements made by all scientists and engineers be compatible and interchangeable. He emphasized the Bureau's concern with devising standard measurement techniques that can be applied at local levels.

Fundamentals

The sessions of the symposium devoted to fundamentals included papers and discussion on the fundamental laws, principles and relationships governing the behaviour of water vapour–gas mixtures, mainly moist air, and on the properties of water as basic to instruments and processes involving humidity. With the increasing demand for more accurate humidity measurements, a need has arisen for theoretical foundations provided by real gas behaviour, rather than an assumed ideal gas. The papers which were presented provided important new information on real gas behaviour of mixtures of which water vapour is an important constituent, and on the transport and thermodynamic properties of moist air.

Humidity Measuring Instruments

The water-vapour content of gases is measured by a wide diversity of instruments, the methods spanning a broad realm in the fields of physics, chemistry and engineering. A major portion of the symposium was devoted to important methods used in modern hygrometry.

Three sessions were concerned entirely with electric hygrometry, which is utilized in many areas of science and industry because of its high sensitivity, its use of small sensors, and its adaptability to recording or remote indication. Among the sensors considered were those based on electrolytic solutions, carbon films, polyelectrolytic films, ceramics, thin vacuum deposited salt films, oxide films and plastics.

Psychrometry has a history which goes back to the early part of the nineteenth century. Still a major method for measuring the humidity of air, it finds extensive application in meteorology, air conditioning, and industry. Both theoretical and experimental papers treated the use of psychrometers under such unusual conditions as temperatures below freezing and hot, arid atmospheres. Other electric hygrometric instruments that were described included those using the Peltier effect, spectroscopic methods, infra-red and ultra-violet radiation, and, operating in another area of the spectrum, mierowave refractometers and hygrometers.

In dew-point and frost-point hygrometers humidity is measured as the temperature at which dew or frost is deposited on a cooled surface, usually a highly polished mirror. Theoretical aspects of this method of measurement and improved versions of dew-point and frost-point instruments were described. Considerable interest was shown in hygrometers utilizing the Peltier effect to cool the mirror and others providing high accuracy with automatic operation and continuous recording.

Unusual measuring methods were also described, among them a chemical technique for measurements of low water-vapour pressure. Another paper described an instrument detecting the heat generated with water absorption by a desiccant and still others the design of cells which absorb and electrolyse water vapour for measurement of humidity as a function of the electrolysing current. Critical discussions of the advantages and shortcomings of thermal conductivity methods and hair hygrometers were presented in review papers.

Moisture Measurements

The latest advances in the art of measuring moisture in solids and liquids also had a place in the symposium, since moisture critically affects the behaviour of many materials. A session devoted to physical and chemical methods included papers describing gas chromatography, spectrophotometry, chemical extraction, and infra-red analysis. Further sessions treated dielectric, resistive and capacitance methods, as well as nuclear methods, nuclear magnetic resonance in particular. The papers described equipment, methods of calibration, and typical uses and presented data on accuracy.

Standards

The sessions on humidity standards were of special interest to staff members of the National Bureau of Standards, several of whom presented papers on this subject, and in general to scientists needing accurate hygrometry devices. Two of the papers described for the first time the use of the gravimetric hygrometer in making humidity measurements to a degree of accuracy suitable for the most demanding humidity calibrations. Other papers described pneumatic bridges developed at the National Bureau of Standards which make possible calibration-level hygrometric determinations as a function of the pressure differential across the bridge. Also of interest in this area were papers discussing the use of fixed humidity points in hygrometer calibrations.

Applications

The sessions concerned with the application of humidity and moisture measurements included the topics of meteorology, agriculture, biology and medicine, air-conditioning, humidification and de-humidification, environmental chambers and radio propagation and atmospheric refraction. In these sessions, particularly, scientists and engineers had an opportunity to learn about each other's measurement problems and to exchange information among widely separated fields and disciplines.

The part played by humidity in meteorological phenomena was covered in detail by the papers presented. The distribution of moisture in the atmosphere was discussed, and special techniques reported for its determination in the stratosphere. A 'state-of-the-art' survey on the application of hygrometry to meteorology was also presented.

Humidity and moisture are important in agriculture in many ways. Examples discussed were storage of agricultural products, particularly grain, flour and tobacco; curing peanuts and tobacco; the physiological responses of dairy cattle to humidity; the moisture content of butter, dehydrated foods and dry milk; and the moisture content of soils and its influence on plant growth.

The session on biology and medicine included papers on the effects of humidity on man, plants and biological systems. Humidity affects personal comfort, and imposes a stress on those working in hot environments; when controlled it can be used in treating lung disorders, for example.

The papers presented concerning air-conditioning, humidity control, humidification, and de-humidification were of a highly practical and engineering nature. Typical of the problems discussed were air-conditioning calorimetry, moisture in small refrigerating systems, residential humidification, chemical de-humidification, moisture control in dry-cleaning solutions, monitoring moisture in sealed electronic modules, and humidity levels in environmental cabinets and chambers.

Propagation of radio signals, observations of missile trajectories, and monitoring atmospheric turbulence depend to a large extent on the refractive index of the atmosphere which, in turn, is a function of the ambient vapour pressure. Research in this area also was presented. A paper on the potential of radio refractometry for humidity investigations and one on the use of radio refractometers to measure water vapour turbulence were presented. Papers on the use of radio, optical and microwave techniques for humidity measurements also were delivered.

The papers presented at the symposium will be published by the Reinhold Publishing Corp., New York, and are expected to become available early next year.

REPROCESSING FOR IRRADIATED FUELS

A SYMPOSIUM on "Aqueous Reprocessing Chemistry for Irradiated Fuels" was held in Brussels during April 23–26, under the auspices of the European Nuclear Energy Agency of the Organization for European Co-operation and Development and of the European Company for Chemical Processing of Irradiated Fuels (Eurochemic).

The object of the conference was to compare the progress made by the European countries which participate in Eurochemic, with the status of work in the same field in the United States and the United Kingdom. About half the twenty papers presented were concerned with research and development work being carried out either at Mol, Belgium, or elsewhere in Europe for the Eurochemic plant which is under construction at Mol. Other papers from French and Italian authors were related to possible new reprocessing plants in these two countries. As descriptions have been published in recent years on the major reprocessing plants of the United States and the United Kingdom, contributions from these countries were largely limited to surveys of recent developments.

It is apparent that on the Continent, as elsewhere, a solution of tributylphosphate in a hydrocarbon diluent is

regarded as the most reliable solvent extraction system for the recovery of uranium and plutonium from irradiated fuels. The degree to which this system is capable of technical improvement is now largely limited to ways in which the effluents of moderate radioactivity can be reduced in volume, for example, by using only one cycle, or be made capable of being evaporated to small bulk: in papers concerned with the latter aim, the results of research on the substitution of ferrous sulphamate by uranium (IV) nitrate as the reducing agent for the reaction plutonium (IV)→plutonium (III) were described. Otherwise, as was brought out in the contribution by Dr. R. Rometsch, the research director of Eurochemic, the main load that now falls on a research and development team is concerned with the problems involved in 'decladding' the wide variety of fuel elements used in Western European reactors and in bringing their contained fuel into solution of such a composition as to be suitable for the recovery of the fissile elements by solvent extraction.

There is now little work being done on ion exchangers for reprocessing: in the period 1950–60 they were developed and sometimes installed for the final purification of plutonium and uranium-233. The present tendency is to establish for these purification steps a solvent extraction process using a tertiary (or quaternary) amine, in a suitable organic diluent. The results from several laboratories on amine systems indicate that sufficient knowledge has already been accumulated for an amine-cycle to be capable of being successfully applied for this purpose. The two advantages of an amine, compared with the conventional tributylphosphate, for this particular purification-cycle consists in the better decontamination from uranium, and the greater reduction in the volume of the plutonium nitrate stream that the amine can provide.

Although the symposium dealt mainly with aqueous methods, there was a review by Dr. M. D'Hont (Nuclear Energy Centre, Mol, Belgium) on the alternatives, for example, reprocessing by melt refining or by fractional volatilization from halide systems. It is noticeable that these and similar non-aqueous methods, though a popular field for research at the time of the Geneva Conferences of 1955 and 1958, are losing favour. Their development costs seem likely to be prohibitive for any purpose other than an established fuel-cycle operating on a large number of reactors.

The final session was devoted to a discussion on the future role of reprocessing in fuel-cycles. It was introduced by Dr. F. L. Culler (Oak Ridge National Laboratory), who quoted his investigation on a scheme for the distillative purification of sea-water using, as a source of power, very large reactors (each of 8,700-MW thermal) fuelled with natural uranium, and cooled and moderated with heavy water: the lowness of the reprocessing cost (calculated to be about 4 dollars/kg of uranium) for the fuel-cycle concerned was primarily due to its large throughput (about 10 tons of uranium per day). This illustrated the important point that the throughput of a plant can influence costs to a greater degree than possible savings from improved technology. In the discussion which followed, two points of particular interest emerged. First, in the early stages of the expansion of the nuclear reactor industry, storage of irradiated fuels until such time as adequate quantities have accumulated to feed a large reprocessing plant may be preferable, on economic grounds, to the proliferation of many small plants: it would follow as a corollary of this policy, that the number of teams engaged on reprocessing research and development that should support such reprocessing would be relatively few in number. Secondly, for large reprocessing plants to be generally accepted, the problems in the transport of irradiated fuel both by water and on land must be overcome: these problems can be particularly severe where international boundaries have to be crossed.

About 100 persons drawn from fifteen countries as well as from the International Atomic Energy Agency and from Euratom attended the symposium, in addition to the forty scientists and technologists from Eurochemic. The meeting provided the first large gathering of the reprocessing experts of Western Europe and it was appropriate that the delegates could see at Mol the emergence of the Eurochemic plant. Dr. T. J. Barendregt and the others responsible under Dr. E. Pohland, the director-general of Eurochemic, for this plant have had to overcome many problems, new in plant construction, due to the components being supplied by one or other of the various countries which participate in Eurochemic. The plant represents a pioneering effort, new in Europe, from which benefits should accrue to many future co-operative enterprises.

FLOW STUDY OF POLYMER MELTS USING THE INSTRON RHEOMETER

At the meeting of the Cambridge Rheology Club held on March 4, Mr. G. G. Zahler (Instron, Ltd.) spoke on "Flow Study of Polymer Melts using the Instron Rheometer". First, he briefly discussed general flow-characteristics of polymer melts showing that temperature, speed of flow and stress measurement should be accurately controlled, instrument geometry must be accurate and accessible. A rheometer must cover shear rates from at least 1 to 10,000 reciprocal seconds in order to simulate normal processing conditions from compression moulding to injection moulding.

The Instron rheometer, which is an extrusion type and was originally designed by Monsanto Chemicals (United States), is driven by an Instron model *TT-C* tensile testing machine. This machine covers load ranges from 2 g to 10,000 lb., using strain-gauge load cells, to an accuracy of 0·5 per cent on all ranges. Speeds are governed by a synchronous motor and positional servo-system, being instantly selectable through pushbuttons over a range of 10,000 to 1.

The extrusion assembly consists of a barrel surrounded by four heaters connected to a controller giving proportional, integral and differential control from 10° C above ambient to 340° C within a limit of error of ± 0·5° C. Capillaries of different diameters, lengths and entrance angles are inserted into the lower end of the barrel. A plunger is forced through the barrel by the moving crosshead of the tensile testing machine, the load on the plunger is recorded automatically by the load cell on a strip chart recorder. Tests over wide ranges of speed may be carried with one barrel loading. As plunger speed is known, plunger load is measured and dimensions of the extrusion assembly have been accurately determined, shear rate and shear stress can be readily calculated or read directly from nomographs.

Mr. Zahler discussed possible errors such as due to the capillary aspect ratio, plunger friction force, fluid compressibility and temperature rise along the capillary, etc. He showed that all these effects were either negligible or could be easily corrected.

It was suggested that it is possible to measure the dynamic shear modulus (for visco-elastic flow) by steady-state flow in the capillary rheometer. This theory was substantiated by results obtained experimentally. Another parameter that can be measured is the activation

energy of viscous flow. Rheopectic and thixotropic characteristics of materials can also be investigated.

The next meeting of the club will be held on October 28 at the Technological Research Station, Spillers, Ltd., Station Road, Cambridge, when Dr. J. H. C. Vernon (Ministry of Aviation) will speak on "The Rheology of Solid Propellants for Rocket Motors".

E. Mary Nicholas

THE AUSTRALIAN ATOMIC ENERGY COMMISSION

THE tenth annual report of the Australian Atomic Energy Commission covers the year ended June 30, 1962, in which the expenditure was £2,803,787 and capital expenditure £905,275. Revenue from sales, including lease of reactor space, was £83,858, an increase of £28,615 for the year. The cost of the exploration for uranium carried out by the Bureau of Mineral Resources and by Territory Enterprises Pty. Ltd., was £194,000.

On March 23, 1962, two major new buildings were opened by the Prime Minister, the Rt. Hon. R. G. Menzies. One was the Reactor Physics Building, housing the low-power research reactor Moata, and the other the building devoted to Radiation Biology and Health Physics. The *Hifar* Experimental Building, a new Low-Level Radiochemistry Building, and extensions to the Isotope Handling Building, also were completed during the period under review. In a separate suite at the rear of the main block of the Radiochemistry Building is housed the total-body monitor, the radiation detector of which consists of a large scintillation crystal (8 in. diameter and 4 in. thick) of sodium iodide, suspended over the abdomen of the subject seated in a reclining chair. Two heavily shielded rooms with facilities for the irradiation of animals or biological specimens form part of the ground-floor of the building. One room contains a 10-c. cæsium-137 source for low dose-rate exposures and the other a 250-kV X-ray plant for the delivery of doses of much higher levels.

The reactor research programme was mainly concentrated on the feasibility study of a high-temperature gas-cooled reactor, in which the fuel is dispersed in the moderator. Both beryllium metal and beryllium oxide have been investigated as moderators, with carbon dioxide as coolant. Most work has been done on the metal system, but because of the poor economics of the fuel-cycle and the temperature limitations of the metal fuel, the oxide or ceramic system is now receiving greater consideration. The beryllium oxide moderated, all-ceramic fuel reactor seems to hold promise of some long-term advantage and it is believed that, provided certain design problems can be satisfactorily solved, a beryllium oxide based, high-temperature gas-cooled reactor should yield lower plant and equipment costs than most other gas-cooled systems. It would appear that with steels at present available the maximum temperature of the carbon dioxide coolant would be about 750° C, which is a considerable advance on British gas-cooled stations of present design. To assess the value of the proposed type of reactor as a power producer, a design study for a power plant of net electrical output of 300 MW has been started. The most difficult mechanical engineering problem involved is the production of the all-ceramic core of the reactor for as yet nobody has made any serious attempt to produce a satisfactory core based on beryllium oxide for power-station reactors. Several fuel cycles are being considered, with most attention being directed to the uranium-233, thorium, beryllium system, but because of lower initial cost and greater availability of fuel the plutonium-enriched, natural uranium cycle may be preferred for Australia.

In the annual report for 1961, reference was made to the investigation being carried out on the compatibility of steels with carbon dioxide. This is now essentially complete. Carbon steels, low alloy steels, and stainless steels have been studied at high temperatures and pressures, and for various moisture contents of the gas, and firm recommendations can now be made for the most satisfactory materials for use in the temperature range 400°–750° C in the various parts of the gas circuit of a reactor. At the Lucas Heights Research Establishment some research on semi-conductor radiation detectors has been carried out. Silicon-surface barrier counters can now be produced quickly and economically, and their applications to α-particle spectrometry and for scanning neutron flux are being studied. Radiation standards at the microcurie level for cobalt-60, gold-198, sodium-24, iridium-131, antimony-124 and phosphorus-32 have been developed and intercomparisons with standards of other laboratories are to be undertaken.

For neutron diffraction experiments, there will shortly be available, attached to the reactor *Hifar*, two powder spectrometers, two single crystal spectrometers, and one long-wave-length spectrometer. The spectrometers were all designed and built at the Lucas Heights Establishment, and will be of use to the university groups from Western Australia who are interested in the positions of hydrogen atoms in organic crystals, and from the University of New South Wales who are investigating the defect structure of titanium–zirconium–oxygen alloys, the structure of inorganic crystals containing hydrogen and the structure of magnetic transition-metal alloys. The physics division is now operating a neutron time-of-flight spectrometer and a second one is in the design stage. They are to be used for the measurement of the distribution of neutron energies within reactor cores.

There are well-established facilities for the production, handling and dispatch of radioisotopes at the Lucas Heights Establishment, and the annual demand for those produced at the Establishment has increased four-fold. Short-lived isotopes, including sodium-24, potassium-42, copper-64 and gold-198, which are valuable in medical work and industrial investigations, were supplied for the first time. The first cobalt-60 was removed from the reactor *Hifar* during September 1961, after approximately 320 days irradiation. Eighty-eight per cent of the product had a radioactivity of more than 50 c. per gram, with a maximum of 105 c. per gram. 2,600 c. of the 8,270 c. in the batch were used to fabricate the first Australian-made teletherapy source, which was delivered to St. Vincent's Hospital, Sydney, during November 1961. The sales value of the 454 shipments of imported radioisotopes was £14,400 and the value of radioisotopes produced was £12,646. An order for 5,000 c. of cobalt-60 for delivery in 1962–3 was received from the Japan Radioisotope Association, and there are prospects of additional orders from Japan and countries in South-East Asia. The Radioisotope Advisory and Consulting Service of the Commission has carried out a number of interesting and important field and factory investigations using radioactive isotope techniques and these are described in some detail in the annual report.

In May 1962 the Minister for National Development announced that the Government had decided to continue uranium treatment operations at Rum Jungle after the completion of the Combined Development Agency contract. This decision was made in the light of the importance of Rum Jungle to the economy of the Northern

Territory. Uranium oxide will be available at a competitive price, but the Government is prepared to stock-pile the output for a number of years should this be necessary. Production figures were the highest so far recorded. Mary Kathleen Uranium, Ltd., is expected to complete its contract with the United Kingdom Atomic Energy Authority by the end of 1963. The Radium Hill mine and its associated chemical treatment plant at Port Pirie were closed during December 1961. Exploration for uranium is now virtually confined to existing producers, and the Commonwealth's offer to pay rewards for the discovery of uranium in Australia and Territories has been withdrawn, with the final reward instalment during the year of £14,800 in respect of the Eva deposit at Pandamus Creek, N.T.

Visitors to the Commission and to the Research Establishment during the year under review included Sir William Cook, Sir John Cockroft, Air Chief Marshall Sir Claude Pelly, of the United Kingdom Atomic Energy Authority; Dr. G. A. Robb of the New Zealand Atomic Energy Committee; Dr. P. C. Abersold of the United States Atomic Energy Commission and Congressmen J. E. van Zandt and O. E. Teague; Dr. G. A. Siwabessy of the Indonesian Institute of Atomic Energy; Dr. J. P. Hugo of the South African Atomic Energy Board; and Mr. F. R. Herrington and Mr. C. H. Hetherington of Atomic Energy of Canada, Ltd. Training for fellows of the International Atomic Energy Agency at the Research Establishment was continued and a voluntary contribution was made to the general fund of the Agency to assist in its technical assistance programme. The Commission published a large number of photographs, leaflets and booklets to satisfy the lively public interest in atomic energy, in addition to its more scientific and informative quarterly journal *Atomic Energy*. Several major exhibitions were presented, including one at the Sydney Trade Fair, and at the Sydney Town Hall during the convention of the Australian Welding Institute, and on nuclear power in Perth during May and in Adelaide during June.

The research programme at Lucas Heights is supplemented by university research contracts. All the universities in Australia together with the Commission are members of the Australian Institute of Nuclear Science and Engineering, and each university has research projects supported by Institute grants. Approximately fifty research projects involving co-operation with the Research Establishment were being sponsored during the period covered by the annual report. Details are given in a separate section and in an appendix to the report.

LONG-DISTANCE RADIO COMMUNICATION AT HIGH-FREQUENCIES

PENDING the application of satellite relays to intercontinental communications, the world's long-distance radio services have been developed on high-frequencies or short waves, which are reflected from the ionosphere in their transmission around the Earth. A survey of the present state of technique in this field and of modern trends in equipment was conducted by the Electronics Division of the Institution of Electrical Engineers at a convention on "High-frequency Communication" on March 25–27 *.

This convention was attended by some 290 participants, including a number of overseas visitors, and more than 50 papers were presented at the eight technical sessions. The texts of all contributions and formal papers included in the programme were issued in a preprinted booklet, and many of the papers were marked as having been accepted for publication in a future issue of the *Proceedings of the Institution*.

On the first day, two sessions were held dealing respectively with the propagation of high-frequency waves by way of the ionosphere, and with the design of aerial systems for the most efficient communication over distances both below and above 1,000 km. On the succeeding days, the papers read and discussed related to the various systems used in modern radio-telegraph communication and to the special technical problems associated with the development of both fixed and mobile equipment. While much ingenuity has gone into the advance design of signalling techniques and the automatic correction of any errors which occur in transmission, the limiting factor in most long-distance radio links lies in the mode of transmission of high-frequency waves by way of the ionosphere.

For many years now, using a network of ionospheric observatories, conditions in the ionosphere have been investigated by the well-known technique of sounding at vertical incidence. The results of these soundings, which in most cases are made day and night throughout the year, are exchanged on an international basis, and co-ordinated at certain recognized institutions. From these records of past measurements, forecasts are made of the high-frequency radio transmission conditions likely to prevail in the future in various parts of the world. Such forecasts have in general been made for periods of from one to six months ahead; but, as the operation of the observatory network extended over one or two sunspot cycles, each of about eleven-year periods, it has become possible to produce charts for the epochs of maximum and minimum solar activity. Interpolation between these epochs was assisted by the continuing measurements at a number of key stations throughout the world. While such arrangements are satisfactory for the long-term planning of communication circuits, the performance of these have always been subject to erratic, and in many cases unexpected, variations in the ionospheric conditions, and these have prevented the use of many radio circuits to their full capacity.

With the view of overcoming this limitation, an investigation has been in progress in some countries of methods of sounding the ionosphere under oblique incidence conditions, and, so far as is practicable, over the path of the actual communication circuit in question. Such 'oblique ionosphere sounding' as it is termed, is effected by using a transmitter emitting pulses on a series of increasing frequencies, with synchronizing arrangements for maintaining the receiver at the remote station in tune with the same series of frequencies. A paper describing this technique under the title "Oblique Sounding and H.F. Communications" by R. D. Egan and D. S. Pratt was presented at the convention. In the arrangement described, the sounder transmitter is set to begin sending pulses on a predetermined frequency at a particular time within 1 msec after each pulse, the frequency is increased in a series of rapid steps so as to cover the entire high-frequency band of 2–32 Mc/sec in a few seconds. At the receiver, the frequency is kept in step with that of the transmitter by electronic digital control after a starting signal initiates the sequence of frequency stepping. By this means oblique incidence ionograms are produced from which the upper and lower limits of frequency which can be propagated over the chosen path are readily obtained. The authors of the aforementioned paper also describe an extension of their research to the direct control of a communication circuit on a 24-h basis, by locating a sounder transmitter at the communication sending site near Anchorage, Alaska, and a sounder

* Institution of Electrical Engineers: Electronics Division. Convention on H.F. Communication March 25–27, 1963—*Proceedings*. Pp. 444. (London: Institution of Electrical Engineers: 1963.)

receiver at the communication receiving station near San Francisco, California.

Following the publication of the technical paper referred to here, *The Times* of June 19 gave some details of an ionosonde developed by E.M.I.-Cossor Electronics Ltd., Halifax, Nova Scotia; and demonstrated recently to Commonwealth representatives, the Services and other organizations interested in long-distance radio communication. The equipment was shown in operation between a sending station in Nova Scotia and the Post Office radio-receiving station at Cooling Marshes, near Rochester, Kent. At the sender, the frequency was swept in a series of 128 steps from 1·8 to 28·8 Mc/s, and the receiver was synchronized with the aid of standard time-signals. The received signals were displayed on a cathode-ray tube which, with the changing conditions in the ionosphere, indicated the most suitable frequency at any moment for transmission over this trans-Atlantic path. In addition to the direct assistance given to high-frequency communication, the ionosonde can be used for the scientific investigation of ionospheric conditions.

NEW MATERIALS TESTING LABORATORY FOR THE CEMENT AND CONCRETE ASSOCIATION

In a recent issue of the *Magazine of Concrete Research* (15, No. 43; March 1963), J. D. McIntosh gives an interesting account of the imposing new laboratory erected for the Cement and Concrete Association at its research station at Wexham Springs, Stoke Poges, Slough, Bucks. The interest lies not so much in the fact that this is a much desired extension to the existing facilities at Wexham Springs, designed to re-house various departments hitherto operating in temporary accommodation, but in what may be termed the very 'tight' specification to which the building had to conform. The primary function of the new laboratory is research on the engineering properties of concrete and its constituent materials, including soil-cement; all necessary facilities for studying these problems and for structural model testing had to be provided and somewhat stringent measures had to be taken to ensure that working conditions, for example, high degree of temperature control and correct relative humidity, in many of the rooms, were satisfied. In this, air-conditioning of much of the building plays an important part; it influenced the siting, planning and method of construction of this laboratory. "Particular problems included reducing nuisance from the dust and noise of many operations, preventing the spreading of shock and vibration to the rest of the structure, planning a convenient flow pattern for routine operations while allowing adequate versatility for other techniques, and filtering 'live' cement from liquid waste. Although all the desirable refinements were not included at the time of erection, provision was made, where possible, for them to be incorporated later".

Thus the design of a materials-testing laboratory calls for solution of many problems not encountered in ordinary building, or at least much less critically. Every eventuality seems to have been foreseen in the present instance. Although ideally premises in which such fundamental research can be carried out should provide controlled conditions which can be taken for granted, any breakdown in vital equipment should be limited in its effect by appropriate planning in advance. While on one hand the layout should be designed in such a way that frequently recurrent operations can be reduced to a fool-proof routine, the building of this nature must be readily adaptable to new processes or testing procedures. It certainly seems from Mr. McIntosh's detailed description of this new laboratory, coupled with the site-plan, floor plans and other illustrations in his paper, that the latest Wexham Springs project will eventually, if it has not already done so, fulfil the ideals which its sponsors and its architect had in mind. It certainly provides a most intriguing prototype for other buildings destined for similar purposes in the future and as it is intended that visitors will be encouraged to "see something of the laboratories without hindrance to the work in hand" (by provision of large windows between corridors and rooms and special circulation spaces), there will be no obstacle to architects and others concerned with design of special buildings for scientific work obtaining first-hand visible and highly valuable information on basic requirements.

H. B. Milner

ISOSTATIC RECOVERY IN SCOTLAND

By D. F. W. BADEN-POWELL

Department of Geology and Mineralogy, University of Oxford

Some years ago evidence was published for a correspondence in height and fossil content of some British raised beaches and those of the Mediterranean area[1,2]. If the correlations based on that work are correct, there is obviously a contradiction with the theory that northern Britain has been rising during the Holocene as a result of isostatic recovery or that recent extensive tilting has occurred in England. In other words, if some British raised beaches which were originally horizontal are now tilted, their heights cannot be used as evidence of correlation with the Mediterranean area. Recent work on the Pleistocene marine fauna of the Nar Valley Clay of western Norfolk and on an almost identical fauna from other parts of Britain has shed new light on recent crustal movements as a whole, and some widely held opinions on this subject must now be changed.

Jamieson[3] seems to have been one of the first geologists to suggest that many Scottish raised beaches might be due to local uplift, and W. B. Wright[4] later enlarged Jamieson's ideas by assuming that most of the Scottish beds are late- or post-glacial and are not represented in the south of England, whereas the English fossil beaches were supposed to be much more ancient. This idea has been accepted so generally that it is often forgotten that it was challenged by Depéret[5,6], who considered that some of the marine beds in the north can be correlated with those of southern England, and that it is not necessary to invoke any form of crustal movement to explain their distribution. Another nearly related problem is that of the supposed recent tilting of the southern parts of Britain. The original levelling of England and Wales was done by the Ordnance Survey during 1840–60, and when the re-levelling was carried out between 1912 and 1921, a discrepancy of nearly 2 ft. was found near Harwich and the Essex coast, as though there had been a submergence here since the original survey. Sir Charles Close[7] thought this discrepancy was due to changes in sea-level caused by local meteorological effects and not to vertical crustal

movement; but Longfield[8] revived the idea that there might have been real subsidence of this part of the coast. One way of solving these two related problems is to find out whether it is possible to correlate the raised beaches of the north with those of the south by palæontological means; it cannot be stressed too strongly that answers to these questions can never be found by a consideration of heights alone.

The immediate problem was to find a marine horizon which could be traced through by its fossils from the unglaciated part of southern Britain to Scotland where uplift was supposed to have taken place. The opportunity occurred when recent work was done on the Nar Valley Clay of western Norfolk, and Dr. R. G. West and Miss Stevens generously sent me marine shells which they had collected, and these, together with my own collection, were compared with specimens in the British Museum (Natural History), the Geological Survey Museum, and the museums at Norwich, King's Lynn and Wisbech, and the great help given me by Dr. West, Miss Stevens and the authorities in these Museums is gratefully acknowledged.

In her paper on the Nar Valley Clay, Miss Stevens[9] proved by an investigation of the plant remains that this clay is to be correlated with the Clacton Channels on the Essex coast, and an investigation of the marine molluscs from the two sites strongly confirms this opinion. The fauna from Clacton indicates a distinctly warmer climate than that of to-day (Baden-Powell in ref. 10) and the same is true of the Nar fossils. The chief characters which are found in the Clacton and Nar deposits include a lack of extinct forms such as *Nucula cobboldiae*, *Tellina obliqua* and *Nassa reticosa*, which occur in older deposits like the Corton Beds of East Anglia, and the nearest approach to an extinct form in the Nar Valley fauna is *Turritella pliorecens*, which is found together with the recent living form *T. communis*, which already appears at this horizon. Only very few shells indicate a cold climate in the clay, but on the other hand three warm indicators are relatively common; *Tapes decussatus*, *Nassa pygmaea* and *Bela septangularis*, which now live mainly southward from Britain. This assemblage often includes the small cockle *Cardium exiguum* (actually found at Clacton but not so far in the Nar Valley Clay).

The next stage in correlation was to inquire whether this special type of fauna can be found in other parts of Britain. Turning to southern England, it became evident that the shells from a raised beach in Croyde Bay, near Barnstaple, in Devon, and the Selsey Mud Deposit from Sussex agree well with Clacton and Nar in the lack of the extinct shells mentioned and the warm climate represented by the fauna, and it seems reasonable to connect the high-level raised beaches of Sussex with the mud deposit, as suggested by Clement Reid[12]. There is not space here to discuss these various sites in detail, but there are also at least three localities in Scotland where a fauna has been found which is very like that of Clacton and Nar, namely, in Caithness[13], the Isle of Lewis[14] and Kintyre[15]; the shells from these three areas agree with Clacton and Nar in the absence of the extinct shells *Nucula cobboldiae*, *Tellina obliqua* and *Nassa reticosa*, by the presence of *Cardium exiguum* and by the occurrence of warm indicators. Furthermore the *Turritella* shells from both Caithness and Lewis include examples of the form *pliorecens* (originally identified by me as *Turritella tricarinata*), as in the Nar Valley; unfortunately I have not yet had an opportunity to examine examples of *Turritella* from the Kintyre beds. The assemblage from all these places is so similar that it seems highly probable that these deposits were all formed during one marine submergence, and the lack of certain extinct species, combined with the presence of *Turritella pliorecens* with common warm indicators, strongly suggests a Tyrrhenian age for this set of deposits. This age has been suggested for the Sussex beds in an earlier paper[2] (but I must correct my statement in that paper that the Corton Beds are Tyrrhenian, and admit that they are older than was previously thought; this present revision of these faunas has shown that the Corton Beds belong to some phase of the Sicilian–Milazzian group of deposits).

An attempt was then made to find out whether crustal movements have taken place since these Tyrrhenian beds were laid down, working on the assumption that the original Tyrrhenian shore-lines were fairly level. Unfortunately the old beach lines have been seldom preserved, but measurements of the present height of these deposits, which contain a recognizable fauna at least, makes it possible to decide between the rival theories of W. B. Wright and Depéret which are discussed earlier in this communication. The following list shows the heights which are associated with the Tyrrhenian fossils so far:

List of Tyrrhenian sites with amount of submergence (ft.).

Clacton Channels, to 27.
Nar Valley clay, to 65.
Caithness boulder clay, no height possible, because fauna collected so far from glacially disturbed material.
Lewis, measured to 60, and glacially disturbed to 180.
Kintyre, to 135 and ? 200, but may all be glacially disturbed.
Barnstaple, measured to 40, and ? to 80.
Sussex, shingle beaches to 90 and ? 140.

The Caithness shells are so far only from erratics of sea-bottom in the Caithness Boulder Clay; but the Lewis fauna was collected from an interglacial deposit in place[11]; as noted in the list, the height and great thickness of the Kintyre shell beds[15] makes one suspect that they are involved in a push-moraine. The Barnstaple raised beach disappears upwards under a great thickness of local Head, and an enormous amount of excavation would be necessary to prove its real or maximum height; the altitude of the Sussex raised beaches is known accurately; but as they consist partly of huge shingle banks, it is difficult to find out the exact amount of submergence represented. Two of these sites were discussed by Miss Stevens[9], who suggested that late Pleistocene subsidence in East Anglia could account for the discrepancy between the height of the Nar Clay and that of the Clacton Channels, and compared a possible gradient from north-west to south-east with the suggested downward movement of the Essex coast. A strictly local subsidence here is possible, but it seems better at this stage to concentrate on the evidence from Britain as a whole, as is done in this article.

At first sight the heights given in the preceding list may seem extremely vague, but they illustrate two points:

(1) If the correlations suggested here can be accepted, the Tyrrhenian beaches of southern and eastern England are at the same order of height as those in the north, and not at or below sea-level, as predicted by W. B. Wright.

(2) A comparison of the heights for the Isle of Lewis and Sussex show that no extensive tilting like that suggested by Longfield seems to have taken place since Tyrrhenian times. It therefore seems certain that any isostatic adjustment which may have affected Britain did not take place along the lines postulated by W. B. Wright; on the other hand, Depéret seems to have gone too far in suggesting that there has been no movement at all. More detailed conclusions will only be possible after further investigations have been made of the heights of the later Monastirian and Holocene beaches.

A GENERALIZATION OF THE PHASE-LAW OF LUNAR GEOMAGNETIC TIDES

By Dr. OTTO SCHNEIDER
Instituto Antártico Argentino, Buenos Aires

LUNAR geomagnetic variations, or 'geomagnetic tides', are generally supposed to be caused mainly by a semi-(lunar-) diurnal motion of ionospheric layers. The electrical conductivity of these layers is believed to vary with solar time (apart from other variations) in such a way that a maximum is reached about local noon, with low values prevailing during the night hours. The shape of the daily variation of conductivity cannot be assumed to be strictly symmetrical, nor is it centred exactly at noon; this is probably true of both the transverse and Hall conductivities. It is, therefore, impossible to represent the daily variation of conductivity as a function of solar time t by a simple superposition of cosine waves of equal phase. Instead, a more general scheme is required[1] involving terms both in sin t and cos t.

Chapman's phase-law states that the main part of the lunar diurnal variation L of any geomagnetic element is a superposition of harmonic terms $L_\varkappa$ the phases of which change systematically in the course of a month:

$$L = \sum_\varkappa L_\varkappa = \sum_\varkappa l_\varkappa \sin [\varkappa\tau - (2 - \varkappa)\nu + \varepsilon_\varkappa] \qquad (1)$$

τ being lunar time, and:

$$\nu = t - \tau \qquad (2)$$

a measure of the moon's phase. This law was originally found empirically[2,3] and later shown to be in accordance with the assumptions mentioned already, if the motion is supposed to be a simple function of lunar time of the form:

$$M_2(\tau) = m_2 \sin (2\tau + \lambda_2) \qquad (3)$$

and the conductivity:

$$K(t) = a_0 + \sum_\varkappa a_\varkappa \cos \varkappa t + b_\varkappa \sin \varkappa t \qquad (4)$$

a function of solar time. If only terms up to $\varkappa = 2$ are considered in expression (4), multiplication with expression (3) in combination with expression (2) leads to five terms $L_\varkappa$ in expression (1), up to a 6-hourly lunar variation L_4 (and including a fortnightly term L_0); these are the lunar magnetic tides generally investigated. Chapman and Bartels[1] have pointed out, however, that other terms are likely to exist, and that there was observational evidence to support this view.

In an examination of the magnetic east component at Batavia (now Kuyper, near Djakarta) it had been recognized[4] as early as in 1936, though not understood at that time, that the oscillations $L_\varkappa$ found for individual moon-phases $\nu \neq 0$, when reduced to New Moon by shifting the waves by $+(2-\varkappa)\nu$, do not coincide completely. The residuals are greater than the mean errors and show a systematic grouping according to ν, the age of the Moon. These residuals have been examined more closely in the meantime[5] and it has been found that they represent waves of the form:

$$\Xi_1 = \xi_1 \sin (\tau + 3\nu + \gamma_1) \qquad (5)$$

and

$$\Xi_2 = \xi_2 \sin (2\tau + 4\nu + \gamma_2) \qquad (6)$$

The numerical values of their amplitudes and phases are given in Table 1.

Both the main terms and the partial tides as given in Table 1 are still subject to minor corrections (for example, for the length of the lunar day as distinct from the solar day). The amplitudes of L_1 and L_2 differ slightly from the values originally found[4]; this is due to a correction for seasonal change of the S_q-variation which was applied in the recent re-examination; the errors for the amplitudes and phases are probable errors; they are quoted here from ref. 4, as they have not been determined again. It is noteworthy that in this particular set of data, Ξ_1 has nearly half the amplitude of L_1.

Table 1. Geomagnetic partial tides Ξ_1 and Ξ_2, as compared with main terms L_1 and L_2, Batavia (now Kuyper, near Djakarta) east component, southern summer (Nov. 11–Feb. 20), 1906–1929, excluding disturbed days with magnetic character figure > 1·1

	Main terms		Partial tides		Ratios	
	L_1	L_2	Ξ_1	Ξ_2	Ξ_1/L_1	Ξ_2/L_2
Amplitude (unit: 0·01 γ)	150 ± 17	279 ± 17	70	43	0·47	0·15
Phase	255° ± 10°	+86° ± 3°	171°	29°		

In analogy to similar terms appearing in general tidal theory, waves such as Ξ_1 and Ξ_2, being components of the 'geomagnetic tides', may be called 'geomagnetic partial tides', although it should be kept in mind that they do not stem from air oscillations of period $(\tau+3\nu)$ and $(2\tau+4\nu)$ superposed on expression (3); they originate in the conductivity factor (4) rather than in the factor representing the motion of the air. In fact, it is physically most unlikely that the daily variation of the conductivity should have a form that could be fitted by only a diurnal and a semi-diurnal term. If a term with $\varkappa=3$ is introduced in expression (4), multiplication by expression (3) gives the component expression (5), and a term $\varkappa=4$ in expression (4) similarly gives expression (6). However, as will be shown here, Ξ_1 and Ξ_2, if deduced from data comprising one season only, as in this case, will contain a portion not stemming from the process here invoked.

Martyn[7], in his work on lunar tides of the ionosphere at Huancayo, Peru, has found similar features in $h^{\max}F2$, and f^0F2, and Tschu[8] has pointed out that these 'lunar-solar' ionospheric variations contain a term equivalent to our geomagnetic partial tide Ξ_2.

As shown by Chapman and Bartels, a still more complete picture is obtained if the motion is also supposed to have a more general form than the simple 12-hourly wave defined by expression (3). Even though there is little doubt that the air motion is mainly semi-diurnal, a small 24-hourly component is likely to exist. In fact, Doodson's harmonic development[9] of the tide-generating potential shows that there is a diurnal term depending only on τ, the mean lunar time, and not on any other one of the remaining five arguments involved in tidal theory; (its argument-number, in Doodson's notation, is therefore {155·555}). The amplitude of this tide is about 0·7 per cent of that of the main semi-diurnal term M_2, and about 1·8 per cent of O_1, the largest one of the diurnal terms involving other arguments. However, as Bartels[10] has pointed out, the circumstance that the amplitude of lunar diurnal movements in the ionosphere are much bigger than at ground-level suggests the possibility of an independent origin of L in the ionosphere; the relative importance of the amplitude factors may, therefore, be different in the ionosphere.

If, then, a term:

$$M_1(\tau) = m_1 \sin (\tau + \lambda_1) \qquad (7)$$

is included, the product of expressions (3) plus (7) by (4), comprising terms with $\varkappa \geqq 3$, will contain other partial waves, in addition to expressions (5) and (6). For example, the 24-hourly wave will contain the further components:

$$L_1{}^* = l_1{}^* \sin (\tau + \varepsilon_1{}^*) \qquad (8)$$

and

$$\Xi_1{}^* = \xi_1{}^* \sin (\tau + 2\nu + \alpha_1{}^*) \qquad (9)$$

If the geomagnetic partial tides here discussed can be revealed in empirical data, it seems justifiable to restate

Chapman's phase-law in a generalized form. This is conveniently done by converting all formulæ to solar time t by means of expression (2). Then the classical phase-law describes terms $L_\varkappa(t)$ the phases of which decrease by 4π during a month, regardless of $\varkappa$, whereas the partial tides $\Xi_\varkappa$ have phases increasing by 4π during the month; both types stem from the semi-diurnal component of the air motion, and are, therefore, the predominant feature of L. The partial tides $L_\varkappa{}^*$ and $\Xi_\varkappa{}^*$, in turn, arising from the 24-hourly component of the air movement, have phases that decrease by 2π, and increase by 2π, respectively, in the course of each lunation.

Table 2. Geomagnetic partial tides Ξ_1, $\Xi_1{}^*$, and $L_1{}^*$, as compared with the main term L_1, Greenwich, west declination, all months, 1848–63 and 1868–1914, including (most of the) disturbed days; deduced from results obtained by Chapman (ref. 3)

	Main term	Partial tides		
	L_1	$L_1{}^*$	Ξ_1	$\Xi_1{}^*$
Monthly phase change if expressed in lunar time	-2π	0	$+6\pi$	$+4\pi$
Amplitude (unit 0·01γ)	49	0·4	11	14
Phase at new moon	131°	256°	14°	151°
Magnitude in units of main term L_1	1·00	0·008	0·22	0·29

Three of these four types of waves can be shown to be present in Chapman's results which he used in his paper[3] on the lunar variation of magnetic declination at Greenwich, based on more than 20,000 days. As an example, Fig. 1 reproduces Chapman's diagram of the variation of the phase Θ_1 of the 24-hourly wave during one lunation, with the straight line representing his phase-law. This picture is here supplemented by a curve which includes the geomagnetic partial tides Ξ_1 and $\Xi_1{}^*$; the fourth component, $L_1{}^*$, was found to be negligibly small in this particular case. To obtain the new curve, which obviously fits the observed phases better than the straight line, the amplitudes of the 24 empirical waves for each individual moon-phase ν had of course to be taken into account. Fig. 2 gives a harmonic dial, or "dial-gram"[6], in lunar time, of the 24-hourly wave of the same Greenwich data; the observed points (numbered by Arabic figures), which would lie on a circle described clockwise in one lunation, if only the wave L_1 according to expression (1) existed, show a considerable variation of the amplitudes. This is due to the presence of the vectors for Ξ_1 and $\Xi_1{}^*$, which describe three, and two, counterclockwise rotations, respectively, during one month. The sum $L_1+L_1{}^*+\Xi_1+\Xi_1{}^*$ is represented by the continuous curve; also shown, in the lower left insert, is the superposition of $L_1+\Xi_1+\Xi_1{}^*$ for new moon ($\nu=0$). Table 2 gives the amplitudes and phases of these waves.

Although the ratio ξ_1/l_1 is less than half that found for Batavia (Table 1), it is still surprisingly high, and the phase differences between L_1 and Ξ_1 are also similar.

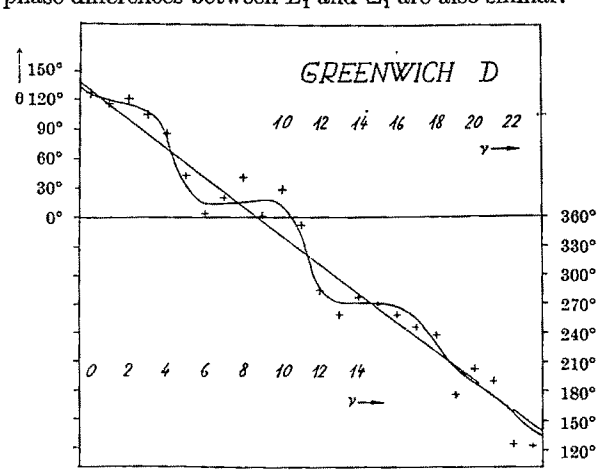

Fig. 1. Phase change, during a lunation, of the 24-hourly lunar geomagnetic tide of east declination, Greenwich, after Chapman. Crosses: observed phases; straight line: Chapman's phase-law[3]; curve: generalized phase-law including partial tides

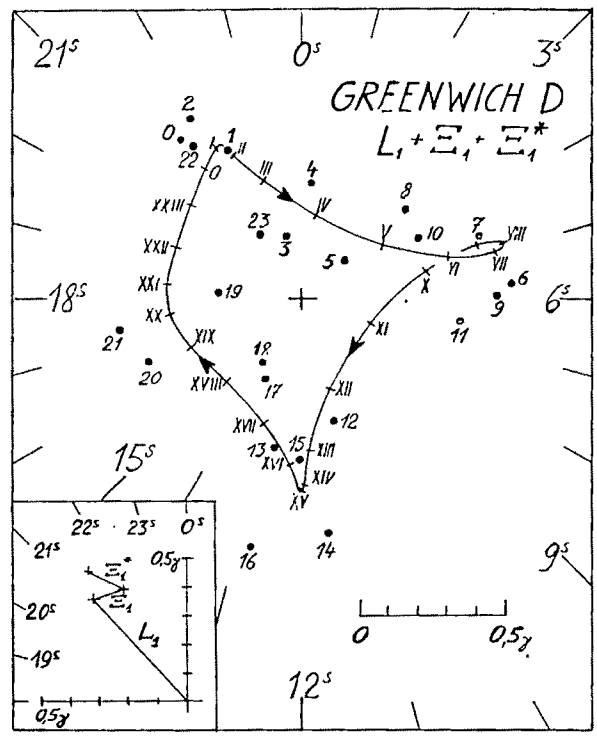

Fig. 2. "Dial-gram" of the same waves as Fig. 1, in lunar time. Dots: observed data; curve: best fit by waves given in Table 2. Inset: main term plus two major partial tides at new moon

It has already been mentioned that waves of type Ξ_1 and Ξ_2, if obtained from data belonging to one season only, will contain a portion of a different origin, in addition to the one arising from the combination of expressions (3) and (4). This portion will be produced by the diurnal tide O_1, which we may suppose not to be negligible at ionospheric levels, and will cause an air-motion of the form:

$$M_1{}^{(o)}(\tau) = m_1{}^{(o)} \sin(\tau - s + \lambda_1{}^{(o)}), \qquad (10)$$

where $s=\nu+h$ is the Moon's mean longitude, and h the Sun's mean longitude. Again, the geomagnetic effect will be obtained by multiplication with expression (4); the expressions resulting in this way have the form:

$$Z_\varkappa = C_{\varkappa+1} \sin(\varkappa\tau + (\varkappa+2)\nu + h - \delta_1) + C_{\varkappa-1} \sin(\varkappa\tau + (\varkappa-2)\nu - h + \delta_1) \qquad (11)$$

As the arguments contain h, both terms of the right hand side would average out in the course of a year, provided that the coefficients $C_{\varkappa+1}$ and $C_{\varkappa-1}$, involving the coefficients of the conductivity function (4), be constant or their annual variation be symmetrical. This, however, cannot be taken for granted, nor do the data generally cover the whole year, that is, the complete range of h; Table 1, for example, comprises only a range of $0{\cdot}56\pi$ in h, while Chapman's data used in Table 2 cover the full cycle of 2π. For a group of days belonging to only a season, then, the average of the waves $Z_\varkappa$ will not vanish and will have a resulting phase-angle involving δ_1 and depending on the length of the season analysed. The resulting form of the first term of $Z_\varkappa$ has an argument like expressions (5) and (6), and this will therefore contribute to $\Xi_\varkappa$, whereas the second term is analogous to expression (1) and contributes to $L_\varkappa$.

The partial waves here discussed are of some theoretical interest in so far as the components $L_\varkappa$, $L_\varkappa{}^*$, $\Xi_\varkappa$, and $\Xi_\varkappa{}^*$ are associated with harmonic coefficients of the conductivity function (4) of order $(\varkappa-2)$, $(\varkappa-1)$, $(\varkappa+1)$, and $(\varkappa+2)$ in diverse combinations. This may open a possibility for determining these coefficients of the conductivity function. From a practical point of view, the

geomagnetic partial tides are of importance because they account for a considerable part of the variability of the main terms that has been considered as statistical noise so far.

A search for similar features in the remaining terms of Chapman's data, and at other geomagnetic stations, including southern hemisphere observatories up to middle latitudes, is under way.

I thank Prof. S. Chapman for critical comments on the manuscript and valuable suggestions.

IMPLICATIONS OF SIMILARITY IN RARE-EARTH FRACTIONATION OF NAKHLITIC METEORITES AND TERRESTRIAL BASALTS

By Dr. R. A. SCHMITT and R. H. SMITH

General Atomic Division of General Dynamics Corporation, John Jay Hopkins Laboratory for Pure and Applied Science, San Diego, California

THE absolute abundances of the 14 rare-earth elements and yttrium and scandium have been determined[1,2] by neutron activation analysis[3,4] in two nakhlitic achondrites, Nakhla and Lafayette. Rare-earth element, yttrium and scandium abundances in parts per million are given in Table 1. Normalized abundances have also been listed in columns 3 and 5 of Table 1 for comparative purposes, and the normalized abundances of the rare-earth elements, yttrium and scandium found in 16 chondritic meteorites[3,5] have been tabulated in the last column.

* Values for elemental abundances were calculated by assuming that meteoritic and terrestrial isotopic ratios were identical for the rare-earth elements. This assumption has been verified for at least five rare-earth element ratios, especially for $^{168}Yb/^{174}Yb$, which is strongly dependent on nucleosynthetic models. Errors are primarily one standard deviation due to counting statistics.
† Parentheses show pairs of radionuclides that were measured.
‡ Values first reported by Schmitt (ref. 1).
§ Values first reported by Schmitt (ref. 2).
¶ Relative rare-earth element, scandium and yttrium abundances were taken from Schmitt, Smith and Haskin (ref. 5).

In Fig. 1 the ratios of the normalized weight per cent of the rare-earth elements, yttrium and scandium in Nakhla and Lafayette (see columns 3 and 5 of Table 1) to the average normalized weight per cent of the rare-earth elements, yttrium and scandium in 16 chondrites (see column 6 of Table 1) have been plotted as a function of the rare-earth element, yttrium and scandium ionic radii of Ahrens[6]. This geochemical procedure, modified after that introduced by Coryell *et al.*[7], clearly demonstrates fractionation of the rare-earth elements, yttrium and scandium in any given system relative to the rare-earth elements, yttrium and scandium in chondritic meteorites, which are considered the best representatives of primordial solar matter[8,9] for non-volatile chemical elements. For comparison, smooth curves have been drawn through the corresponding ratio values of Kilauea basalt[10] and through the average values in seven different sediments[5,11].

In Fig. 2, smooth curves have been drawn through ratio values for the rare-earth elements, yttrium and scandium obtained[2,3] in three 'calcium-poor' achondrites, Johnstown, Shalka and Norton County, and in three 'calcium-rich' achondrites, Nuevo Laredo, Pasamonte and Juvinas. Essentially, no rare-earth element and yttrium fractionation relative to the chondrites has been found in the calcium-rich achondrites.

On an absolute basis, the abundances of the rare-earth elements and yttrium in Nakhla and Lafayette are only ~ 10 per cent different from each other; however, on a normalized basis, which is a more severe criterion of fractionation, the rare-earth elements and yttrium agree within the 95 per cent confidence-level, with minor exceptions for the elements, cerium, ytterbium and scandium. These deviations have been discussed elsewhere[3].

Fig. 1 and Table 1 clearly show that the rare-earth elements and yttrium in Nakhla and Lafayette have been fractionated to nearly the same degree relative to the primordial rare-earth element distribution, while the element scandium has been enriched in these nakhlitic achondrites by ~ 6 relative to scandium in chondritic meteorites. The difference in scandium fractionation may be attributed to the geochemical differences[12] of scandium compared with rare-earth element and yttrium properties. Furthermore, the fractionation of the rare-earth elements and yttrium in these two nakhlitic achondrites is very similar in shape to that found in a Kilauea basalt (Fig. 1). For the light rare-earth elements, lanthanum to europium, the differences in fractionation between nakhlitic and Kilauea basalts vary smoothly from 0 per cent (by definition) for lanthanum to ~ 15 per cent for europium; for the heavy rare-earth elements, gadolinium to lutetium, the fractionation difference widens uniformly to ~ 40 per cent for the element lutetium. The smooth trend in rare-earth element fractionation, which is observed in Kilauea basalt, has been confirmed by Chase *et al.*[13], who determined three rare-earth elements, lanthanum, europium and dysprosium, in three oceanic basalts.

The rare-earth element and yttrium distribution curve of the nakhlites does not match well the corresponding distribution curve in seven sediments; the latter is considered[5] to represent best the rare-earth element and yttrium distribution in the Earth's crust. Furthermore, from Fig. 2, it is evident that rare-earth element and

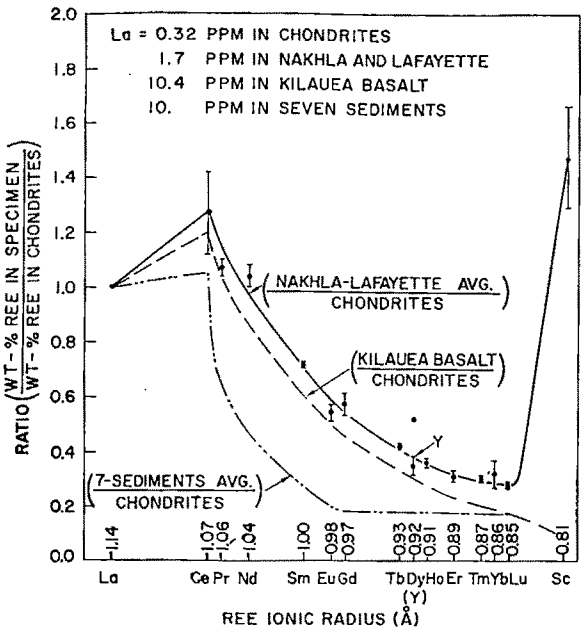

Fig. 1. Ratios of the average normalized weight per cent of the rare-earth elements, yttrium and scandium in Nakhla and Lafayette to those in sixteen chondrites (solid curve) as a function of ionic radius. For comparison, dashed curves have been drawn through corresponding ratios for Kilauea basalt (*Iki*-22) and through the average ratios in seven different terrestrial sediments

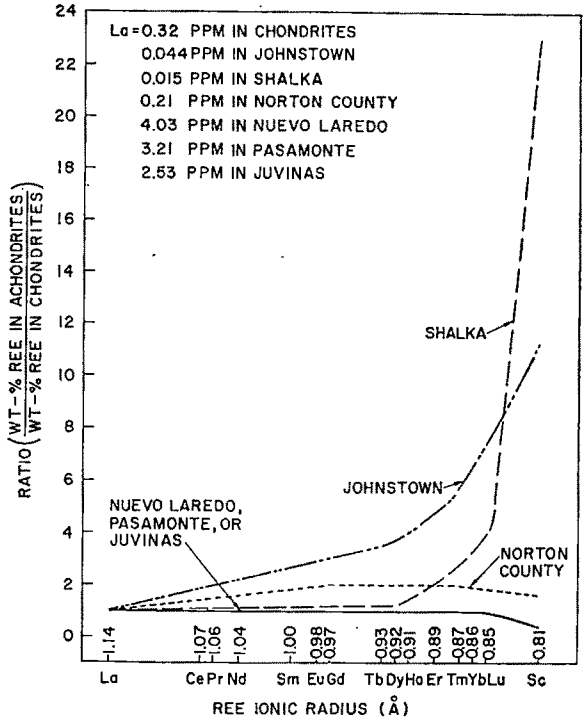

Fig. 2. Ratios of the normalized weight per cent of the rare-earth elements, yttrium and scandium in three calcium-poor achondrites, Johnstown, Norton County, and Shalka, and in three calcium-rich achondrites, Nuevo Laredo, Pasamonte, and Juvinas, to those in sixteen chondrites as a function of ionic radius

yttrium fractionation differs markedly in the calcium-poor achondrites, whereas no fractionation for the rare-earth elements and yttrium has been found in the three calcium-rich achondrites.

In an earlier report[2] we have shown that the rare-earth element, yttrium and scandium fractionation results presented in Table 1 and depicted in Figs. 1 and 2, together with abundances of the rare-earth elements, yttrium and scandium determined in a total of 27 meteorites which cover the entire spectrum of meteorites, are consistent with the concept of a single parent meteoritic body[2], perhaps intermediate in size between those suggested by Ringwood[14] and Fish *et al.*[15]. With increasing radius the various shells are: iron-nickel core, pallasitic, calcium-poor achondritic, chondritic, mesosideritic, calcium-rich achondritic, Type II carbonaceous chondritic, and finally, nakhlitic achondrites scattered over the surface of the meteoritic body. Volcanic action, terrestrial-like[14] on the parent meteoritic body, may have produced the similarity in the fractionation of rare-earth elements and yttrium to the Kilauea basalt. Goles[16] has suggested that, according to the model of Fish *et al.*[15], the basaltic or nakhlitic meteorites could be chilled and embedded just below, or in, the carbonaceous meteoritic shell.

These nakhlitic meteorites account for only ~ 0·3 per cent of observed meteoritic falls; furthermore, Prior[17] reported that Nakhla resembled a fine-grained basalt. Mason[18] states that the two meteorites Nakhla and Lafayette are mineralogically indistinguishable. If the volcanic root originated[2] in the calcium-rich achondritic (4·8 per cent of observed falls) shell, only ~ 0·3/4·8, or 6 per cent of the calcium-rich achondrites in that shell may be enriched in the heavy rare-earth elements and yttrium. With no convection, about 2 of the 37 calcium-rich achondrites observed may show an enrichment factor. With sufficient convection in this shell, changes in rare-earth element and yttrium abundances would not be reflected in the calcium-rich achondrites, since the data are good ~ ±5 to ~ 10 per cent.

Many other tests may provide corroborative evidence for the above suggestions, for example, macroconstituency and trace elemental content, cosmic-ray exposure ages, gas-retention ages, etc. A cosmic-ray exposure age similar to ordinary chondrites would be more compatible with Goles's suggestion[16]. On the other hand, a shorter cosmic-ray exposure age (compared with ordinary chondrites) and similar to carbonaceous chondrites, which have been postulated for surface matter[15], would suggest[19] that nakhlitic meteorites may be of surface lunar origin as proposed by Urey[20]. Therefore, if a lunar origin is postulated, and the rare-earth element distribution in chondritic meteorites is primordial, volcanic action may have prevailed on the Moon in order to produce the smooth fractionation so similar to terrestrial basalts. Such fractionation on a lunar surface might conceivably occur during the crystallization of the melt, generated by the heat associated with lunar crater formation[21].

DETERMINATION OF GOLD AND OF SILVER IN SOLUTION BY ATOMIC ABSORPTION SPECTROSCOPY

By M. C. GREAVES
H. B. Selby and Co., Pty., Ltd., Melbourne

GOLD. Following the development of a method for the determination of silver in lead sulphide concentrate[1], attempts have been made to apply atomic absorption spectroscopy to the determination of gold in metallurgical samples.

Lockyer and Hames[2], working with dilute aqueous solutions of the noble metals, reported only moderate sensitivity for gold, together with pronounced drift of transmission readings as their burner warmed up. More recently, Gatehouse and Willis[3] reported a detection limit of 0·3 p.p.m., indicating an approximately six-fold reduction in sensitivity compared with that for silver using their equipment. They did not obtain the drift in transmission readings reported by Lockyer and Hames.

The work reported here was done on the equipment described formerly[1] except for the substitution of a stainless steel burner head having 20 × $\frac{1}{8}$ in. diameter collinear holes. With this head, the total flame-length was 10 cm. The limit of detection for aqueous gold solutions was 0·3 p.p.m. In agreement with Gatehouse and Willis, no transmission drift was observed.

This detection limit for gold clearly indicated the need for sensitivity enhancement if atomic absorption spectroscopy were to be applied to the determination of gold down to the 0·5 dwt. gold/ton (approx. 8×10^{-5} per cent by weight) level.

From preliminary trials on aqueous gold solutions, solvent extraction offered the advantage of both preconcentration and of sensitivity enhancement by appropriate choice of solvent[4]. Of those tested, methyl isobutyl ketone appeared the most promising, having the least effect on the combustion characteristics of the flame. Moreover, flame background at the resonance wave-length of 2428 Å was slight and reproducible.

Gold (III) ions readily form complexes with the halides. That with bromide ion has been much favoured for subsequent treatment. Solvent extraction for 30 sec with methyl isobutyl ketone of aqueous solutions containing the bromaurate anion in the presence of excess hydrobromic acid showed organic phase maximum absorption when the axis of the optical path was 8·5 mm above the burner top. No detectable concentrations of gold were found in the aqueous phases from these extractions.

Enhancement of sensitivity for gold was determined by repeated comparisons between aqueous and organic media solutions. Typically, 3·00 ml. aliquots of 1, 3, 4, 5 and 10 p.p.m. aqueous auric ion solutions were rendered 3 molar in hydrobromic acid in a total aqueous volume of 30 ml. Extractions were made with 10·00 ml. methyl isobutyl ketone, the separated organic phases then being atomized into the coal-gas/air flame for measurement. For comparison, a portion of each of the aqueous standard solution stocks was atomized without prior extraction. Typical results are given in Table 1.

The average slopes of the calibration curves of closest fit to these results are: organic extracts 0·056 absorbance units/p.p.m. gold; aqueous solutions 0·011 absorbance units/p.p.m. gold, or an uncorrected increase in sensitivity of 5·1 : 1. The volume of the organic phase was never less than 9 ml. after a period of 1 min from completion of extraction. Solubility data for water indicate an equilibrium volume of 9·4 ml. at 20° C.

Neither lead nor tellurium ions interfere with either the extraction or the subsequent absorption measurement. This has led to the use of co-precipitation of gold with lead sulphide as a means of collection and separation from the bulk of the ions present in solution.

Sensitivity is such that sufficient gold is present in 5 g of sample to permit its determination at the 0·5 dwt./ton-level, once adequate dissolution methods have been found. The combined precision of measurement and of collection of gold by lead sulphide is within ± 1 per cent relative, thus comparing favourably with the fire-assay method. Conditions for the quantitative collection of gold from metallurgical samples are currently being established for both lead sulphide and tellurium metal, while the rationale of solvent extraction from chloride and cyanide solutions is also being examined.

Silver. In a recent paper on the determination of silver in lead sulphide concentrate[1], the final solution for atomization was approximately 3·25 molar with respect to hydrochloric acid. Although the corrosive effect of this concentrated acid solution on the standard EEL atomizer could be overcome by using a platinum iridium atomizer capillary, other means were sought to overcome this. This article records one of a number of methods developed for this purpose.

Forward *et al.*[5] have shown that certain of the alkylpolyamines form stable, highly soluble complexes with lead ions. Their solubility data suggested the means for keeping lead salts in solution and, at the same time, for reducing the acidity to levels where atomizer corrosion was no longer a problem.

The reagent selected for testing was diethylene triamine, available in 'laboratory reagent' grade. Preliminary qualitative tests showed that the reagent would readily dissolve the equivalent of the lead ion content of 1-g samples of lead sulphide concentrate after the normal hydrochloric and nitric acid digestion.

The resultant solutions, whether made acid, neutral or alkaline with the reagent, were stable and did not re-precipitate lead salts on long standing or extensive dilution. Similar tests with solid silver chloride suspension in hydrochloric acid showed that this compound was also readily dissolved by addition of diethylene triamine. Such solutions were stable under both acid and neutral conditions, although incipient precipitation occurred when they were rendered alkaline with the amine.

Synthetic samples of lead sulphide concentrate were prepared from A.R. grade lead acetate trihydrate, silver free, to which measured amounts of a standard silver ion solution were added. Precipitation of the sulphides, followed by quantitative solids separation, drying to and

Table 1. Sensitivity Enhancement by Solvent Extraction

Gold conc. in aqueous standard (p.p.m.)	Nominal gold conc. in organic phase (p.p.m.)	Transmission (per cent)	Absorbance
0	0	97·5	0·011
1	0·3	95·0	0·022
3	0·9	88·8	0·052
4	1·2	84·8	0·072
5	1·5	81·0	0·092
10	3·0	68·0	0·168
0	—	100·0	Nil
1	—	97·9	0·009
3	—	93·6	0·029
4	—	91·2	0·040
5	—	88·5	0·053
10	—	77·6	0·110

Hollow-cathode tube supplied by Ransley Glass Instruments, Melbourne; lamp current, 8 m.amp; monochromator spectral band-width = 2 Å; solution up-take rate approximately 50 per cent greater for the organic solvent solutions than for the aqueous solutions.

weighing at atmospheric equilibrium enabled calculation of the silver contents.

The standard silver solution was prepared from spectroscopically pure silver wire. The filtrates from sulphide precipitation, diluted to a standard volume of 500 ml., were examined by atomic absorption spectroscopy for silver. None was ever found. The detection limit for silver with the absorption equipment used was $0{\cdot}0_5$ p.p.m.

These synthetic samples were used to test the diethylene triamine method by dissolving 1 g portions in 100 ml. of 10 N hydrochloric acid to remove the bulk of the sulphides, adding 16 N nitric acid as oxidant, followed by evaporation to 20–25 ml. volume. After cooling, the solutions were transferred to 100 ml. volumetric flasks, 8 ml. diethylene triamine added slowly, with vigorous agitation, both to complex precipitated lead salts and to reduce the acidity to approximately *p*H of 1. After making to final volume, the absorption of each was measured concurrently with those of similarly prepared standard silver solutions.

Measurement was made using the original equipment with a 10-cm coal-gas/air flame, air-pressure 6 p.s.i.g., lamp current 6 m.amp, *DU* monochromator slit-width 0·05 mm., at the silver resonance wave-length of 2381 Å. The optical axis traversed the flame at the optimum value of 8·5 mm above the burner top. Coal-gas flow-rate was the minimum consistent with stable combustion. Typical results are given in Table 2.

Table 2. Use of Diethylene Triamine for the Determination of Silver

Synthetic Sample No.	Theoretical assay (oz. Ag/ton)	Atomic absorption assay (oz. Ag/ton)	Ag recovery (per cent)
I	$22{\cdot}4_5$	$22{\cdot}0_1$	98·0
		$22{\cdot}4_0$	99·8
		$22{\cdot}6_5$	100·9
III	$22{\cdot}5_7$	$22{\cdot}4_1$	99·3
		$22{\cdot}2_8$	98·7
		Mean =	99·3

During the period of development of this method, several hundred atomizations were made without any noticeable corrosion of the atomizer, while the use of a test solution completely free from insoluble lead salts was an incidental advantage.

I thank the management of the Zinc Corporation, Ltd., Broken Hill, New South Wales, for equipment and facilities used at the time of this investigation.

This work was undertaken in partial fulfilment of the requirements for the M.Sc. degree, University of New South Wales.

COHERENCE TIME MEASUREMENTS OF LIGHT FROM RUBY OPTICAL MASERS

By MORLEY S. LIPSETT and Dr. L. MANDEL
Department of Physics, Imperial College of Science and Technology, London, S.W.7

THE coherence time[1] of the light pulses emitted by a ruby optical maser can be inferred from measurements of the spectral distributions made by several workers[2–6]. However, objections can be raised against the interpretation of most results reported so far. We have attempted to measure the coherence time directly in the following experiment, by a method which avoids most of these objections. We have detected the beat notes in the photoelectric fluctuations resulting from the superposition of light beams from two independent ruby masers on a photocell (cf. experiments of Forrester[7,8]). A preliminary account of this work was given at the Third International Conference on Quantum Electronics[9]. A similar spectral analysis for two continuously operating He–Ne optical masers has already been reported by Javan, Ballik and Bond[10].

Most workers[2–5] attempting to measure the spectrum of light from a ruby maser have made use of high-resolution interferometric or dispersive methods; but, because of the extremely narrow spectral width of the light, transient features of the spectrum (cf., for example, ref. 11) are easily lost in such experiments. Values obtained for the line-widths of individual components of the maser emission have ranged from a few[2] to many megacycles[4]. Berkley and Wolga[12] have examined the interference produced by two parts of a divided wave-front from a ruby maser, and have reported that the fringe visibility falls to below 1 per cent for delay times of order 0·1 μsec. However, it is doubtful whether this is a measure of the coherence time. On the other hand, McMurtry and Siegman[6] have measured the spectrum of beats between axial modes from a single ruby maser (cf. also Herriott[13]). On the assumption that phase correlation between modes is negligible, the widths of individual components were shown to be of the order of 2 mc/s, which suggests that the coherence time is $\sim 0{\cdot}5$ μsec and primarily limited by the finite duration of each pulse or 'spike'. However, phase relations between modes of a He–Ne maser have recently been found[14] and indeed are predicted theoretically for gaseous[15] and solid-state[16] optical masers. The possibility of similar effects in ruby cannot therefore be completely ruled out. The beats produced by two independent beams should therefore provide a less ambiguous measure of the coherence time.

Consider two plane, fully polarized maser beams incident on photocells singly and in superposition. The two complex classical wave amplitudes which we denote by $V_a(t)$ and $V_b(t)$ can be expanded in the form[17]:

$$V_a(t) = \sqrt{I_a(t)}\,\exp\,[2\pi i\nu_a t + i\varphi_a(t)]$$
$$V_b(t) = \sqrt{I_b(t)}\,\exp\,[2\pi i\nu_b t + i\varphi_b(t)] \qquad (1)$$

where ν_a and ν_b are the centre frequencies of the two light beams, $\varphi_a(t)$ and $\varphi_b(t)$ are their phases, and $I_a(t)$ and $I_b(t)$ are their instantaneous intensities (given by $V_a^*(t)V_a(t)$ and $V_b^*(t)V_b(t)$ respectively). $\varphi_a(t)$, $\varphi_b(t)$, $I_a(t)$ and $I_b(t)$ can be shown to be nearly constant within a time shorter than the coherence time of the light[17]. The beams, when incident singly and perpendicularly on two photocells, will give rise to the instantaneous photoelectric signals:

$$S_a(t) = \alpha D I_a(t)$$
$$S_b(t) = \alpha D I_b(t) \qquad (2)$$

respectively, where α is a constant representing the quantum sensitivity of the photodetector (assumed constant over the spectral range of the light) and D is the width of the accepted beam. The photocurrent $S_c(t)$, at the output of a third photocell, resulting from the superposition of the two light beams, will be:

$$S_c(t) = \alpha \int_x^{x+D} |V_a(t) + V_b(t+\tau)|^2\,dx \qquad (3)$$

where x is a point on the photocathode corresponding to an optical path difference $c\tau$, as measured from an arbi-

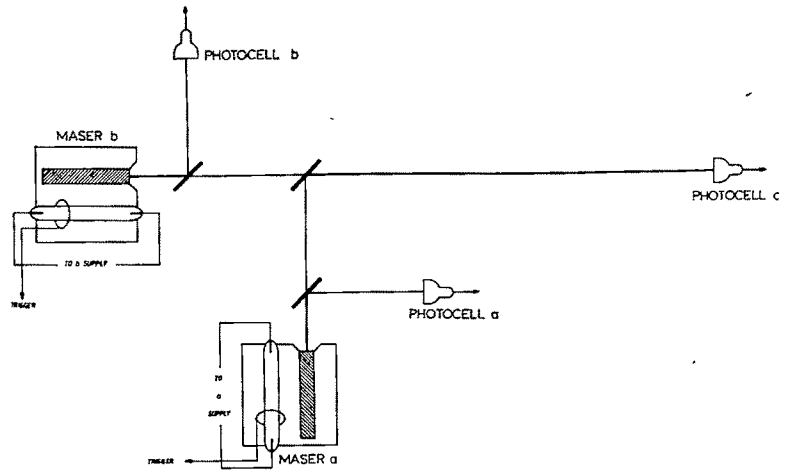

Fig. 1. Overall arrangement of the system

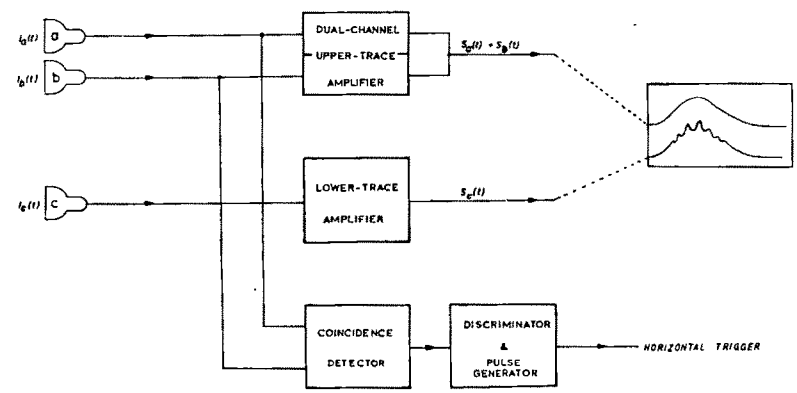

Fig. 2. Layout of the apparatus

trary origin. In the evaluation of $S_c(t)$ it is necessary to take into account a possible inclination β between the wave-fronts and an inclination β' between one of the wave-fronts and the photocathode. From equations (1), (2) and (3) we arrive at (cf. also equation 5 in ref. 18):

$$S_c(t) = S_a(t) + S_b(t) + 2k(\beta,\beta')\sqrt{S_a(t)S_b(t)}\cos[2\pi(\nu_a - \nu_b)t - \Phi(\beta,\beta') + \varphi_a(t) + \varphi_b(t)] \quad (4)$$

where:

$$k(\beta,\beta') = \frac{\sin\Phi(\beta,\beta')}{\Phi(\beta,\beta')},$$

$$\Phi(\beta,\beta') = \pi(\nu_a - \nu_b)\beta' D/c + \pi\nu_b\beta D/c$$

and c is the velocity of light.

From equation (4) we can see that the superposition signal is modulated sinusoidally at the difference frequency $|\nu_a - \nu_b|$. As long as the phases $\varphi_a(t)$ and $\varphi_b(t)$, together with the factor $\sqrt{S_a(t)S_b(t)}$, are constant the beat note remains steady. In the absence of other effects, the duration of a steady beat note is therefore a measure of the coherence time.

From the factor $k(\beta,\beta')$ in equation (4) it is evident that the wave-fronts must be nearly parallel $\left(\beta \ll \frac{c}{D\nu_b}\right)$ for $k(\beta,\beta')$ to be close to unity. On the other hand, the orientation of the photocathode (that is, the value of β') is critical only for very large difference frequencies $|\nu_a - \nu_b|$.

In practice the interpretation of the beats obtained with ruby maser light is complicated because the photoelectric signals tend to be heavily modulated in intensity by the envelope of the spikes. Moreover, high-frequency oscillations of the instantaneous light intensity $I(t)$ are sometimes observed[19] and these may mask the modulation due to the difference frequency. To avoid ambiguities in the identification of the beats, the intensity of the superposed beam and the sum of the individual beam intensities are recorded simultaneously in this experiment.

The system illustrated in Fig. 1 is arranged to detect chance coincidences of spikes after both masers are triggered simultaneously. The two light beams are sampled individually at the photocells a and b and are then combined by a beam splitter that directs the superposed beams to photocell c. The actual apparatus is reminiscent of a Michelson interferometer. The beams are superposed to within 0·03 mm and aligned to within 0·1 milliradians by means of the fine adjustments provided.

Small diameter (2·5 mm) ruby rods were chosen for this experiment to improve the chances of obtaining simple modes. The modes of one rod were controlled by flexing it in the way described by Lipsett and Strandberg[20]. With these precautions, nearly identical beams could be produced.

Fig. 2 is a block diagram of the electronic circuits. Photocells a and b serve the dual purpose of feeding a coincidence detection and discrimination circuit that triggers the oscilloscope sweep, and of providing the algebraic sum $S_a(t) + S_b(t)$ for the upper trace of the oscilloscope. The superposition signal $S_c(t)$ appears directly on the lower trace. Comparison of the two traces allows the cosine term of equation (4) to be identified with little ambiguity.

The maximum frequency $|\nu_a - \nu_b|$ that the system can detect is more than 60 mc/s, and is limited mainly by the response of the oscilloscope. Frequencies below about 10 mc/s tend to be obscured by the spike envelopes. The centre frequencies of the fluorescence lines will differ by almost 4 gc/s per °C temperature difference between crystals[21]. In addition, each spike may or may not be due to oscillation in more than one axial mode and the frequency may vary from one spike to the next. Moreover, because of thermal effects, the oscillation frequency can sweep through several megacycles during a single spike[2]. However, since both rubies experience similar temperature changes this should not affect our results, at least to a first order. Frequency shifts due to the effect of anomalous

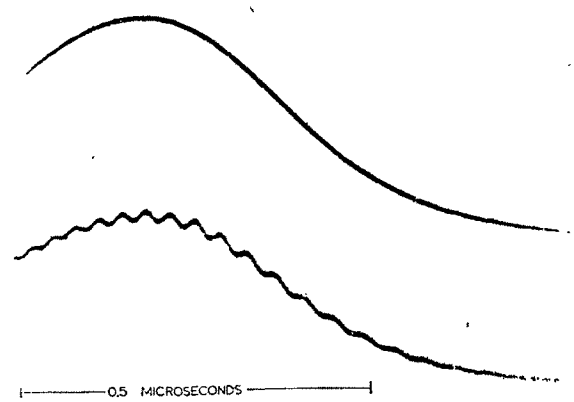

Fig. 3. Oscilloscope trace of the sum of the intensities of the maser beams (upper) and the intensity of the superposed maser beams (lower)

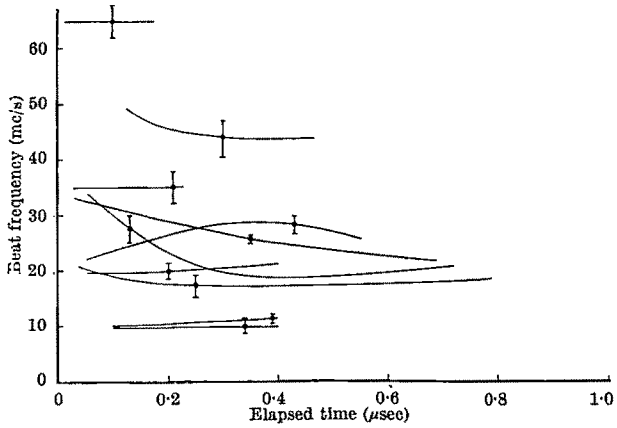

Fig. 4. Observed variation of beat frequencies with time. A single experimental point is shown for each curve merely to indicate the estimated accuracy of measurement from the photographs

dispersion are likely to be small[11], and in any event, should be nearly equal for both rubies emitting in coincidence. For the ~ 40 mm crystal lengths in this experiment adjacent axial modes are separated in frequency by 2·2 gc/s. The two lengths differ by 2 per cent, which assures that only beats between one axial mode of each ruby will fall within the detection band-width of the system. In fact, our detection band-width is about two orders of magnitude smaller than the possible range of beat notes. With this restriction we find in practice that slight variations from one maser flash to the next lead to one observable beat note in about 50 trials. The pumping conditions are so adjusted that on the average one spike coincidence occurs per maser flash, and this happens close to threshold for both rubies.

A photograph of a typical beat note is reproduced in Fig. 3, and shows a modulation on the lower trace. This beat note can be seen to persist for the full duration of the spike, drifting in frequency from 33 mc/s to about 21 mc/s in the course of 0·7 μsec. No systematic trend for the beat frequency to increase or decrease was evident from other similar photographs. This is shown by Fig. 4, which summarizes the results. It can be seen that the coherence time is of the order of ½ μsec, which is also the half-width of a typical spike.

Our results therefore show that transient coherence[1,22] can exist between independent ruby masers for periods of the same order as the spike width. This corresponds to a line-width for a single mode of a few mc/s and agrees with the results of McMurtry and Siegman[6].

We plan to apply a similar technique to measure the coherence time under conditions of quasi-continuous oscillation[23].

ION EXCHANGE THEORY OF COAGULATION

By Prof. M. MIRNIK
Institute "Rudjer Bošković" and Laboratory of Physical Chemistry, Faculty of Science, Zagreb, Yugoslavia

RECENTLY, S. Levine and E. Matijević have criticized[1] my ion exchange theory of colloid stability[2]. From this criticism it should follow that the thermodynamic deduction of the theory is incorrect, and that in order to confirm it the experimental results given were not correctly interpreted by me.

This article is restricted to point out the main errors on which the criticisms of Levine and Matijević are based.

(1) Their basic assumptions[1] concerning the ion exchange theory were summarized, and in my opinion an erroneous interpretation of this theory was given. This interpretation in connexion with the simplified notation used does not correctly explain the ion exchange theory neither is this note helpful in elucidating it to the readers.

The original version[2] of the interpretation of the ion exchange theory was based on chemical thermodynamics applied to the experimentally observed counter ion exchange on coagulated silver iodide. Later[3] electrical terms, namely, electrochemical potentials, were introduced into the theory, and on the basis of electrochemical thermodynamics and double-layer electrostatics, it was possible to extend the theory to the interpretation of electrokinetic phenomena. The theory of electrokinetic phenomena could be confirmed by available electrokinetic results. In this way the same theoretical postulates as in the original deductions in ref. 2 concerning counter ion exchange and coagulation could be obtained.

(2) The first point of the criticism, from which it should follow that the thermodynamic deduction of the theory is incorrect or impossible, is based on the opinion that the chemical potential of the adsorbed constituent ion $\mu_{A^-,ads}$ cannot be different from the chemical potential of the same ion in the solution phase μ_{A^-}. This would be an anomaly contradicting laws of thermodynamics. Consequently, $\mu_{A^-,ads}$ could not be independent of the activity of the same ions in the liquid phase as supposed in the ion exchange theory. A consequence of this statement would be that all particles of a two-phase system should be in distribution equilibrium and that all particles should follow the same thermodynamics. According to this requirement, the logarithm of the adsorbed quantity of constituent ions should be proportional to the logarithm of their activity. The existing experimental evidence on silver iodide, however, is that either the amount Γ of adsorbed constituent ions I^- (determined potentiometrically[4,5]) is approximately proportional to $p\mathrm{I}$ or decreasing with $p\mathrm{I}$, or that the amount γ (determined by the adsorbed

amount of labelled counter ions which cannot be decanted or washed out from the coagulated silver iodide) is constant with pI (refs. 6 and 7). Recently[18], the independency of the adsorbed bromide ions of their activity in the adsorption saturation region was observed. Thus none of the experimental methods of determination of the adsorbed constituent ions (I^-) confirms the thermodynamic postulate of Levine and Matijević.

On the other hand, it follows from experiments that the adsorbed quantity of two counter ions $x\gamma$ and $(1-x)\gamma$ varies as required by the equality of their (electro) chemical potentials in the adsorbed state and in the liquid phase. The total adsorbed amount of two counter ions γ, and the maximal adsorbed amount of one counter ion are equal and independent of the concentration of counter ions and of pI (refs. 6–8). Therefore the only possible logical conclusion is that these counter ions are in a reversible distribution equilibrium, while the constituent I^- ions in the amount which is equivalent to the adsorbed amount of counter ions are irreversibly adsorbed and are consequently not in a distribution equilibrium. The experimental evidence suggests that the quantity of adsorbed constituent ion γ which is constant with pI and which causes the selective adsorption of counter ions is determined by the specific surface of silver iodide and that the forces by which the constituent ions are fixed in the surface are great compared with the coulombic forces by which counter ions are adsorbed. Therefore the constituent ions are assumed as tightly bound or fixed at the surface (inner Helmholtz layer) while the counter ions form the outer (Helmholtz) layer. Experimental results cannot be in contradiction with thermodynamics and therefore theoretical explanations which explain the same experimental results cannot be in contradiction with thermodynamics either.

According to the second main point of the criticism of Levine and Matijević the standard distribution coefficients D'_0 and D''_0 of two different counter ions M' and M'' defined by:

$$\ln D'_0 = (\mu^0_{AM',\text{ads}} - \mu^0_{M'})/RT \text{ and } \ln D''_0 = (\mu^0_{AM'',\text{ads}} - \mu^0_{M''})/RT \quad (1)$$

cannot be equal as supposed by the ion exchange theory since standard chemical potentials of two different species should be different. (The notation of ref. 1 was adopted here.)

One of the basic suppositions of the theory of solutions is that different ideal solute particles exhibit the same thermodynamic action if present in systems of the same mole fraction (concentration). For example, the osmotic pressure, the freezing point depression, the liquid junction tension, Donnan equilibria, etc., depend on the number of present ideal particles only and not on their kind. The differences in thermodynamic action of real particles are accounted for by activity factors. The differences in valency of ions are accounted for by the number of ions taking part in the reactions and by the valency factors in the electrochemical potentials. For example, from the limiting law of the Debye–Hückel theory it follows that the activity factors depend on the valencies of ions only and not on their kind.

A proof for the correctness of this opinion can be given directly by the selectivity coefficient S of ion exchangers, which can be defined by:

$$\ln S = \ln\{F[c_{M''}x\gamma/c_{M'}(1-x)\gamma]\} = a(z'-z'') - [(\mu^0_{AM',\text{ads}} - \mu^0_{M'}) - (\mu^0_{AM'',\text{ads}} - \mu^0_{M''})]/RT = a(z'-z'') - \ln(D'_0/D''_0) \quad (2)$$

F is the product of all activity factors occurring in the expression. For ideal exchanging ions of equal valencies $F = 1$ and $z' = z''$. In the classical theory of ion exchange the opinion that for ideal exchanging ions $S = 1$ is generally accepted as valid. The experimental deviations of S from 1 with real ions are accounted for by activity factors in which case $F \neq 1$.

Therefore, according to the classical theory of ion exchangers as well as to the elementary theory of electrolyte solutions, it is correct to assume that:

$$D'_0 = D''_0,\ \mu^0_{M'} = \mu^0_{M''} \text{ and } \mu^0_{AM',\text{ads}} = \mu^0_{AM'',\text{ads}}$$

if the concentrations are measured in moles per litre. Therefore, Levine and Matijević erroneously claim that the terms D'_0 and D''_0, $\mu^0_{M'}$ and $\mu^0_{M''}$, and $\mu^0_{AM',\text{ads}}$ and $\mu^0_{AM'',\text{ads}}$ cannot be equal.

As experimental support of the latter argument, Levine and Matijević quote our own results on ion exchange on silver iodide for the ion pairs $Y^{3+} - La^{3+}$ and $Y^{3+} - Nd^{3+}$ (ref. 7, Fig. 8). The fact that for each ion pair two lines can be obtained (correctly by the last square method) they consider as the proof that standard chemical potentials of these ions are different. The maximal deviation in the logarithm concentration scale of the two points, from the drawn theoretical line having a slope of 45°, is 0·1. These deviations can apparently be attributed to an experimental error (eventually counting error in counting lower radioactivity in lower ion concentrations) and to necessary different activity factors of the two ions. This experimental (not reproduced) deviation in the slope is not significant and cannot certainly be accepted as a proof for the correctness of the assumption that $D'_0 \neq D''_0$ as claimed by Levine and Matijević. Eventually, if the deviation would be significant, it could be accepted as the proof that $f_{M''} = f(c)$ and that $f_{M'} \neq f_{M''}$, namely, that the activity factor is a function of concentration and that, in general, activity factors of different ions are different.

The maximal spread of the a values obtained in counter ion exchange, summarized in ref. 7, Tables 1 and 2, and reproduced in Table 2 here, is 1·5–1·7 for seven measurements of different ion pairs. For three ions (Th^{4+}, La^{3+}, Ba^{2+}) in combination with Nd^{3+} this value is constant and equals 1·2. The results with thorium (1·0) have to be discarded because the hydrolysis was not controlled. The spread between 1·5 to 1·7 can be attributed to activity factors and the lower values (1·3) to specific effects of some ions. This spread is equal or even smaller than the spread normally encountered in experiments with ion exchangers. Despite deviations of this kind the classical thermodynamics of ion exchangers is generally accepted and considered as valid. It follows that the scatter of the results on the value a is not significant enough and cannot be used as an argument against the ion exchange theory as it was proposed by Levine and Matijević.

(3) Equation (7) in ref. 1:

$$\ln(c''/c_0) = -z''a + \ln[x/(1-x)] \quad (3)$$

can be obtained for:

$$\ln c_0 = \ln c' + z'a \quad (4)$$

from equation (6) which reads:

$$\ln(c''/c') = (z'-z'')\,a + \ln[x/(1-x)] \quad (5)$$

and the latter was obtained from the equality of the sum of the values of equations (2) and (4).

In ion exchange experiments with two counter ions M' and M'' present in a total concentration greater than the coagulation value, the physical meaning of c_0 is that of a (calculated) concentration of the hypothetical non-existent counter ion of valency $z = 0$. This particle

† Considered as specific cases.

was introduced to simplify the equation (only one z term!). In ion exchange experiments c' is an independent variable or a parameter of the experiment and therefore c_0 is an independently variable parameter too.

In coagulation experiments only one counter ion is present in a variable concentration c''. If we assume that the stabilizing particle M' is a constituent of the liquid (solvent) and therefore present in a constant activity c'_{stab}, which is independent of the variable concentration c'' of the coagulating counter ion M'':

$$\ln c_{0,\,coag} = \ln c'_{stab} + z'a \qquad (6)$$

is equal to the extrapolated constant coagulating concentration of the non-existent hypothetical particle of zero valency. According to experiments the coagulation concentration $c_{0,coag}$ is a constant and by the ion exchange theory it is explained as a constant because of the constant activity of the stabilizing particles c'_{stab}. This concentration was neither by Težak nor by the ion exchange theory assumed as constant because it is so much greater than the coagulation concentration of counter ions as incorrectly purported by Levine and Matijević.

The concentration c''_{coag} is in coagulation experiments a critical limiting concentration: in smaller concentrations the sols are stable or coagulate very slowly, in greater concentrations the coagulation is for orders of magnitude faster. Theoretically this coagulation concentration can be explained by a critical fraction $x = x_{coag}$ of adsorbed counter ions on stable sols and by a fraction $(1 - x_{coag})$ of adsorbed stabilizing particles which are the same for ions of different valencies. The coagulation concentration can then be defined for z = const. by:

$$c''_{coag} = c''_{(x\,=\,0\cdot5)}\,(1 - x_{coag})/x_{coag} = c''(1 - x)/x = \text{const.} \qquad (7)$$

This equation was obtained from the difference of two corresponding equations (6) or (7) in ref. 1.

Consequently no contradiction between equations (2), (4), (6) and (7) could be found and therefore the criticism of Levine and Matijević on this point is not justified.

(4) Table 1 shows results on coagulation values of different halides from ref. 9. From these it may be concluded that the coagulation values of Ba^{2+} are equal for silver chloride, bromide and iodide and that the Schulze–Hardy rule constant a is different for each halide. The same result was quoted in ref. 10, Fig. 6. The precision of the results is high enough and they may be summarized by the equation:

$$\log c''_{coag} = (2 - z'')a + \log c_{M^{z+},coag} \qquad (8)$$

($c_{M^{z+},coag}$ is the coagulation concentration of a bivalent cation).

On the basis of the hypothesis that the stabilizing particles M' are bivalent, the same equation can be obtained by the ionic exchange theory and the logarithm coagulation value of the bivalent ion can be defined by:

$$\ln c_{M^{2+},coag} = (\mu_{M'} - \overset{0}{\mu}_{M^{2+}})/RT \qquad (9)$$

($\mu_{M'}$ is the constant chemical potential of the stabilizing particle).

In pure water and in solutions of low concentrations of counter ions no other particles than water molecules are present, and only these can be assumed as bivalent. Therefore water molecules were accepted for the explanation of the stabilizing action. This conclusion is valid in the same extent in which the experimental result obtained by Matijević and Schulz[9] on which it is based is reliable. The conclusion is simple and logical and there is no reason to be called by Levine and Matijević a controversial conjecture.

The assumption that in the coagulation concentration $x = x_{coag} = 0{\cdot}5$ may be explained in the following way. The adsorption isotherm equations (6) or (7) in ref. 1 is a continuous function in which the only characteristic point is determined by $x = 1 - x = 0{\cdot}5$. For $x < x_{coag}$ the repulsing forces between the particles due to the stabilizing action are greater than the attracting Van der Waals forces. For $x > x_{coag}$ the electrostatic repulsing forces of the prevailing counter ions in the compressed outer layer are smaller than the Van der Waals forces. This assumption is equivalent to the basic assumption of the Derjaguin–Landau–Verwey–Overbeek theory except for the principle of the derivation of the electrostatic tension explained in ref. 3, which is a function of x, z'' and $c_{M''}$.

Fig. 1 shows the plots logarithm adsorbed quantity $x\gamma$ of Eu^{3+} and Co^{2+} against logarithm of their concentration in the region $(\log c''_{coag} - 1{\cdot}5)$ to $(\log c''_{coag} + 1{\cdot}0)$. (Experiments by M. J. Herak of this laboratory.) In low concentrations $c'' < c''_{coag}$ the silver iodide is present in a finely divided stable form (see electronmicrographs ref. 11, Fig. 12.1) and could be separated from the liquid by high-speed centrifugation only. In concentrations greater than the coagulation value the silver iodide is present in the coagulated form (electronmicrographs in ref. 11, Figs. 6, 7 and 8). Therefore the adsorption isotherm:

$$\log (c''/c_{0,coag}) = -z''a + \log [(x\gamma/(1 - x)\gamma] \qquad (10.$$

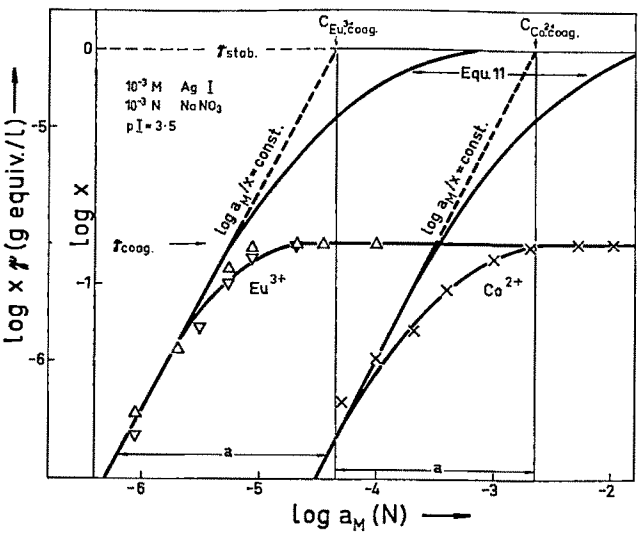

Fig. 1. The adsorbed quantity against the logarithm of Eu^{3+} and Co^{2+} concentration in the region of their coagulation values (10^{-3} M AgI, *p*I 3·5). Theoretical adsorption isotherms (equation (3) or (10)) for the stable state of AgI characterized by the value γ_{stab}. (Experiments by M. J. Herak, to be published.)

if measured on finely-divided stable silver iodide is different from that measured on the coagulated silver iodide. Therefore it should be expected that the measured plot will be a transition from the isotherm characterized by the value γ_{stab} valid in low concentrations of counter ions ($c'' < c''_{coag}$) to the horizontal part of the isotherm characterized by the directly measured value γ_{coag} in high concentrations.

Therefore it is not surprising, in fact it is necessary, that the measured plots of Fig. 1 do not fit the elementary isotherm equation (3) or (10) which would be valid if the solid would be present in the same state above and below the coagulation value. In low concentrations the plot asymptotically approaches the tangent with a 45° slope, while in high concentrations it becomes a horizontal line. However, the second important argument for the theory is that the plots are shifted for the constant $a - 1{\cdot}8$, which value is within the limits of the statistical scatter of this value (Table 2). Consequently the fact that the experimental isotherm does not fit the theoretical one is no argument against the ion exchange theory as purported by Levine and Matijević.

In Table 2 a collection of the values for the constant a obtained by different experimental techniques—electrokinetics, counter ion adsorption on stable silver iodide, counter ion exchange on coagulated AgI and coagulation—is presented. The maximal variation of this constant for the silver iodide system lies between 1·48 and 1·91 when some cases with effects which can be recognized as specific are not considered (for example, hydrolysis of Th^{4+}). This latter value (1·91) when corrected for the probable activity factor ($\log f = -0{\cdot}1$ to $-0{\cdot}2$ in 0·1 N solutions of monovalent electrolytes, in the corresponding solutions of bi- and tri-valent ions $\log f$ is $< 0{\cdot}05$) would be 1·8 to 1·7 or even less. This maximal variation includes the differences of the slope pointed out by Levine and Matijević in their discussion of ref. 7, Fig. 4. At present the number of available results is not great enough to make a statistical analysis which would eventually prove that the slopes of the lines 'valency-logarithm coagulation value' and 'valency-logarithm desorption concentration' are significantly different. Levine and Matijević claim, namely, that these experimental slopes ($= a$) cannot be considered as equal. The statistical variation of the different a value cannot certainly be used as an argument according to which the value a should not for theoretical interpretation be considered as a constant.

Levine and Matijević claim that there are examples which follow other formulations than the linear Schulze–Hardy rule, and quote the arsene sulphide sol. Presumably this statement is based on a work by Freundlich from 1910 cited in ref. 12, p. 307, Table 1. The result on arsene sulphide should be first reproduced by an up-to-date technique and the proof should be given that the logarithm activity factor correction does not cause the differences in the a values. The activity factors of 2–2 and 2–3 electrolytes ($S^{2-} - Ba^{2+}$, $S^{2-} - La^{3+}$) are irregular and as a rule smaller than those of monovalent electrolytes. If this result alone is accepted as sufficient to confirm the rule:

$$\log c''_{coag} = \text{const.} - 6 \log z \qquad (11)$$

then the evidence given in Table 2 for silver halides in the range up to about 11 *p*I units and the following values on different other sols should be accepted as confirming the linear rule for a larger number of different systems. Other examples which confirm the linear rule by the constancy of a are:

— Au (ref. 12, Table 1) 1·8 ($K^+ - Ba^{2+}$) and 1·8 ($Ba^{2+} - La^{3+}$)

— AgCNS (ref. 13, Fig. 15) 1·53 ($K^+ - Ba^{2+}$) and 1·63 ($Ba^{2+} - La^{3+}$)

— Cross-linked polystyrene (ref. 14, Fig. 5) 0·93 ($K^+ - Ca^{2+}$) and 1·06 ($Ca^{2+} - La^{3+}$)

The discussion of Levine and Bell[10], according to which the linear Schulze–Hardy rule is approximately true only in certain favourable cases at a discrete value for the surface potential (that is at a discrete *p*I value), cannot certainly be valid for the silver halide systems. Figs. 3, 4 and 5 and Table 1 of ref. 15 are an additional experimental argument that this rule may be valid over 9–11 *p*I units and that significant deviation from this rule occur only in the region $p\text{Ag}_{limit}$ to $p\text{Ag}_{limit} + 1$ and log c''_{coag} to log $c''_{coag} - 1$ ($p\text{Ag}_{limit} = p\text{Ag}$ at which the 'isoelectric' coagulation sets in) for ions of valency one and two.

Moreover, not even a qualitative similarity between these experimental plots and the theoretical plots obtained by Levine and Bell can be observed. Comparison made by ref. 10, Figs. 2 and 5, is meaningless since the plots in the equivalency region are poorly defined and because the abscissa values are incorrectly assigned. The maximum on the experimental plots of Fig. 3 is caused by a variation of the log c_{coag} value not greater than 0·2 for monovalent ions and can be attributed to irregularities in the activity factors in higher concentrations. The plots for bi- and tri-valent ions are constant with *p*I showing deviations smaller than 0·05. The corresponding theoretical plots of Levine and Bell are decreasing with decreasing *p*I in the greater part of the negative stability region.

EIGHT CO-ORDINATION IN THE EARLY TRANSITION SERIES

By Dr. R. J. H. CLARK, D. L. KEPERT and Prof. R. S. NYHOLM, F.R.S.
Department of Chemistry, University College, London
AND
Prof. J. LEWIS
Department of Chemistry, University of Manchester

ALTHOUGH a few compounds containing an eight-co-ordinate metal atom have been known for some time, for example, the dodecahedral molybdenum and tungsten octacyanide[1] anions and the square antiprismatic octafluorotantalate[2] ion, it is only recently that the widespread occurrence of this co-ordination number in the early part of the three transition series has been recognized. Many elements display eight-co-ordination by forming polymers in three dimensions, for example, metals with a body-centred cubic lattice or salts having the cæsium chloride structure, but discrete eight-co-ordinate cations, anions or uncharged molecules were very uncommon. However, we reported recently a series of isomorphous monomeric compounds of the general type $MCl_4.2$diarsine[3] (Fig. 1) (where $M = Ti^{IV}$, V^{IV}, Zr^{IV} and Hf^{IV} and diarsine is as shown in Fig. 2) in which the metal atom is eight-co-ordinated.

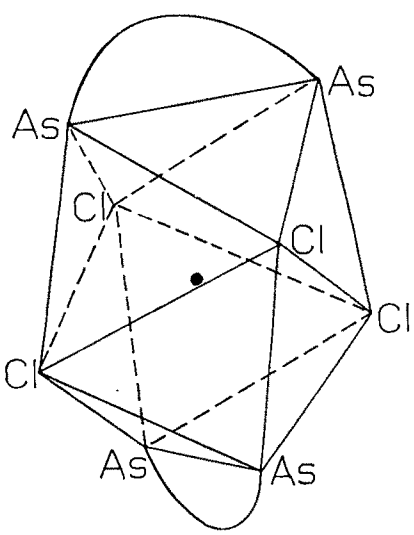

Fig. 1

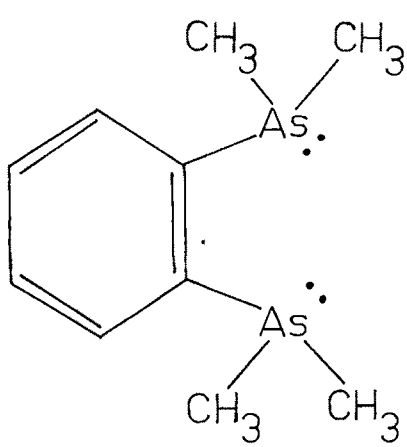

Fig. 2

Titanium[4], zirconium and hafnium tetrabromide[5,6] have since been found to form the iso-structural complexes $MBr_4.2$diarsine. In addition, we have now been able to obtain the corresponding eight-co-ordinate derivatives of niobium tetrachloride and niobium tetrabromide; these are the first magnetically dilute paramagnetic compounds of niobium to be reported.

Some general principles appear to be emerging concerning the formation of these compounds, and it seems timely for us to present a survey of the metals for which eight-co-ordination has been observed and to look for any relationship between the stereochemistry and the nature of the ligand employed.

High crystallographic co-ordination numbers are well known in metals and alloys, where for hexagonal and cubic close packing, there are twelve nearest neighbours and for body-centred cubic close packing, eight (Fig. 3). The co-ordination number is, however, somewhat ill-defined, for in the latter case there is a further set of six next nearest neighbours at a slightly greater distance (15 per cent) away from the metal. Alloys containing an eight-co-ordinated early transition metal include the isomorphous Th_3P_4, Th_3As_4, U_3As_4, U_3Bi_4, U_3Sb_4, and U_3Te_4 (ref. 15) and Th_7S_{12} and Th_7Se_{12} in which half the metal atoms are eight-co-ordinate and half nine-co-ordinate[16].

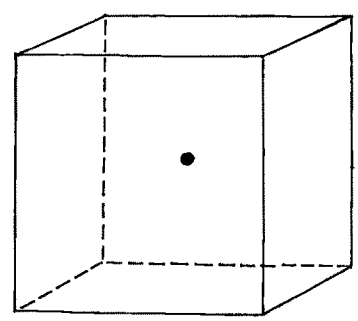

Fig. 3. Body-centred cube

The second general class of compounds exhibiting the crystallographic co-ordination number eight are the ionic crystalline solids. The simplest example is the body-centred cæsium chloride type of compound. The lattice is, of course, three-dimensional without discrete molecules. This structure is found also for CsCN, TlCN, CsSH, TlCl, and for all the rubidium halides at high pressures[18]; it also occurs in the compound ThTe[17]. The other common type of eight-co-ordinate crystalline lattice is that exhibited by fluorite, CaF_2. Those early transition metals having fluorite or distorted fluorite structures include TiH_2, ZrO_2, ZrH_2, HfO_2, $HfH_{1.5-1.75}$, ThO_2, ThH_2, PaO_2, UO_2, UC_2, UN_2 and NpO_2; in addition, the following have a similar structure with eight-co-ordination of both metals: K_2ThF_6, Na_2ThF_6, K_2UF_6, Na_2UF_6 and $CeUO_4$ (refs. 15, 18, 19).

The most extensive class of compounds exhibiting high co-ordination numbers may, broadly speaking, be termed "covalent", and subdivided according as the metal is part of a monomeric unit (Table 1), a finite polymeric unit, or polymerized in one, two or three dimensions (Table 2).

a, dodecahedron; *b*, square antiprism; *c*, hexagonal bipyramid; *d*, $Mo(CN)_8^{4-}$ appears to be square antiprism in solution (20); *e*, eight-co-ordination not definitely established; acacH, acetylacetone; Bz_2CH_2, dibenzoylmethane; O_2^{2-}, peroxide ion; $N(OAc)_3^{3-}$, nitrilotriacetate.

Several different arrangements of the ligands about the central metal atom have been reported for eight-co-ordinate compounds. These are: (1) The body-centred cube, O_h, $m3m$, point symmetry of the metal atom, as shown in Fig. 3. This arrangement is not favoured energetically in covalent compounds (the hybridization scheme necessary for this stereochemistry requires the use of higher-energy *f*-orbitals) but occurs in many metals, alloys and ionic compounds, for example, Th_3P_4 and CsCl, where packing considerations appear to be more important than covalent bond formation. (2) The dodecahedron (Fig. 4) with D_{2d}, $\bar{4}2m$ point symmetry of the metal atom, in which the eight vertices form two interpenetrating tetrahedra about the metal atom, one flattened (atoms *B*) and one elongated (atoms *A*) about the fourfold inversion axis. (3) The square antiprism (Fig. 5) with D_{4d}, $82m$ point symmetry of the metal atom is structurally similar to the dodecahedron. (4) The hexagonal bipyramid (Fig. 6) D_{6h}, $6/mmm$ symmetry; (5) The puckered hexagonal bipyramid (Fig. 7) D_{3d}, $\bar{3}m$ symmetry; (4) and (5) are commonly found in actinide chemistry, but not elsewhere. (6) The triangular prism with an additional group outside two of the square faces (Fig. 8), C_{2v}, mm point symmetry of the metal atom. It occurs in the compound Th_7S_{12}, and is also found in

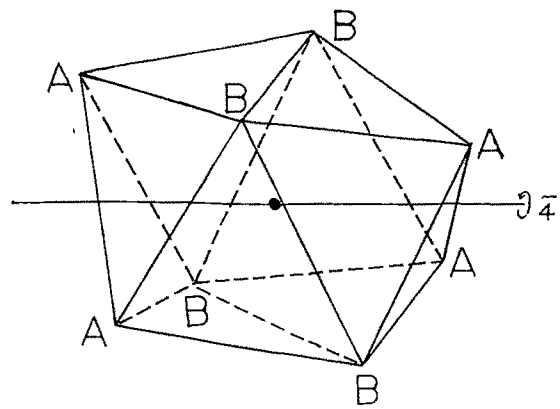

Fig. 4. Dodecahedron

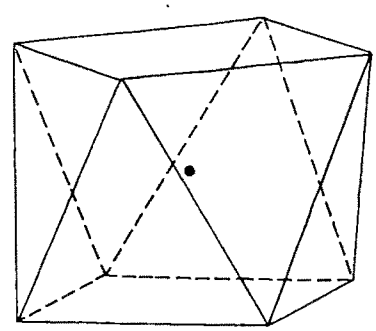

Fig. 5. Square antiprism

compounds having the $PuBr_3$ structure. It could be considered as midway between the dodecahedron and the square antiprism.

It should also be noticed that the puckered hexagonal bipyramid is midway in structure between the hexagonal bipyramid and the cube. Thus, as the puckering angle θ approaches 24°, the structure approaches a cube; in UO_2F_2 for example, it is 14°.

In addition to the foregoing, a number of *cyclo*pentadienyl compounds are known in which the metal can be regarded as being formally eight-co-ordinate if the assumption is made that the π-*cyclo*pentadienyl group (C_5H_5) occupies three co-ordination positions. Examples of this type include $(\pi\text{-}C_5H_5)_2MX_2$, where *M* is Ti, Zr, Hf, V, Mo, W and *X* is halogen, hydrogen, σ-alkyl, σ-aryl or carbon monoxide[46].

In Table 3 are summarized the known complexes of the diarsine with the metal in eight-co-ordination. The niobium complexes are reported here for the first time. Those of the type MX_4,2diarsine (M = metal atom, and X = chlorine or bromine) are all isomorphous and dodecahedral, with the arsenic atoms forming the elongated tetrahedron (atoms A) (Fig. 4) while the halogen atoms form the squashed tetrahedron (atoms B). The niobium complexes of this type were prepared by treating the niobium tetrahalide or pentahalide with excess of the diarsine in sealed tubes at 100° (the pentabromide or tetrachloride) and 200° (the pentachloride). These are green compounds, insoluble in all solvents tried, and paramagnetic with a magnetic moment of about 2 B.M. Satisfactory analytical data have been obtained for these compounds and will be reported in full elsewhere, together with details of their diffuse reflectance spectra and magnetism.

Table 3. EIGHT-CO-ORDINATE DIARSINE COMPLEXES

Group IV	V	VI	VII
[a] $TiCl_4$.2diarsine (3)	[a] VCl_4.2diarsine (3)		
[a] $TiBr_4$.2diarsine (4)			
[a] $ZrCl_4$.2diarsine (3)	[a] $NbCl_4$.2diarsine		[b] $[TcCl_4.2diarsine]^+$ (50)
[a] $ZrBr_4$.2diarsine (51)	[a] $NbBr_4$.2diarsine		
[a] $HfCl_4$.2diarsine (3)	[b] NbI_4.2diarsine		[b] $[ReCl_4.2diarsine]^+$ (49)
[a] $HfBr_4$.2diarsine (51)	[b] WCl_4.diarsine		[b] $[ReBr_4.2diarsine]^+$ (50)

(*a*) Isomorphous dodecahedron; (*b*) Not definitely shown to be eight-co-ordinate, but probably dodecahedral.

For a molecule using d^4sp^3 hybrid bond orbitals, Racah[48] has calculated that the bonds divide into two sets of four (with the representation $2A_1+2B_2+2E$) yielding a dodecahedral stereochemistry. It is interesting to compare the angles predicted for this hybridization scheme, that is, θ_A, θ_B, the angles, respectively, between atoms A, B and the tetragonal axis, with those found experimentally for complexes in which the metal atom is eight-co-ordinated with D_{2d} point symmetry.

	θ_A	θ_B
Calc. for d^4sp^3 hybridization	34·6°	72·8°
$[Zr(C_2O_4)_4]^{4-}$	35·2°	73·5°
$TiCl_4$.2diarsine	36·3°	72·8°
$[ZrF_8]^{3-}$	34·7° and 35·9°	72·1° and 77·2°
$[CrO_8]^{3-}$	43·4°	86·8°
$[Mo(CN)_8]^{4-}$	36·0°	71·8°

Hence, except for the peroxychromate ion, in which the short O–O distance brings about a large distortion from the norm, all known compounds with this stereochemistry form their bonds at angles very close to that predicted for strictly covalent d^4sp^3 hydridization. For the purposes of this article, the peroxy compounds have been regarded as eight-co-ordinate, but the mode of bonding is not known. A distorted tetrahedron of four π-donor peroxy groups also seems possible[56]. For dodecahedral stereochemistry, it is the d_{xy} orbital (B_1 symmetry) which is necessarily excluded from this σ-bonding scheme. (This is the orbital which most effectively avoids the directions of the ligands.) It is thus the most stable orbital, and hence the one in which the single d electron of $[CrO_8]^{3-}$, VCl_4.2diarsine and NbX_4.2diarsine is presumed to lie, leading to magnetic moments close to the spin-only value of 1·73 B.M. In the d^2 complexes $[Mo(CN)_8]^{4-}$, $[W(CN)_8]^{4-}$ and $U(Bz_2CH)_4$, the two d electrons are presumed to pair off in the d_{xy} orbital leading to diamagnetism as observed. Thus the addition of one or two d electrons need not alter the hybridization scheme. Spectral assignments have been made for the octacyanides, but with evident disagreement between different authors[20].

In the square antiprism the representation of the hybrid bonds is $A_1+B_2+E_1+E_2+E_3$ and hence two schemes are possible: either d^4sp^3 hybridization with the d_{z^2} orbital (A_1 symmetry) not included, or d^5p^3 hybridization with the s orbital (A_1 symmetry) left out. For either scheme there is thus a stable orbital available for the accommodation of one or two d electrons, and it is perhaps surprising that the U(IV) compounds are the only known examples of d^1 or d^2 compounds with square antiprismatic stereochemistry.

Calculations by Hoard[22] suggest that there can be little if anything (energetically) to choose between the dodecahedral and antiprismatic structures.

The occurrence of eight-co-ordination in the early part of the transition series is considered to arise from one or more of several causes all acting uniquely in this part of the periodic table in favour of high co-ordination numbers. These are: (*a*) Since the number of non-bonding d electrons is small, there are many vacant d orbitals at least potentially available for covalent bond formation. Where the formation of a complex is dependent on utilizing all nine orbitals, as in simple metal carbonyls or substituted metal carbonyls (five(n-1)d, one ns and three np type), eight-co-ordination is specially favoured for the configurations d^1, for example, V^{IV}, Mo^V, W^V, Re^{VI}, etc., and d^2 (spin-paired), for example, Mo^{IV}, W^{IV}, Tc^V, Re^V. (*b*) The high formal charge on these ions arising from their high

oxidation states, usually +4 or +5, enables the attachment of a large number of ligands to acquire neutrality. (*c*) The relatively smaller overall energy separation between $(n\text{-}1)d$, *ns* and *np* orbitals, for a given oxidation state, at the beginning of the transition series is in marked contrast with that for the corresponding *ns*, *np* and *nd* separation for the metals in the early post transition series. The following figures illustrate this point.

Metal	Ti^{3+}	Zr^{3+}	Hf^{3+}	Si^{3+}
Electron transition	$3d' \rightarrow 4p'$	$4d' \rightarrow 5p'$	$5d' \rightarrow 6p'$	$3s' \rightarrow 3d'$
Promotion energy (eV)	15·9	10·2	8·4	19·8
4th ionization potential	43·3	34·4	33·3	45·3
Sum of first four ionization potentials	91·5	77·5	78·0	103·0

Metal	Ge^{3+}	Sn^{3+}	Pb^{3+}
Electron transition	$4s' \rightarrow 4d'$	$5s' \rightarrow 5d'$	$6s' \rightarrow 6d'$
Promotion energy (eV)	23·7	21·2	22·8
4th ionization potential	45·3	40·8	42·2
Sum of first four ionization potentials	103·5	93·5	96·5

These figures offer a reasonable explanation for the fact that the quadrivalent post transition halides, for example, $SnCl_4$, do not form eight-co-ordinate complexes readily as do the halides of Ti, Zr, and Hf.

It appears that for early transition metals having discrete eight-co-ordination the choice of stereochemistry lies mainly between the dodecahedron and square antiprism. The more polarizable ligands (for example, cyanide, diarsine and peroxide) appear to form the dodecahedral structure, whereas the less polarizable ligands (for example, fluorine and acetylacetone) seem to prefer the square antiprism arrangement. This correlation is purely tentative as it relates only to a very limited number of experimental data.

The ability of the diarsine to form eight-co-ordinate complexes with titanium and vanadium is remarkable, especially as the bidentate ligands $\alpha\alpha'$-dipyridyl, *o*-phenanthroline[52] and *o*-phenylene bisdiethylphosphine[47] have failed to do so. Whether the reason for this lies in the stereochemistry of the ligand, which seems unlikely, or in the nature of the donor arsenic atoms is a matter which cannot be decided at present.

ENERGETICS OF ION MOLECULE REACTIONS IN ALKANES

By Dr. LARRY KEVAN

Department of Chemistry, King's College, Newcastle upon Tyne

THE energetics of ion molecule reactions are of interest in the radiation chemistry of hydrocarbons since they may provide a guide to those ion molecule reactions which are most likely to occur. Williams[1] has calculated that in low-molecular-weight alkanes the parent ion radical may undergo energetically favourable dimerization and olefin formation reactions even in the liquid phase and concludes that such reactions may also be important in long chain alkanes. Libby[2] has considered the general principles of the chemistry of such ions and postulates dimer formation for both the parent ion radical and the parent carbonium ion in alkanes and polyethylene. However, Barker[3] presents calculations on alkanes which he interprets to mean that dimerization reactions of the carbonium ion are unlikely in molecules of more than three carbons.

This article presents a consistent set of heats of formation for alkane ions and shows that the heats of reaction of various ion molecule reactions reach a limiting value $\leqslant 0{\cdot}5$ eV. This suggests that these reactions are not energetically prohibited in long chain alkanes.

Heats of formation. The heats of formation of alkane ions are given in Tables 1 and 2. The values for the parent ions were obtained from the measured ionization potentials (IP) and the other experimental values were determined from the appearance potential (AP) of the ion as

measured up through the butyl radicals, but at th[illegible] in the series the radical ionization potentials conver[illegible] constant value. This rapid convergence was found [illegible] follows. The alkyl radical ionization potentials can be calculated by the group orbital method[9] as simplified by Franklin[10]. Each carbon atom is assumed to have a pseudo-π-orbital which contains two 'mobile' electrons except for the radical carbon, which has only one. The linear combination of atomic orbitals method is then used to obtain the secular equation where one atomic orbital is associated with each CH_2 group, and the necessary coulomb and exchange integrals are determined empirically. The energy of the highest filled energy level is identified with the ionization potential. Using the ionization potentials for methane, ethane and methyl radical[4] as parameters, the secular equations were solved on an IBM 7090 computer for the normal, iso, secondary and tertiary radicals having up to twelve carbons. It was found that the radical ionization potentials converged to a constant value for each structural type at the butyl radicals. Thus the values measured for the butyl radicals can be used for the higher alkyl radicals. A similar convergence is well known for the ionization potentials for the *n*-alkanes, but it does not occur until *n*-dodecane. Whenever these constant values are reached, the heats of formation of the ions in Tables 1 and 2 vary only with the heats of formation of the associated alkanes and therefore decrease by 5 kcal/mole for each successive carbon atom. The convergence of the ionization potentials means that the reactions discussed below will reach a limiting heat of reaction for a certain chain-length.

Table 1. Heats of Formation of Alkane Ions at 25° C in kcal/mole

n-Alkanes		iso-Alkanes		Protonated Alkanes	
CH_4^+	285			CH_5^+	180*
$C_2H_3^+$	249			$C_2H_7^+$	(175)
$C_3H_3^+$	234			$C_3H_9^+$	(170)
n-$C_4H_{10}^+$	219	iso-$C_4H_{10}^+$	212	$C_4H_{11}^+$	(165)
n-$C_5H_{12}^+$	208	iso-$C_5H_{12}^+$	196	$C_5H_{13}^+$	(160)
n-$C_6H_{14}^+$	202	iso-$C_6H_{14}^+$	188	$C_6H_{15}^+$	(155)
n-$C_7H_{16}^+$	194				
n-$C_8H_{18}^+$	186				
n-$C_9H_{20}^+$	180				
n-$C_{10}H_{22}^+$	175				

* Calculated from the proton affinity of $CH_4 = 7{\cdot}26$ eV (ref. 11). Extrapolated values in brackets; other values are experimental (ref. 4).

Table 2. Heats of Formation of Alkane Carbonium Ions at 25° C in kcal/mole

Ion formula	*n*-Alkyl ion		*sec*-Alkyl ion		iso-Alkyl ion		*t*-Alkyl ion	
	Exptl.	Calc.	Exptl.	Calc.	Exptl.	Calc.	Exptl.	Calc.

Experimental values from ref. 5; calculated values, see text.

	1	2	3	4	5	6	7	8	≥9
1	−18	3	3	7	12	13	13	13	13
2		−10	−6	3	6	4	6	9	9
3			−7	0	3	3	6	9	10
4				−3	2	3	6	9	10
5					2	3	6	9	10
6						3	6	9	10
7							6	9	10
8								9	10
≥9									10

If the product ion in reaction (1) isomerizes the heats of reaction are all decreased by about 10 kcal/mole. This statement also applies to those reactions tabulated later:

Condensation with molecular splitting:

$$n - C_nH_{2n+2}^+ + n - C_mH_{2m+2} = n - C_{n+m-p}H_{2(n+m-p)+2}^+ + n - C_pH_{2p+2} \quad (2)$$

Limiting value of $\Delta H_{\text{reaction}(2)} = -3$ kcal/mole for $p = 1$; 0 kcal/mole for $p \geqslant 2$

Olefin formation:

$$n - C_nH_{2n+2}^+ = 1 - C_nH_{2n}^+ + H_2 \quad (3)$$

Limiting value for $\Delta H_{\text{reaction}(3)} = 14$ kcal/mole

$$n - C_nH_{2n+2}^+ = \textit{trans} - 2 - C_nH_{2n} + H_2 \quad (4)$$

Limiting value for $\Delta H_{\text{reaction}(4)} = 3$ kcal/mole

Hydrogen atom transfer:

$$n - C_nH_{2n+2}^+ + n - C_mH_{2m+2} = C_nH_{2n+3}^+ + n - C_mH_{2m+1} \quad (5)$$

Limiting value for $\Delta H_{\text{reaction}(5)} = 5$ kcal/mole.

Parent carbonium ion reactions: dimerization:

$$n - C_nH_{2n+1}^+ + n - C_mH_{2m+2} = n - C_{n+m}H_{2(n+m)+1}^+ + H_2 \quad (6)$$

The various limiting values are given in Table 4.

For iso, secondary, or tertiary product ions in equation (6) the heats of reaction in Table 4 are lowered by 9, 21, and 38 kcal/mole respectively.

Condensation with molecular splitting:

$$n - C_nH_{2n+1}^+ + n - C_mH_{2m+2} = n - C_{n+m-p}H_{2,n+m-p)+1}^+ + n - C_pH_{2p+2} \quad (7)$$

Limiting value for $\Delta H_{\text{reaction}(7)} = -3$ kcal/mole for $p = 1$; 0 kcal/mole for $p \geqslant 2$

here are energetically important in systems of [illegible] radiation chemistry. If the product ion isomeriz[illegible] reactions for any chain length are thermoneutra[illegible] exothermic, and even if no isomerization occurs [illegible] maximum endothermicity of 10 kcal/mole may easily be overcome by the excitation energy of the ion. Stevenson and Schissler[12] have recently considered the average excitation energy of an ion formed in mass spectrometry and show that an average excitation energy of 3 eV (69 kcal/mole) is quite reasonable.

Examples of many of the foregoing reactions have been observed by mass spectrometry[13] for lower molecular

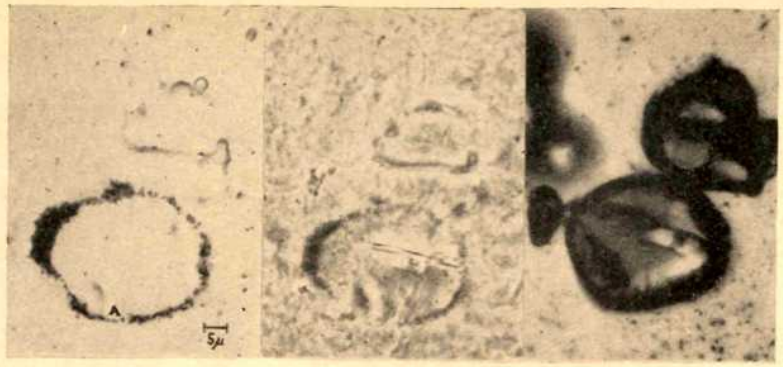
RECENT ADVANCES IN CYCLOL CHEMISTRY

By Dr. DOROTHY WRINCH

Smith College, Northampton, Mass.

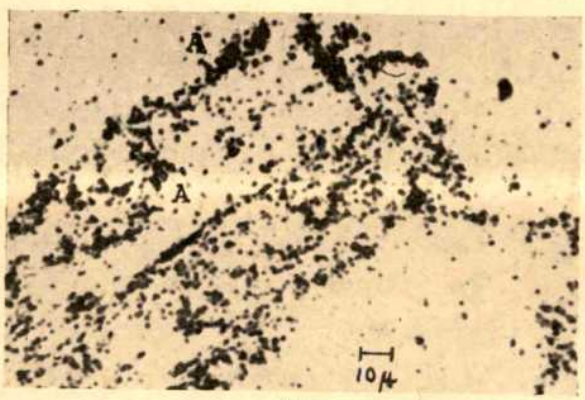
ACCORDING to the amide hypothesis, the amino-acid components of peptides are united solely in acid amide groupings. According to the cyclol hypothesis[1,2], which depends essentially on the reactivity of amide groupings in peptides, the amino-acid components are united not only in the acid amide or one-bond peptide groupings, but also in the multiple peptide or cyclol groupings:



in which Z = NH, O, S. Generalizing the classical hypothesis in this way raises two crucial issues which, in the main, are expressions of the labile character of the cyclol groupings, a matter which has been under investigation ever since the original formulation of the cyclol hypothesis in 1936 [3–5]. (*A*) What are the types of atomic architecture within which cyclol groupings attain conditioned stability and to what structural features of these architectural types may their stabilizing influence be attributed ? (*B*) What types of labile bonds are expected in the cyclol system, and of what nature are the rearrangements, or syntheses and cleavages, of peptides which result from the formation of 'intermediates' containing such bonds ?

In this communication I am considering the cyclol syntheses recently announced. These are examined in the setting provided by the body of organic chemical findings which demonstrate the reactivity of the amide grouping in peptides when it is attacked at its nitrogen atom by an electrophilic reagent or at its carbonyl group by a nucleophilic reagent[6–12]. We conclude that a beginning can now be made in the systematic exploration of both these issues, making use of model molecules of simple kinds.

The researches of Stoll *et al.*[13], which prepared the way for most of the cyclol syntheses, showed that the ergot alkaloids, namely, the compounds (1) in Fig. 1, with *R*— = lysergyl—NH—, contain the three-bond cyclol grouping —(—O—)C(OH)—(—CO—)N— within their tripeptide moiety. Corresponding to the two degenerations by proton migration of this surely very labile grouping, to —OH, —CO—(—CO—)N— or to —O—CO—, —CO—NH—, the alkaloids would degenerate into the N-substituted diketopiperazine shown on the left of (1) or into the lactone peptide which had been adopted as the correct structure until 1951 shown on the right. Both these structures, related to the cyclol structure by proton migration and indicating alternative paths to its synthesis proved to be of significance in a recent discussion of the heat of formation of cyclol groupings (ref. 1, pp. 133–4, 179–81) in which stress was laid on the need to consider the non-bonded energy terms following the precedents set in various simpler cases[14].



(*a*) In May 1961, Hofmann *et al.*[15] announced the synthesis of the ergotamine tripeptide, namely, the structure (1) with $R = NH_2$, R_1 = Me, $R_2 = CH_2Ph$. This, the first cyclol synthesis to be reported, proceeded by way of an *N*-acyl derivative of [L-phenylalanyl-L-prolyl-]diketopiperazine.

During 1962–63, Shemyakin *et al.*[16], Antonov *et al.*[17,20], Jones *et al.*[18], and Sheppard[19] announced cyclol syntheses which were confirmed by infra-red spectra, including the following: (*b*) Synthesis of 'ergotamine analogue'[16]

Fig. 2

particles, resolution is limited to 3–5μ and is much worse for radioisotopes emitting particles of higher energy. A similar resolution can be obtained from very flat specimens using contact autoradiography and very dry conditions, but as resolution depends critically on the closeness of contact between the specimen and the emulsion the resolution achieved in a particular autoradiograph can be uncertain. The technique described in this article uses a film consisting of a single layer of sensitive silver bromide crystals at the surface of a plastic film. The film is softened in an organic solvent and applied to the specimen. As the solvent evaporates the film conforms to the surface and, when hard, forms a replica of the surface topography. After exposure the film is stripped from the specimen and developed. As the plastic is unaffected by water, the final autoradiograph retains a replica of the specimen surface. For use on the most highly reactive specimens a thin (about 0·3μ) supercoat of a second plastic is applied on top of the silver bromide. This is removed before development in a second non-polar solvent which does not affect the backing plastic. A supercoat of this thickness would not protect silver bromide in contact with a reactive specimen in the presence of water, for example, during *in situ* development.

To prepare a film a microscope slide is coated with silver by vacuum evaporation and converted to silver bromide in bromine vapour. The silver bromide grain size varies with the surface density of silver evaporated and with the conditions of bromination. A resolution of 1μ requires grains $< 0{\cdot}3\mu$ in diameter. As the effective sensitivity tends to increase with increasing grain size, conditions were selected which gave grains of approximately 0·3μ diameter. The silver bromide layer is backed with polyvinyl formal ('Formvar') applied from a 5–10 per cent dioxan solution. A backing about 10 microns thick has been found satisfactory. If the backing is too thin the film is difficult to handle; if it is too thick it does not soften satisfactorily and takes too long to harden on the specimen. The supercoat is prepared separately on a second slide. It is a 0·3μ thick layer of polyisobutylene prepared by dipping the slide in a solution of polyisobutylene in toluene and spinning horizontally until dry. The silver bromide/'Formvar' film is stripped from its slide, softened with methyl ethyl ketone, and applied to the supercoat. Controlled water treatment has been found to sensitize the silver bromide. The film can be sensitized by adding 80–90 per cent water to the methyl ethyl ketone. After drying the film is ready for use.

To take an autoradiograph, a portion of film is carefully stripped from the slide, dipped in pure methyl ethyl ketone, applied to the specimen and dried quickly. The exposure is made in a desiccator containing silica gel. After exposure the film is stripped from the specimen, washed in toluene or carbon tetrachloride to remove the supercoat, developed in 'Promicrol', and fixed in hypo.

Faint images can be located by examining the replica dry or mounted in glycol at low magnification. For examination at the highest resolution the autoradiograph is mounted in oil. The replica can then best be examined using phase contrast.

Fig. 1 shows an autoradiograph, replica, and micrograph of zinc sulphide crystals. The surfaces of some of the crystals had been coated with a tritium-containing polymer. The crystals were mounted in 'Araldite' and sectioned. The autoradiograph (*a*) shows that only one of the two crystals appearing in the micrograph (*c*) was tritium-coated. The replica (*b*), viewed using phase contrast, shows both crystals. Fig. 2 shows an autoradiograph (*a*) and micrograph (*b*) of a specimen of steel containing carbon-14. The steel was heat-treated to give a coarse pearlitic structure. As the specimen was a thick one carbon-14 within about 10μ of the surface contributed to the image and this reduced the resolution.

The plastic film technique described gives a resolution of better than 2μ with tritium *A* (Fig. 1) and 3–4μ with carbon-14 *A* (Fig. 2) and sulphur-35. Autoradiographs can be obtained free from chemical artefacts on surfaces as reactive as magnesium. The replica of the surface on the autoradiograph assists its interpretation. A number of autoradiographs can be taken from one specimen and a flat specimen surface is not required.

We thank D. E. Glanville and C. S. Lees for their help in this work.

SOME UNUSUAL OBSERVATIONS IN A COMPARISON OF LIQUID AND SOLID PHASE AUTOXIDATION

By A. T. BETTS and Dr. N. URI

Ministry of Aviation, Explosives Research and Development Establishment, Waltham Abbey, Essex

As a rule autoxidation research in the past has been confined to pure liquids being used as model substances such as methyl linoleate, tetralin, cyclohexene, etc., or composite solids such as lard, butter, rubber and a variety of polymers, but the information available concerning the autoxidation of well-defined pure solids is negligible. In an attempt to simulate polyethylene which, in practice, always has some residual double bonds, purified, peroxide-free docosane ($C_{22}H_{46}$; m.p. 44° C) and docos-1-ene ($C_{22}H_{44}$; m.p. 41° C) were selected as model substances. These hydrocarbons can be investigated at convenient temperatures both in the solid and in the liquid phase when autoxidation is induced by added metal catalysts or by ionizing radiations. Docos-1-ene has not only the additional advantage of readily measurable rates of autoxidation but has also, in common with all alk-1-enes, a single α-methylenic carbon atom with a weakened C . . . H bond. The preferential attack leads to a single product in the early stages of autoxidation thus facilitating a kinetic investigation. First it was established that the order of magnitude of the rates of autoxidation of alk-1-enes, as measured by oxygen uptake and hydroperoxide formation, did not vary with the chain length when the number of carbon atoms was $\geqslant 16$. Hexadec-1-ene (m.p. 4° C) and docos-1-ene were found to be particularly suitable for a comparison of liquid and solid phase autoxidation.

The following results indicate that *ceteris paribus* autoxidation proceeds more rapidly in the solid phase than in the liquid phase. Table 1 shows the results for γ-ray induced autoxidation with liquids, solidified melt and crystalline powders. The differences are best interpreted as due to a sharp reduction in the solid phase of the diffusion-controlled rate of termination by free radical recombination ($RO^{\bullet}_2 + RO^{\bullet}_2 \rightarrow$ products) in comparison with the rate-determining propagation reaction ($RO^{\bullet}_2 + RH \rightarrow ROOH + R^{\bullet}$), where $RO^{\bullet}_2$ reacts with the substrate itself. The latter reaction being largely dependent on the activation energy is expected to proceed at only a slightly reduced rate in the solid phase. The results presented in Table 1 made it apparent, however, that oxygen diffusion was also a significant superimposed factor under these conditions. Hence experiments were carried out with thin films of docos-1-ene on silica tubing and gold foil (Table 2). The reproducible rate of hydroperoxide formation was found to be independent of film thickness in the range of four to thirty microns. This suggests that oxygen diffusion was no longer a significant factor under these conditions. However, this rate, which in the early stages of autoxidation is proportional to dose, was found to be dependent on the nature of the surface on which the docos-1-ene film was deposited. Conceivably some surface-catalysed radical recombination occurs. From a quantitative point of view it is noteworthy that the rate of autoxidation of the solid docos-1-ene film on gold foil is about thirty times that of liquid hexadec-1-ene under the conditions of the experiment.

After finding that the recently discovered *N*-butyl salicylaldimino cobalt (II) complex[1,2] was an efficient autoxidation catalyst, use was made of this compound for a comparison of metal-catalysed liquid and solid phase autoxidation. The experimental findings recorded in Fig. 1 were similar, in principle, to those in γ-ray induced autoxidation. The catalyst was incorporated into the solid docos-1-ene by dissolving it in the molten hydrocarbon and grinding the solidified melt into a fine powder.

Table 1. Hydroperoxide Formation in γ-Ray Induced Autoxidation of Hydrocarbons at 25° C
(Dose rate = 0·21 megarad/h, dose = 4·7 megarad)

Hydrocarbon	P.V. *ROOH* formed (μmol/g)	G(*ROOH*) = P.V./0·96 g megarad
Hexadecane ($C_{16}H_{34}$) (liquid)	7·5	1·7
Hexadec-1-ene ($C_{16}H_{32}$) (liquid)	9·5	2·1
Docosane ($C_{22}H_{46}$) (crystalline powder)	19·2	4·3
Docos-1-ene ($C_{22}H_{44}$) (crystalline powder)	101	22·4
Docos-1-ene ($C_{22}H_{44}$) (crystalline mass of solidified melt)	41	9·1

Table 2. Gamma-ray Induced Autoxidation of Docos-1-ene Films

Film deposit on	Weight of film (mg)	Thickness of film (μ)	Time of irradiation (h)	Dose (megarads)	P.V. (μmoles *ROOH*/g)	G(*ROOH*) = P.V./0·96 g megarad
Gold foil	12·25	14	17·5	3·73	240	64·1
Silica tube	143·5	26			171	45·7
Gold foil	3·71	4·1	23·75	5·06	318	62·6
Silica tube	129·1	21·5			214	42·1

Furthermore, the apparently uncatalysed autoxidation, which according to one of us[3] should be regarded as trace-metal catalysed, exhibited similar features. While the rate of hydroperoxide formation with hexadec-1-ene drops by a factor of approximately ten between 50° C and 25° C, the rate with solid powdered crystalline docos-1-ene stored in air was found at 25° C to be almost identical with that measured at 50° C when the hydrocarbon is liquid (that is, 8 μmol hydroperoxide/g docos-1-ene/month). When peroxide-free docos-1-ene was stored at 7° C for three months the amount of peroxide formation was found to be 5 μmol/g, indicating a temperature dependence in the solid phase similar to that in the liquid phase. All peroxide values were measured iodometrically[4].

This anomalous aspect of autoxidation would explain the lower than expected stability of many solid materials.

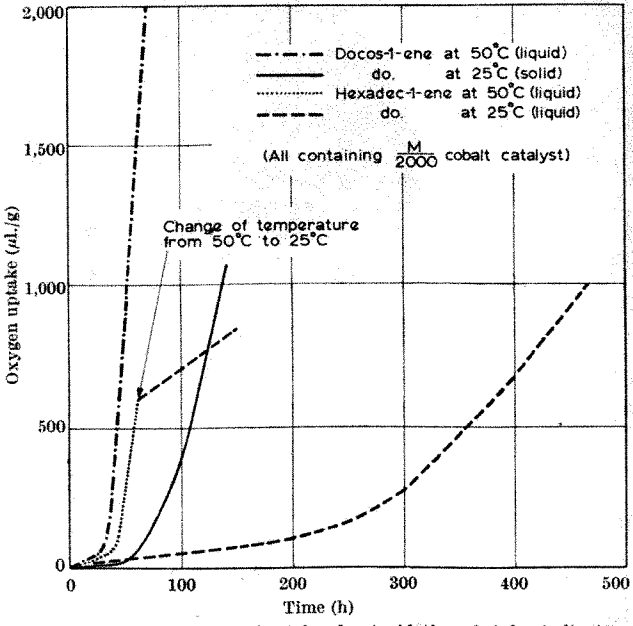

Fig. 1. Comparison of metal catalysed autoxidation of olefins in liquid and solid states

It also sheds some light on earlier observations[5,6] on the effect of ionizing radiations on butter-fat where a maximum rate of hydroperoxide formation was obtained at −20° C. Presumably at higher temperatures butter-fat is behaving more like a liquid and in this case, too, the most likely explanation of the anomalous temperature effect is not to be found in a changed rate of hydroperoxide decomposition but in a sharply reduced rate of $RO'_2 + RO'_2$ termination in the solid phase.

Work is also proceeding on the effect of crystal size and structure on the rate of autoxidation and it is hoped to publish a more detailed account elsewhere.

A COMPARISON OF THE DISACCHARIDES OBTAINED FROM HUMAN BLOOD-GROUP A, B, H AND Le^a SUBSTANCES BY PARTIAL ACID HYDROLYSIS

By Dr. T. J. PAINTER, Mrs. VAIJAYANTI P. REGE and Prof. W. T. J. MORGAN, C.B.E., F.R.S.

Lister Institute of Preventive Medicine, Chelsea Bridge Road, London, S.W.1

ATTEMPTS to correlate the chemical fine structures of the A, B, H and Le^a human blood-group substances with their serological specificities have been undertaken in a number of laboratories[1,2] and recently several di- and tri-saccharides have been obtained from these materials by partial acid hydrolysis[3–6]. The results of these investigations, together with the experimental findings now described, establish that four disaccharides are common to the partial acid hydrolysates of all four substances. It is also established that the serologically A-active disaccharide, 3-*O*-(*N*-acetyl-α-D-galactosaminopyranosyl)-D-galactose, already identified as a hydrolysis product of A substance[3], is not present in the acid hydrolysis products of B, H or Le^a substances, and that the B-active disaccharide, 3-*O*-α-D-galactopyranosyl-D-galactose, obtained earlier from B substance[4], is absent from the hydrolysis products of A, H and Le^a substances.

The specific substances examined were obtained from human ovarian cyst fluids[2,7], and appeared to be essentially homogeneous in the analytical ultracentrifuge and on free-boundary electrophoresis. The four substances (A, 4·5 g; B, 3·6 g; H, 2·7 g; and Le^a, 2·7 g) were hydrolysed separately with polystyrenesulphonic acid, as described earlier[8], and the yield of mono- and oligo-saccharides represented, in each experiment, about 80 per cent of the weight of the starting material, equivalent to about 95 per cent of the total carbohydrate.

The four hydrolysates were fractionated separately on columns (about 3 × 20 cm) of charcoal–Celite (1 : 1 w/w) by successive elution with water and 1·5, 2·5 and 5 per cent (v/v) aqueous ethanol respectively. When necessary, the materials obtained were further fractionated by preparative paper chromatography, or on small charcoal–Celite columns.

Each hydrolysate contained the same four monosaccharides, L-fucose, D-galactose, *N*-acetyl-D-glucosamine and *N*-acetyl-D-galactosamine. Four disaccharides were also common to all four hydrolysates, and were identified as (1) 3-*O*-β-D-galactopyranosyl-*N*-acetyl-D-galactosamine, (2) 3-*O*-(*N*-acetyl-β-D-glucosaminopyranosyl)-D-galactose, (3) 3-*O*-β-D-galactopyranosyl-*N*-acetyl-D-glucosamine and (4) 4-*O*-β-D-galactopyranosyl-*N*-acetyl-D-glucosamine, respectively. In addition, the hydrolysates of A and B substances contained, respectively, the A-active disaccharide[3] and the B-active disaccharide[4] described earlier. The hydrolysates of H and Le^a substances did not appear to contain appreciable amounts of disaccharides other than the four (1–4) already named.

Disaccharide 1 was obtained crystalline from each blood-group substance, and was identified by comparison with the preparation of this disaccharide already isolated from A substance[5]. Disaccharides 3 and 4 were also obtained crystalline from each hydrolysate, and were identified by comparison with authentic specimens kindly provided by Prof. R. Kuhn and Prof. P. György, respectively.

A disaccharide, tentatively given the structure of disaccharide 2, was isolated from A substance by Côté and Morgan[3]. This structure has now been confirmed for a disaccharide which has been isolated from all four blood-group substances. Disaccharide 2 was obtained as a colourless syrup, having $[\alpha]_D^{22} = +33{\cdot}5°$ in water. Chromatography of acid hydrolysates of the disaccharide showed that glucosamine and galactose were present, and analysis by the Elson–Morgan[9] and phenol-sulphuric acid[10] methods indicated that these sugars occurred in approximately equimolar proportions. After reduction of the disaccharide with sodium borohydride[11], the galactose content was negligible, whereas the hexosamine content was essentially unchanged.

Disaccharide 2 (12 mg) was oxidized in 0·01 M sodium metaperiodate (50 ml.) at 22°. In the initial rapid phase of oxidation, which was complete in about 5 h, 2·2 moles/mole of periodate were consumed, and 0·4 mole/mole each of formic acid and formaldehyde were liberated. Oxidation under the same conditions, after reduction with borohydride[12], resulted in immediate liberation of 2·0 moles/mole of formaldehyde, followed by rapid over-oxidation.

Oxidation of disaccharide 2 to the corresponding aldobionic acid with bromine water, followed by mild oxidation with sodium metaperiodate under the conditions recommended by Clancy and Whelan[13], failed to liberate glyoxylic acid. The same behaviour was observed with authentic (1 → 3)-linked disaccharides of similar type, whereas authentic (1→4)-linked disaccharides readily afforded glyoxylic acid under the same conditions. That disaccharide 2 was (1→3)-linked was also suggested by the similarity of its rate of degradation by alkali, determined colorimetrically[14], to that of known (1→3)-linked disaccharides, and by its capacity to form a methyl glycoside under conditions leading to selective formation of methyl glycofuranosides (that is, in cold, 1 per cent w/w methanolic hydrogen chloride). On the basis of these observations, disaccharide 2 is considered to be 3-*O*-(*N*-acetyl-β-D-glucosaminopyranosyl)-D-galactose, a disaccharide first isolated by Kuhn and Baer[15] from human milk.

The relative amounts of the disaccharides (1–4) in the hydrolysates of the four group substances differed appreciably. The significance of this observation is uncertain, since it is not yet known whether the hydrolysis products obtained from different mucopolysaccharide preparations,

having the same specificity, would show a similar variation in composition.

Very small amounts of disaccharides, other than those just described, were present in the four hydrolysates, but it is doubtful at present whether significance should be attached to them, since these small amounts could have arisen as artefacts produced by the acid-reversion of monosaccharides. This possibility has already been suggested[16] for the disaccharide, 6-*O*-α-L-fucosyl-*N*-acetyl-D-glucosamine, obtained from the acid hydrolysis products of A substance[3].

The failure to isolate significant amounts of fucose-containing disaccharides in the present work reflects the extreme sensitivity to acid of the fucosidic linkages in the blood-group substances. The L-fucose residues, which are almost certainly attached as terminal, non-reducing branches to the main carbohydrate chains in the specific substances are, in our experience, split off rapidly and almost completely in the early stages of acid hydrolysis, before the galactosidic and hexosaminidic linkages are appreciably cleaved.

The disaccharides (1–4) had no detectable A, B or Le^a activity. Disaccharide 4 has already been shown to possess *Pneumococcus* type XIV activity[17], and disaccharide 2 inhibits the agglutination of O cells by *Cytisus sessilifolius* and *Laburnum alpinum* seed agglutinins[18], but does not inhibit[19] other anti-H reagents. However, since the results of enzymatic decomposition experiments[20] and enzymatic[21] and serological[18,22] inhibition studies indicate that L-fucose residues play an important part in H and Le^a specificity, the fucose-free fragments obtained by acid hydrolysis cannot be expected to provide evidence in support of this conclusion. An alternative method of degrading specific substances that gives good yields of fucose-containing fragments has now been developed, and the products will be described later.

In the present work, the demonstration that four disaccharides are common to the partial acid hydrolysates of A, B, H and Le^a specific substances strongly supports a view expressed earlier[2], that there is a close similarity in the general structural pattern of these serologically active mucopolysaccharides. The present findings are also consistent with a scheme for the biosynthesis of the blood-group substances proposed by Watkins[23] and later extended[24], in which it is envisaged that a precursor substance is common to all individuals, and that the specific blood-group characters arise from the addition, by genetically-determined enzymes, of single, non-reducing terminal sugar units to the carbohydrate chains in the precursor substance.

We thank Dr. W. M. Watkins for the serological examination of the disaccharides in inhibition tests, and for much valuable discussion. This work was supported by a grant from the Medical Research Council.

A TUMOUR-INHIBITORY FACTOR IN THE POST-COITAL UTERINE FLUID

By Dr. RACHEL STEIN-WERBLOWSKY

Department of Physiology, Royal Veterinary College, London, N.W.1

IN previous investigations it has been shown that tumour cells transplanted into the uterine horn of rats grow well at that site irrespective of the phase of the cycle. However, I have already shown that the tumour cells fail to grow in a large percentage of animals if inoculated within 18 h after mating[1,2].

This article is an attempt to ascertain the factors responsible for this inhibition.

White Wistar rats weighing 150 g were obtained commercially and fed on 'Diet 41' and water *ad lib.* The tumour used was one induced by benzpyrene in the uterus. Suspensions were prepared by mixing one volume of tumour with 1·5 volumes of saline. 0·2 ml. of this suspension was injected into the uterine horn and a ligature placed above the injection site to prevent escape of the inoculum. Unfortunately, escape of some tumour cells on withdrawal of the needle could not always be prevented, with the result that extra-uterine growth sometimes developed.

To effect matings, female rats were placed in cages with males at 5 p.m. and removed the next day at 9 a.m. The following criteria were utilized to ascertain whether coitus had occurred: (1) the presence of a vaginal plug; (2) the presence of spermatozoa in uterus or vagina; (3) the presence of a hæmorrhagic discharge at the vulva (sign of evacuation of uterine contents); (4) the presence of embryos.

Several hours after mating there is an accumulation of purplish fluid in the uterus, varying from 0·1 to 1·0 ml. in amount. For the *in vitro* experiments this fluid was withdrawn and mixed with varying amounts of tumour suspension.

Spermatozoa were obtained by mincing testes and epididymes of a male rat in 1·0–5·0 ml. saline.

The viability of the treated tumour cells was assessed by intraperitoneal or subcutaneous injections into weanling rats as in Exps. 2 and 3.

Exp. 1. Tumour suspensions were inoculated into the uterine horns of young virgin rats (controls) and into the uterine horns of animals mated within the preceding 16 h. Preliminary investigations of the virgin controls had shown microscopic evidence of implantation of tumour

cells as early as 2·5 h after intra-uterine inoculation. Moreover, uterine lavage 3 h after tumour injection failed to inhibit tumour growth.

It seems likely that all mated rats have an accumulation of uterine fluid at some stage. Probably this is maximal 6–10 h after mating, and this fluid remains in the uterine horn for a short period, after which it is evacuated. The best result in respect of tumour inhibition is obtained if the tumour is inoculated into the horn during the period when it is full of fluid, as evidenced by the results of Table 1. The results with the remaining 45 rats, in which no fluid or little fluid was present at inoculation, are given in Table 1*A*.

Table 1. Intra-uterine Inoculation of Tumour Suspensions into Mated Rats with Copious Post-coital Fluid, and into Virgin Females

Experimental		Controls	
Mated females with copious post-coital fluid		Virgins	
T+	*T*−	*T*+	*T*−
2* (8%)	23 (92%)	38 (88%)	5 (12%)

* Tumours at site of inoculation only.
T+, tumour growth; *T*−, tumour inhibition, that is, no tumour growth.

Table 1*A*. Intra-uterine Inoculation of Tumour Suspensions into Mated Rats having Little or No Intra-uterine Post-coital Fluid

Condition of uterus				Other evidence of mating					
Little post-coital fluid		Fluid evacuated spontaneously or artificially		Mated 20 min previously		Plug but no fluid		No evidence of mating until embryos found 10 days later

5	10	9	5	3	1	2	4	6	0

From a comparison of the Tables 1 and 1*A* it is clear that the presence of fluid is an important factor in inhibiting tumour growth.

Another factor affecting the inhibition was the length of time between mating and inoculation. In animals known to be mated within 20 min prior to tumour inoculation there was no apparent inhibition, whereas in those in which the interval was longer, inhibition was observed. It thus appears that tumour inhibition will only occur if the tumour is implanted more than 20 min after mating. Whether this inhibition is due to an alteration in the receptivity of the endometrium or to an oncolytic property of the post-coital fluids was tested by exposing tumour cells to uterine environments of various types.

Exp. 2. In this experiment the uterine contents of animals, treated with tumour as in Exp. 1, were evacuated and re-inoculated intraperitoneally or subcutaneously into weanling rats (Table 2) thus producing tumours at the site of inoculation. The tumours of the control recipients (that is, those receiving re-inoculations from virgin females) were larger than those of the experimental group. A minimal period of exposure of the tumour cells to the uterine environment was required before the cells lost their viability and transplantability.

Since the free tumour cells appeared to be inactivated by the post-coital uterine fluid *in vivo*, the possibility of an *in vitro* inactivation was then investigated.

Table 2. Aspiration of Uterine Contents from the Animals as in Tables 1 and 1*A* 6 h after Inoculation. Re-inoculation into Weanling Rats

Contents of donor uterus (mated rats)								
Copious fluid + tumour			Little or no fluid + tumour			Virgin + tumour

10	1	25	3	15	16	2	25	4

D, died.

Exp. 3. In a series of preliminary experiments it has been established that tumour cells retain their viability and transplantability for up to 18 h *in vivo* and up to 24 h *in vitro*. Tumour suspensions were mixed with varying concentrations of post-coital fluid for varying periods of time (2–6 h). The results for 2- and 6-h exposures are shown in Table 3, which suggests that the post-coital uterine fluid retains its anti-tumour activity *in vitro*—but that it must remain in contact with the tumour cells for about 6 h.

Table 3. Exposure of Tumour to Post-coital Fluid *in vitro* with Subsequent Inoculation into Weanling Rats

Exposure (h)	Proportion of fluid to tumour						Control		
	2/1			1/1 or 1/2			Various prop. saline/tumour		
	D	*T*+	*T*−	*D*	*T*+	*T*−	*D*	*T*+	*T*−
2	0	3	1	0	1	0			
6	3	5*	33	0	5	0	0	33	2

* Tumours tiny.

Prof. G. A. H. Buttle of the School of Pharmacy, London, kindly agreed to carry out further *in vitro* tests, with the Walker carcinoma, the Crocker mouse sarcoma and the human *HS* 1 tumour, using the fluid from my mated rats and has confirmed my findings with these other tumours.

In Exps. 2 and 3, toxic effects were observed in some of the recipient weanling rats; such toxic effects were abscess formation and peritonitis. This toxicity proved to be due to an overwhelming infection by *Pasteurella* and *Streptococci*—both sensitive to penicillin. Intraperitoneal inoculation of uterine aspirates from virgin rats, or of tumour suspensions alone, or of epididymal sperm, did not produce any morbidity.

Exp. 4. When uterine fluid was injected directly into the tumour bed of animals with established tumours, no inhibition was observed: on the contrary, growth appeared to be enhanced.

The post-coital uterine fluid, which has an inhibitory effect on unattached tumour cells, consists of blood cells, capacitated sperm, œstrus fluid, seminal plasma and possibly also of substances secreted in reponse to insemination.

Exps. 5–8 were designed to identify the active factor.

Exp. 5. To test the effects of distension on the uterus, tumour suspensions (0·15, 0·1, 0·05 ml.) were injected into the uterine horns, which were then distended to capacity with saline. 6 h later the uterine contents from one horn were aspirated and re-inoculated into weanlings. Since the tumours grew well in both donors and recipients it may be concluded that their growth was unaffected by uterine distension or dilution of tumour suspension.

Exp. 6. Spermatozoa obtained from excised gonads were incubated with tumour suspension in proportion 2 : 1, and afterwards injected into weanling rats. In 11/12 recipients the tumour grew at the normal rate.

Exp. 7. Tumour suspensions were transplanted into uteri of animals in œstrus and the uterine contents evacuated 5–6 h later and re-inoculated into weanling rats. Œstrus fluid was also collected for *in vitro* assays. As shown in Table 4, the œstrus fluid appears to be devoid of tumour-inhibiting properties.

Table 4. Growth of Tumours Exposed to Œstrus Fluid

(1) Tumour inoculated into uteri of œstrus rats		Uterine contents of (1) inoculated into weanlings after 6 h		Tumour and œstrus fluid incubated *in vitro* 6 h inoculated into weanlings	
T+	*T*−	*T*+	*T*−	*T*+	*T*−
7	3	3	1	6	3

Exp. 8. Rats mated with vasectomized males were treated as in the previous experiment. The results suggest that post-coital fluid devoid of spermatozoa, or seminal plasma, had no antitumour activity.

Thus tumour inhibition could not be demonstrated with testicular or epididymal sperm, with œstrus fluid or with fluid obtained from uteri after mating with vasectomized males. It would appear therefore that tumour inhibition is associated with the presence of capacitated sperm.

The experiments described here suggest that the post-coital uterine fluid of the rat contains a factor—probably associated with capacitated sperm—which inhibits the viability and transplantability of free, unattached tumour cells *in vivo* and *in vitro*.

I thank Prof. E. C. Amoroso for his advice and help in this work. I also thank Prof. G. A. H. Buttle for his interest.

PRODUCTION OF ERYTHROPOIETIN BY ANOXIC PERFUSION OF THE ISOLATED KIDNEY OF A DOG

By E. O. ZANGHERI, H. CAMPANA, F. PONCE, J. C. SILVA, F. O. FERNÁNDEZ and Prof. J. R. E. SUÁREZ

Departamento de Fisiología, Universidad Nacional de Cuyo, Mendoza, Argentina

SINCE the publication of the communication by Jacobson *et al.*[1] many authors have directed their attention to the kidney as the site of the production of erythropoietin. Mirand *et al.*[2], who demonstrated the production in binephrectomized rats, consider the kidney an organ essential for complete erythropoietic response. Reisman *et al.*[3] were able to demonstrate erythropoietin on ureter ligated rats. But they obtained negative results with bilaterally nephrectomized or mercury–bichloride poisoned (kidney tubular necrosis) rats. Richet *et al.*[4], examining 21 patients with acute renal insufficiency, found no erythroblasts in the bone marrow at about the fifth day of illness.

The following experiments represent further attempts to examine the role of the kidney as the site of production of erythropoietin.

Mongrel dogs were anæsthetized with nembutal (30 mg/kg of body-weight) and heparinized (8 mg/kg).

900 ml. of blood were drawn from the jugular vein or the carotid artery. About 2/3 was filtered through gauze and used in the perfusion experiment; 1/3 (unfiltered) served as control.

After the bleeding a mid-line abdominal incision was made. The ureter of one kidney was cannulated and the kidney was removed. The organ was immediately transferred to a plastic container in a water bath controlled at 37° ± 1° C. The artery was cannulated by connexion with a Shuster–Dale pump and the apparatus previously described[5]. All tubes in contact with the blood had been siliconized. Perfusion was begun at once. The renal vein was allowed to drain directly into the plastic reservoir without cannulation, and the level of the blood was regulated to cover the organ. Perfusion pressure was 95–110 mm mercury. After perfusion without any oxygenation for 3 h, the blood was centrifuged and the plasma collected.

In another series of experiments, using the same technique, the kidneys were perfused with 10 per cent erythrocytes in plasma, prepared from the blood of the same animal. Full oxygenation (pO_2 350 mm mercury) with a gaseous mixture of 50 per cent oxygen, 5 per cent carbon dioxide and 45 per cent nitrogen was maintained throughout the perfusion.

The erythropoietic activity of the plasma was assayed either in the whole plasma or in a plasma extract prepared according to the technique of Borsook *et al.*[6] and further precipitation with 80 per cent ethanol described elsewhere[7].

Fasted (water *ad lib.*) male albino rats grown in our animal annex were used (strain from the Instituto de Biología y Medicina Experimental, Buenos Aires). When whole plasma was injected, only a single subcutaneous dose of 4 ml. was given, in order to avoid hæmolytic reactions to heterologous proteins. In the case of boiled plasma extract two abdominal injections were made on consecutive days.

The erythropoiesis was estimated by the 3-h iron-59 assay of Hodgson *et al.*[8,9] using 0·1–0·3 μc. injected into the saphena under light ether anæsthesia, 48 h after the whole plasma or 24 h after the second boiled plasma injection. 3 h after the injection of iron-59, 5 ml. of blood were removed through the abdominal aorta with a heparinized syringe.

Measurements of iron-59, plasma volume, blood volume, plasma iron and Biuret determination were made as usual[7].

79	4 ml. renal perfusion plasma (3 h). Anæmic blood oxygenated with gas mixture 50 per cent oxygen	4	230	23·2	3·5	8·2	48	1·9	7·8	110
	Same as above. Another dog	4	224	18·7	5·2	6·5	58	1·8	7·8	
	Same as above. Another dog 4 h of perfusion	5	222	17·5	5·0	7·8	59	1·5	6·9	
	Control 4 ml. plasma before perfusion	4	224	19·6	3·2	6·2	54	1·9	7·5	

The iron-59 turnover constant (K; per cent/h) and the total iron turnover (μg/h) were calculated[8].

The mean uptake of iron-59 by erythrocytes was submitted to statistical analysis using the Fisher t test.

In the three experiments, both the whole plasma and the boiled extract from isolated perfused kidneys without any oxygenation had a significant stimulating erythropoietic effect compared with the same plasma without perfusion (Table 1).

The positive samples show higher erythrocyte iron-59 uptake (statistically significant), lower residual plasma and liver iron-59, as well as a higher iron-59 turnover constant, K. All these results indicate an erythropoietic stimulation of these groups when compared with the controls. The discrepancy between these results and the total plasma iron turnover is in agreement with the findings of Hodgson *et al.*[10], who showed that this parameter is an unsatisfactory index if the plasma iron is less than 2 μg/ml.

The positive results obtained with hypoxic perfusion are significant since an aliquot of the same plasma (non-perfused) was used for the controls. The erythropoietic stimulation observed is evidently due to a specific effect. The amount of protein injected was the same in the control groups as in the active ones. Furthermore, experiment 110 shows a high erythrocyte iron-59 uptake with a small amount of protein injected (12·8 mg total dose). The erythropoietic effect cannot be attributed to a hæmolytic action of the extract or of the active plasma because the hæmatocrits in the active (46·6 per cent) and in the control (47·9 per cent) groups were very similar.

The active substance seems to be 'erythropoietin': it is heat-stable at pH 5·5 (ref. 6) and is precipitated with 80 per cent ethanol[11] at pH 4·5.

These results agree with those of Kuratowska *et al.*[12] although we used a different animal and also a different bioassay.

The experiments described here provide direct evidence of the production of erythropoietin by the hypoxic kidney *in vitro*. Nevertheless, we cannot conclude that this is a normal mechanism in the whole animal. We cannot dismiss the possibility that autolysis of the renal tissue induced by the strong hypoxia liberates the active substance.

When we applied the same technique to the perfusion of isolated kidneys with 10 per cent erythrocytes in plasma prepared from the blood of the same animal but fully oxygenated (pO_2 350 mm mercury) the results were quite negative (Table 2).

These findings are compatible with the homœostatic mechanism theory of Jacobson and Goldwasser[13], which explains the production of erythropoietin as a function of the balance between oxygen supply and oxygen demand of the tissues rather than of either factor alone.

SURVIVAL OF MOUSE ERYTHROCYTES IN HISTOINCOMPATIBLE RECIPIENTS

By GÖRAN MÖLLER

Department of Tumor Biology, Karolinska Institutet Medical School, Sweden

THE strong histocompatibility-2 (H-2) locus in mice creates an efficient barrier against successful transplantation of normal tissues of various histological origin. The cellular H-2 isoantigens initiating the immunological rejection are at the same time blood group antigens and can be demonstrated on erythrocytes by agglutination hæmolysis, absorption and complement fixation[1–4]. The antigens on red blood cells and somatic tissue cells are determined by the same genes and have the same immunological specificity (for review see ref. 5). However, it has been demonstrated[6] that erythrocytes purified from contaminating white blood cells were unable to induce transplantation immunity against skin grafts. It was suggested, therefore, that red blood cells possessed a different kind of isoantigenic receptors, which could not stimulate the cell-bound transplantation immunity[6]. Contradictory results were reported, however, indicating that erythrocytes could efficiently immunize against tumour homografts[7].

The investigation recorded here represents an attempt to examine the transplantation behaviour of erythrocytes by following the elimination cells labelled with chromium-

51 transfused into compatible and H-2 incompatible recipients.

Fresh strain *A* red cells were used throughout as donor material. The cells were washed once in isotonic citrate solution (0·1 M) and twice in balanced salt solution, and thereafter re-suspended in an equal volume of balanced salt solution. To this was added 200–500 μc. chromium-51 per ml. of packed red cells in the form of $^{51}Na_2CrO_4$ and the suspension was incubated for 30 min at 37° C. The amount of chromium added never exceeded 10 μg per ml. packed red cells. After incubation the cells were washed three times in balanced salt solution. 0·2 ml. of a 10–30 per cent v/v suspension was injected intravenously into compatible strain *A* mice or into hybrids between *A* and other strains and into incompatible *A.CA* or *A.BY* recipients. Each recipient received between 2 and 20 μc. chromium-51 in different experiments.

The fate of the injected cells was followed by bleeding the recipients at 3–6 days' intervals. 0·05 ml. whole blood was taken and suspended in 3 ml. of water. Radioactive determinations were carried out in a well-type scintillation detector (Tracerlab). At the beginning of each experiment the samples had count rates 70–200 times higher than the background. All count rates were corrected for background and radioactive decay.

The elimination curves of strain *A* erythrocytes transfused into compatible recipients were linear when the count rates were plotted on a logarithmic scale. The survival times (arbitrarily taken as the day when 5 per cent of the original activity was still detectable) varied between 20 and 30 days (mean 26·3 days) in different individuals (Table 1). The same results were obtained after transfusion of *A* cells into *A.CA* or *A.BY* recipients: the elimination curves were linear without any evidence of immune elimination, and the survival times varied between 20 and 30 days (mean 24·6 days) (Table 1). There was no significant difference ($P > 2$) between the survival in compatible and incompatible recipients. The variation of survival times within one experiment was considerably smaller than between different experiments.

The persistence of chromium-51 in the circulation of the incompatible recipients was not due to transfer of chromium-51 to host erythrocytes. It could be demonstrated that all chromium-51 labelled cells could be lysed *in vitro* in the presence of complement with humoral isoantibodies directed specifically against the transfused *A* cells (*A.CA* anti-*A* serum). The lysate contained all the radioactive activity present in the total samples. Furthermore, injection of chromium-51 labelled cells which had been hæmolysed by the addition of water did not result in labelling of host cells.

Table 1. Survival Times* of Strain *A* Erythrocytes Labelled with Chromium-51 in Various Recipients

Recipients	No. of mice	Pretreated with:	50% survival times of transfused cells (days)	5% survival times of transfused cells (days)
A hybrids	14	—	5,5,6,6,6,7,7,7,7,7,8,9,9, Mean = 6·8	20,21,25,25,26,27,27,28,28,29,30,30, Mean = 26·3†
A.CA and *A.BY*	15	—	5,5,6,6,6,6,7,7,7,7,7,7,8,9, Mean = 6·6	20,21,22,22,23,23,24,25,25,26,27,27,28,29,30, Mean = 24·8†
A.CA and *A.BY*	24	A.*CA* or *A.BY* anti-*A* serum	4,5,6,6,6,6,7,7,7,7,7,8,8,8,8,8,8,8,8,8,9,9,9,9, Mean = 7·3	18,20,20,21,21,21,21,22,22,24,25,25,25,25,26,26,26,27,27,28,28,28,29,29, Mean = 24·2†

* The activity present at the first bleeding after transfusion (day 0 or 1) was taken as 100 per cent survival.

† There are no statistically significant differences ($P > 2$) between the mean survival times.

The absence of immune elimination in foreign recipients was not a characteristic for the intravenous route of injection. It was found that chromium-51 labelled strain *A* erythrocytes injected intraperitoneally into compatible and incompatible recipients were eliminated from the blood in a similar way and without evidence of immune elimination.

Incompatible *A.CA* recipients which received *A* cells developed humoral isoantibodies demonstrable as hæmagglutinins and hæmolysins. Detectable titres were observed 6 days after transfusion and reached a maximum after about 11 days. Antibodies were still detectable after 20 days. The antibody response was not strong, however, compared with that found after transfer of lymphoid cells, and the maximum titres varied between 1/32 and 1/256. Since no attempt was made to purify the red cells from contaminating white blood cells it cannot be decided whether the antibodies were actually induced by the erythrocytes.

Since erythrocytes can be agglutinated and hæmolysed *in vitro* by humoral antibodies it is noteworthy that no immune elimination occurred in spite of the fact that antibodies and target cells were circulating in the same hosts. A study was made, therefore, on the effect of humoral isoantibodies on the elimination of strain *A* red cells in *A.CA* recipients. Between 0·05 and 0·4 ml. *A.CA* anti-*A* serum was injected intraperitoneally into groups of *A.CA* hosts 30 min prior to the intravenous transfusion of red cells. It was found that antibodies could diminish the amount of circulating red blood cells from 10·0 to 88·8 per cent of the originally injected dose (Table 2). This elimination occurred very rapidly and was detected after only 1 h. However, antibodies had no effect on the subsequent elimination of the residual cells and elimination curves were strictly parallel in untreated and antibody treated groups (Table 1). Since the amount of antibody injected was sufficiently large to agglutinate and hæmolyse all the transfused red cells *in vitro*, it seemed less likely that the failure to accomplish complete elimination was caused by inadequate quantities of antibody. This was further emphasized by experiments in which the effect of various antibody doses were compared. In several experiments it was found that 8-fold differences in the antibody dose did not detectably change the extent of the initial elimination. The variation between different mice in the same experiment was sometimes large.

It seemed possible that insufficient complement-levels were responsible for the limited effect of antibodies *in vivo*. Therefore, 0·5 ml. fresh guinea pig serum as a source of complement was injected intraperitoneally together with antiserum and the effect compared with that of antiserum alone. In none of six mice did complement increase

Table 2. Effect of Antiserum* *in vivo* on the Removal of Transfused Strain *A* Erythrocytes

Recipients	No. of mice	Pretreatment of recipients	Mean destruction of transfused erythrocytes in % of the dose injected	Removal of transfused erythrocytes in % of the original dose. Distribution of mice				
				10–19·9	20–39·9	40–59·9	60–79·9	80–89·9
A.CA and *A.BY*	38	*A.CA* or *A.BY* anti-*A* serum	47·5	4	11	10	11	2
A.CA and *A.BY*	6	*A.CA* or *A.BY* anti-*A* serum and complement	19·5†	3	3			

* An intraperitoneal injection of 0·05 to 0·4 ml. antiserum was given to the recipients 30 min prior to the transfusion of the red cells.

† Seven controls which were injected with antiserum only showed a mean removal of transfused erythrocytes of 19·7 per cent of the originally injected dose.

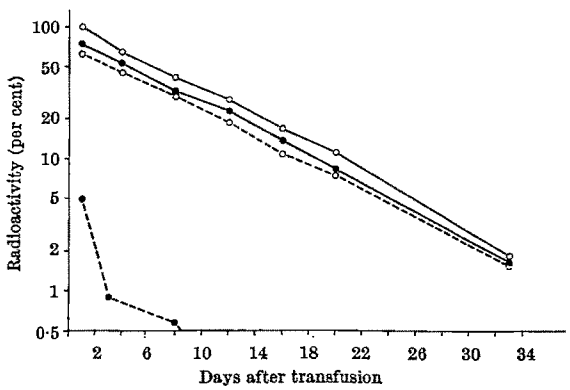

Fig. 1. Survival of strain *A* erythrocytes labelled with chromium-51 in compatible $(A \times A.CA)F_1$ hybrids (group, *A*, —○—), in incompatible *A.CA* recipients (group *B*, —●—), in *A.CA* pretreated with 0·2 ml. *A.CA* anti-*A* serum (group *C*, — —○— —) and in *A.CA* hosts repeatedly immunized against strain *A* normal tissue (group *D*, — —●— —). Each point represents the mean value of three mice

the initial elimination (Table 2). No effect was detectable on the slope of the elimination curves.

Although immune elimination of foreign red blood cells could not be achieved by passive immunization with humoral antibodies, it was found that active hyperimmunization of *A.CA* recipients with strain *A* normal tissue made them capable of immunological elimination of *A* erythrocytes (Fig. 1). However, repeated inoculations of the recipients with *A* tissue was a necessary prerequisite for the observed effect: a single subcutaneous or intraperitoneal inoculation did not make the *A.CA* recipients capable of immune elimination and the effect detectable was an initial elimination similar to that found with passive transfer of antiserum.

The absence of immune elimination of H-2 incompatible erythrocytes is in marked contrast to the results obtained with other cell types. It cannot be ascribed to absence of antigenic receptors on the blood cells, as indicated by various tests *in vitro*, nor to the absence of an immune response of the recipients, as shown by their production of humoral antibodies. Passive transfer of antibodies could accomplish partial removal of the red cells only, without significant effect on the survival time of the residual unaffected cells. This finding would be in agreement with that of Winn[4], who demonstrated that a fraction of red cells is often completely resistant to humoral antibodies *in vitro*. However, complete immune elimination was found in hyperimmunized recipients, indicating that the possible resistance of the red cells was not complete. The present findings cannot be adequately explained by the assumption that erythrocytes differ from somatic tissue cells with regard to the kind of isoantigenic receptors they carry, since complete elimination did not occur after passive transfer of humoral antibodies either, which are presumably specifically directed against the receptors of red blood cells[6]. Although the mechanism of this phenomenon is not known at present, it may be speculated that it is akin to the findings with certain tumours, capable of growing in foreign strains in spite of a homograft reaction. Such tumours have a low concentration of antigenic receptors but they are capable of inducing humoral antibody formation. As a result, the antigenic receptors are blocked and this subsequently leads to enhanced tumour growth[8,9].

ULTRASTRUCTURE OF THE NODE OF RANVIER

By D. N. LANDON and P. L. WILLIAMS
Anatomy Department, Guy's Hospital Medical School, London, S.E.1

THE theory of saltatory conduction in peripheral myelinated nerve fibres of mammals is now generally accepted[1,2]. The myelin sheath is considered to act as an insulator confining the active generation of current to the nodes of Ranvier, the propagation of the impulse along the internode being effected by local electrotonic circuits. The active axonal membrane at the node will therefore be the site of relatively large ionic fluxes requiring the expenditure of energy. It would be expected that some provision for these energy requirements might be found in the ultrastructure of the cellular elements which contribute to the formation of the node.

In a previous communication[3] attention was directed to the deviation of the myelin sheath in the paranodal region from the cylindrical form generally held to characterize the internode. It was shown that in the rabbit, rat and mouse the myelin sheath becomes crenated as it approaches the node and that the external grooves are filled with Schwann cell cytoplasm containing numerous mitochondria. Mitochondria have been described near the node[4,5], but not in these large numbers, the concentration greatly exceeding that found in the Schwann cell cytoplasm immediately surrounding the nucleus, the region usually considered to contain the majority of Schwann cell organelles[6]. The Schwann cell columns end as a collar of cytoplasm over the zone of termination of the myelin lamellæ, and this collar has been shown to give rise to finger-like processes which surround the nodal axon[4,7–11]. These processes have been described in the frog as being about 500 Å in diameter, forming an irregular mesh around the nodal axon, and separated from it by a gap of 200–250 Å. In an investigation of the cochlear ganglion of the rat[11] a node is illustrated in which some processes abut against the nodal axon membrane, and appear to contain a single filament. The present study demonstrates the intimate relationship of the ends of these processes and the nodal axon membrane, and it is suggested that the close connexion thus established between the mitochondria rich paranodal Schwann cell cytoplasm and the nodal axolemma may be significant in energy exchanges across the latter, and will also affect the electrotonic current distribution through the nodal membrane.

The tissues examined have been the saphenous nerve of the rat and the sciatic nerve of the mouse. These have been fixed by immersion in ice-cold 1 per cent osmium tetroxide, buffered, for 1 h. The nerves were then dehydrated in ethanol, stained for 1 h in 1 per cent phosphotungstic acid, and embedded in 'Araldite'. Ultrathin sections were mounted on carbon-coated grids and examined in the R.C.A. *EMU 3E* electron microscope.

The appearance of a longitudinal section of the nodal region of an intermediate-sized myelinated nerve fibre is seen at low power in Fig. 1. The basement membrane, an

amorphous dense layer about 250 Å thick, separated from the underlying Schwann cell unit membrane by a gap of approximately 300 Å, is continuous across the nodal gap. External to it are the small endoneurial collagen fibres of the sheath of Plenk and Laidlaw; these also dip in at the node. Between the basement membrane and the nodal axon is the 'gap substance', apparently structureless material of noticeably greater electron density than the endoneurial ground substance external to the basement membrane. Embedded in this 'gap substance' are the finger-like Schwann cell processes.

The internal ultrastructure of the axon at the node has been well described[7]; but less attention has been paid to its overall dimensions. Through the juxtanodal region of termination of the myelin lamellæ, in larger fibres, the axon is reduced to about one-third of its mean internodal diameter, expanding to about half the internodal diameter at the node itself. The axolemma at the node is densely osmophilic and presents an irregular biconical profile in longitudinal sections; the juxtanodal axolemma is also osmophilic and is very closely applied to the Schwann unit membrane loops at the ends of the myelin lamellæ[7]. The nodal axoplasm is traversed by neurofilaments, more densely packed than in the internodal axon, and these occasionally appear to make contact with the nodal axolemma. It contains mitochondria, one or two being a constant feature of the expanded portion of the nodal axon, often closely related to the axolemma, and also large and small vesicular profiles sometimes identified as endoplasmic reticulum[7].

The collar of Schwann cell cytoplasm over the end of the myelin sheath is continuous with the columns of cytoplasm in the crenated outer aspect of the paranodal myelin. Like these columns it contains numerous small mitochondria and 200 Å cytoplasmic filaments, and, in addition, small densely osmophilic bodies of about 1000 Å diameter. This collar of cytoplasm gives rise to the finger-like process which surround the nodal axoplasm (Fig. 1). These are slender cytoplasmic processes 700–800 Å in diameter, limited externally by a continuation of the Schwann cell unit membrane, and containing longitudinal filaments of approximately 100 Å diameter. There are usually five filaments, occasionally four or six, arranged in a ring within the process and without any evident basal apparatus in the Schwann cell collar. In small myelinated fibres, where the length of exposed axon at the node is larger, the processes are irregularly arranged, running

(scale = 0·5μ)

the greater part of their length parallel to the axon surface. In large myelinated fibres the processes are radially disposed in a regular hexagonal array (Fig. 2). They are embedded in the amorphous 'gap substance' and have a minimum separation of about 800 Å. A transverse section at the node (Fig. 3) shows the regular palisade of Schwann cell processes (Fig. 4) and the very close apposition of their distal ends to the axon unit membrane. It has not been possible to resolve any gap between the two and it may be that it is of the same order as the gap between the loops of termination of the myelin lamellæ and the axolemma in the juxtanodal region, about 20 Å (ref. 7). At the point of contact the axolemma shows greatly increased electron density with diffuse osmophilia in the immediately underlying axoplasm. On occasions axon filaments appear to enter this region. There is no evidence of a syncytial connexion between adjacent Schwann cells.

Previous investigators of the dimensions of the axon membrane at the node of Ranvier in vertebrate myelinated nerve fibres, in relation to its electrical properties, have assumed that the exposed axon is in the form of a short cylinder, of homogeneous external surface, and of length equal to the optically visible nodal gap[12,13]. The observations reported suggest, however, that the nodal axon membrane is a non-cylindrical mosaic, some areas being related to the ends of the Schwann cell processes, others to the 'gap substance'. The potential difference across this membrane is dependent on the presence of ionic gradients, and the process of maintaining these gradients requires metabolic activity. Although one or two mitochondria are usually visible in the nodal axoplasm they are not impressive as an energy source for so active a region. On the other hand, the mitochondria rich Schwann cell cytoplasm of the paranodal furrows is directly continuous with the nodal processes, so closely applied at their distal ends to the axon membrane. It is therefore possible that one of the functions of the Schwann cell, as the axon's satellite, is to provide the energy mechanism necessary for the ionic pump at the node. Investigations into the concentration and distribution of energy-releasing enzymes in the nodal region are in progress.

A further problem concerns what part of the axolemma at the node is involved in the active generation of current. It is suggested that the point of contact of the loop of termination of the external myelin lamella with the axon provides the longitudinal limit of the active nodal membrane. Within these limits the mosaic structure of the membrane allows two anatomically distinct sites for ionic flux. Interchange may occur either between axoplasm and 'gap substance', or between the axoplasm and the cytoplasm of the Schwann cell processes at their point of contact. At the first site only one unit membrane is concerned, but movement of ions across it may well be affected by the nature of the 'gap substance'. That this may possibly be an unsulphonated hyaluronic acid–protein complex is suggested by histochemical evidence of hyaluronic acid in the axon and 'neurilemma' of mammalian myelinated nerves, noted to be especially dense around the nodes[14]. Such a complex has been shown to be a cation acceptor, binding potassium in preference to sodium. At the second site the unit membranes of both axon and Schwann cell are involved, together with the small intervening gap. A similar exchange between axon and satellite cell cytoplasm has been suggested for the route of ionic flux in unmyelinated mammalian and invertebrate nerves[15,16].

A commonly held view of the external part of the local electrotonic circuit, by which activation of neighbouring nodes occurs, is that it traverses the tissue fluid which bathes the external surface of the axolemma at the node. It has been shown that the axon is separated from the endoneurial tissue fluid spaces by the relatively more dense 'gap substance' and the satellite cell basement membrane, and these therefore must necessarily be included in such a circuit. This view has been questioned by Tasaki, who has suggested a significant role for the Schwann cell cytoplasm[12]. Such an external Schwann cell cytoplasmic route would be provided in series by the nodal processes, the perinodal collar, the longitudinal paranodal cytoplasmic columns, and the more attenuated external internodal Schwann cell cytoplasm with its small perinuclear concentration.

Finally, it is possible that the Schwann cell processes and the 'gap substance' may have a mechanical function in protecting the ostensibly weakest portion of the peripheral myelinated nerve fibre from damage when stretched. In this connexion it is of interest that fresh teased nerve fibres when pulled, stretch at the internode and not at the node[17]; moreover, glial cell processes and 'gap substance' have not yet been reported at the nodes of myelinated fibres in the central nervous system[10].

THE PERINEURAL EPITHELIUM: NATURE AND SIGNIFICANCE

By Dr. T. R. SHANTHAVEERAPPA* and Prof. GEOFFREY H. BOURNE

Emory University, Atlanta, Georgia

NATURE of perineural epithelium. We have shown a 2–5 layered flat squamous-celled epithelium surrounding the nerve trunks and nerve fasciculi of peripheral nerves, found immediately under the perineurium[1–3] (Fig. 3). Such a structure has been indicated by other authors[4–7]. Further investigations have demonstrated[1,2] that this membrane represents an extension of the pia arachnoid mater (Figs. 1 and 2), which has been traced on to the spinal roots and then on to the peripheral nerve fasciculi, in serial isolations. It has the same number of cellular layers and the same types of cells with identical nuclei (Figs. 1, 2 and 3) as the pia arachnoid mater. The nuclei show well-defined sex chromatin in the female cat and rat in both perineural epithelial cells and those of the pia arachnoid. We have also shown that small blood vessels ramify between the layers of the perineural epithelium in the same way as they do in the pia arachnoid mater.

The perineural epithelium also covers the spinal ganglia (it has been described by histologists to date, as the 'capsule' of the ganglion). An identical membrane covers the optic nerve and the whole of the autonomic system: the vagus nerves[8], the sympathetic ganglia and the rami communicantes[9].

Fig. 2. Rat spinal root covered with its membrane. Isolated under dissecting microscope and stained to demonstrate cellular borders. Note the spinal root (arrow) is covered by leptomeningeal squamous epithelial cells. (× *c.* 85)
Fig. 3. Cat sciatic nerve. Isolated perineural epithelium from peripheral nerve fasciculus under dissecting microscope. Stained for cellular borders and nuclei. Note clear flat squamous epithelial sheet with nuclei. (× *c.* 200)
Fig. 4. Choroid from the rat eye, isolated under dissecting microscope and stained for cellular borders. Note the whole choroid is made up of flat squamous epithelial cells. By altering the fine adjustment of the photomicroscope we can see blood vessels and pigment cells in between these layers of cells. (× *c.* 200)

As the individual nerve bundles divide and become smaller, the epithelium divides with them until it finally surrounds each terminal nerve fibre. In motor nerves the epithelium ends as a funnel surrounding and covering the motor end-plate and makes direct contact with the sarcolemma (the bell mouth of Henle). In sensory nerves the epithelium is shown to be associated with the formation of the end organs. This is especially true of the Pacinian corpuscle, the lamellæ of which are formed by flat squamous epithelial cells and not by fibroblasts as was previously thought (Fig. 5) (ref. 10). The lamellæ of the Herbst corpuscle of the duck[11] and the capsule of the muscle spindle[12] are also made up of a squamous epithelial cell layer which is an extension of the perineural epithelium.

Its relation to the membranes of the eye. The perineural epithelium of the eye appears to extend under the sclera (Fig. 4); it develops pigment and becomes highly vascularized, too, and, in fact, becomes the choroid membrane. The squamous cells (Fig. 4) of the choroid are continuous anteriorly with a layer of squamous cells at the back of the cornea and on the front of the iris and are probably further continuous with the internal limiting membrane of the retina (Fig. 6). The internal limiting membrane has been thought to be a structureless homogeneous mass, but in fact it appears to be made up of squamous epithelial cells together with the expanded ends of Muller's fibres (Fig. 6). Further details of the relation of the perineural epithelium to the structures of the eye will be published elsewhere. However, it might be noted that like the terminations of other peripheral nerves the retina is physiologically isolated by a continuous cellular membrane composed of the choroid and the internal limiting membrane.

Its physiological significance. In the light of all these results we have to envisage the whole of the peripheral nervous system as being surrounded by a membrane similar in structure to, and continuous with, the pia arachnoid mater. Furthermore, this membrane, like the pia arachnoid, is rich in dephosphorylating enzymes, for example, ATPase, 5-nucleotidase, creatine phosphatase, glycerophosphatase, etc.[2], indicating that it represents a metabolically active diffusion barrier. In addition, it becomes obvious that the space between the perineural epithelium and the nerve fibres is continuous with the sub-pial space of the brain and spinal cord and the fluid in the latter space must therefore be able to circulate to the furthermost reaches of the peripheral nervous system. The peripheral nervous system is thus encased in an environment which can be kept independent of that of the surrounding tissue fluids, and more or less identical with that of the central nervous system. One of the functions, presumably, of this membrane is to maintain a certain concentration of Na^+ and K^+ ions and glucose in the vicinity of the nerve fibres. Removal of fluid from this sub-perineural space and analysis for these and other constituents is obviously an important future step.

It is of interest that Vorontsov[13] has shown that in the genesis of physical electrotonus the fast part of the electrotonus is for the most part due to what he calls "the connective tissue sheath of the nerve fibre and especially to the perineurium". If a nerve fasciculus is denuded of its perineurium the nerve fails almost completely to exhibit the fast part of the electrotonus. Vorontsov concludes that this effect can only be brought about if the perineurium acts as an obstacle to the passage of ions and to the same extent for anions and cations. It appears that this property of the perineurium is most likely due to the presence of the perineural epithelium, which as an intact protoplasmic membrane is the most likely structure in the perineurium to have such properties. This is supported by the fact that the epineurium, which has no such membrane, does not have the same properties as the perineurium. This difference between the two sheaths also provides the solution to the controversy between Lorente de No[14] and Feng and Liu[15] concerning the permeability of nerve membranes. The former, who found the membranes acted as a diffusion barrier,

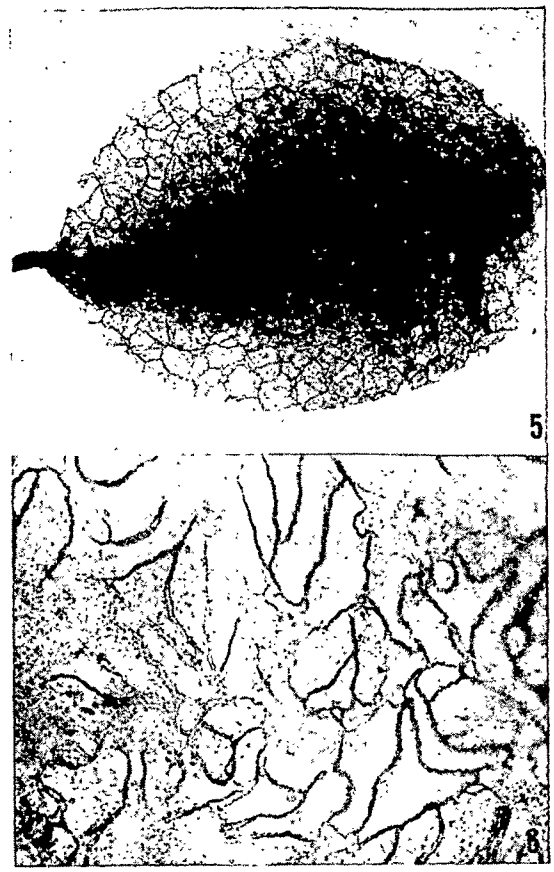

Fig. 5. Whole mount of Pacinian corpuscle, isolated from rat mesentery and stained for cellular borders. Note that the whole Pacinian corpuscle is made up of continuous sheets of flat squamous epithelial cell lamellæ. (× *c.* 90)

Fig. 6. Internal limiting membrane from the rat retina, isolated under the dissecting microscope. Stained to demonstrate cellular borders. It appears that the whole internal limiting membrane is made up of the expanded ends of Muller fibres along with flat squamous cells. (× *c.* 665)

used perineurium, and the latter, who did not, used epineurium.

When a nerve is damaged and degenerates the perineural epithelium does not degenerate but remains as an intact tube which helps to guide the regeneration sprouts of the nerve fibre into the proper region where they can find their way through the neurilemmal tubes leading them to their peripheral destination. There is no evidence of proliferation of the cells of this epithelium after injury[16]. It is of interest that the 'nuclear mass' which is said to remain at the motor end-plate area after severance and degeneration of the nerve is simply composed of the nuclei of the perineural epithelium, which remains as a bell-shaped structure covering the end-plate region, through which the regenerating nerve fibre reaches the proper locus on the muscle fibre.

The presence of the perineural epithelium has a number of implications in neurological diseases as noted below.

Peripheral neuritis. It is of interest that as a nerve extends distally the number of squamous cell lamellæ in the perineural epithelium becomes decreased. It seems likely that one of the functions of the perineural epithelium is protection of the nerves from infection, as well as protection from surrounding body fluids. The degree of protection should be directly related to the number of epithelial layers. Around the very small nerve bundles and in the terminal nerves the number of layers is reduced to one or two. Oedema fluid and toxic substances could penetrate more easily between the cells of such thin layers and reach and damage the nerve fibres. It is possible that the distal distribution of peripheral neuritis develops because of the greater vulnerability of the smaller more peripheral nerves. The presence of a considerable number of mast cells associated with the perineural epithelium is undoubtedly part of its defensive mechanism.

Neurotropic virus infections. The small fibres of the olfactory and gustatory nerves are also surrounded by perineural epithelium[17] so it is possible that once the olfactory and gustatory perineural epithelium has been penetrated by an infective agent (for example, encephalitis virus, meningococcus) it has a ready-made path straight to the central nervous system underneath this perineural epithelium. We feel that it is much more likely that neurotropic viruses and bacteria are transported in this way than that they are transported within the nerve fibre itself.

Sympathetic ophthalmia. The transfer of an affection from one eye to another in sympathetic ophthalmia is probably a good example of the role of the perineural epithelium in the transport of infective or affective agents.

Sympathetic ophthalmia usually commences with traumatic injury to the uveal system of one eye; after a lapse of 2 weeks to 2 months the other eye (the sympathizing eye) gives indications of the development of uveitis. Damage to a single member of other paired organs in the body, for example, parotid glands, testes and kidneys does not usually result in involvement of the other member.

We have noted earlier that the pia arachnoid mater of the optic nerve is continued into the eye as the choroid (perineural epithelium). The pia arachnoid of the optic nerve on one side is continuous with that of the optic nerve on the other side through the optic chiasma. The causative agent of sympathetic ophthalmia, whether bacterial, rickettsial, viral or homologous uveal antigen in nature, thus could travel from the eye originally damaged directly to the other eye through this route.

Neurofibromatosis. The work recorded here suggests that the small tumours of neurofibromatosis may be derived from the perineural epithelium. The perineural epithelium is derived embryologically from the ectoderm and it is possible that small masses of undifferentiated embryological cells may be scattered along the peripheral nerves providing areas capable of spasmodic growth. It is possible, too, that the perineural epithelial cells themselves may retain the ability of rapid growth under stimulation by some activating agent.

Conclusions. The examples we have given suggest that we need to think of a number of neurological diseases in terms of the presence of the perineural epithelium; the normal functioning of the peripheral nervous system must also be thought of in terms of an enclosed system with an environment probably identical with that of the central nervous system.

In Figs. 1–6 note similarity of cells which form the leptomeninges, and which cover the spinal roots, peripheral nerve fasciculi, Pacinian corpuscles, choroid of the eye and form the internal limiting membrane of the eye.

ASTROPHYSICS

Interplanetary Magnetic Fields as a Cause of Comet Tails

It has been generally recognized recently that the historic explanation of comet tails in terms of solar radiation pressure by either light or particles is impossible. Solar light pressure has been found to be insufficient by several orders of magnitude. Coulomb collisions or acceleration coupled with charge transfer by protons in the solar wind have also been shown by Biermann and Treffitz[1], in particular, to be grossly insufficient processes to account for comet tails streaming within a cylinder of small diameter and great length away from the Sun. It is the purpose of this communication to point out that the gases in cometary comas will be efficiently ionized by the solar wind of ionized hydrogen embedded in a magnetic field[2-4] and that an interplanetary magnetic field will couple the cometary gas to the solar wind.

The neutral gases evaporated from comet nuclei will be ionized both by thermal electrons[4] in the solar wind which have energies of several tens of electron volts and, as Heubner[5] has emphasized, by Alfvén's[6] process of ionization of a neutral gas by a fast moving plasma embedded in a magnetic field.

A comet head may be regarded as a densely ionized plasma essentially stationary in a high-pressure solar wind containing a low-pressure magnetic field moving with the wind. Recent satellite measurements[4] have established that the solar wind consists of plasma the protons of which have an isotropic thermal energy of a few electron volts and a kinetic energy due to their stream velocity of a kilovolt or so. The interplanetary magnetic field observed to be embedded in the plasma is about 5γ (1γ is 10^{-5} gauss). Thus the magnetic pressure, $H^2/8\pi$, is about equal to the thermal (isotropic) pressure of the wind in the moving co-ordinate frame of the wind.

The stream pressure of the solar wind, however, is the overwhelmingly dominant pressure in space, being two orders of magnitude larger than the free space magnetic pressure. Hence, the interplanetary magnetic field is compressed against any obstacle such as the stationary plasma provided by the comet coma or the stationary magnetic field provided by the geomagnetic dipole. Just as in the case of the example furnished by the geomagnetic dipole[7], the interplanetary field is compressed against the obstacle offered by the comet coma so that the magnetic pressure increases to approximate equality with the stream pressure. If the interplanetary field is parallel to the solar wind velocity, the compressed field tails off parallel to the solar wind in a cylindrical shape for a large distance downstream from the comet coma confining the comet plasma within this volume. If the interplanetary field is perpendicular to the wind velocity, the compressed field lines on the solar side of the comet slip around the edge of the comet and then continue moving with the solar wind[7]. The comet plasma will become embedded in the moving field lines and will be carried radially away from the Sun, acquiring the velocity of the magnetic field as Heubner[5] first proposed.

Quite simply the magnetic field may be regarded as the mechanism by which the solar wind is efficiently coupled to the comet plasma which Coulomb collisions are not able to provide. Fluctuations in solar wind pressure, or the magnetohydrodynamic waves the fluctuations generate, will also create the accelerations in comet tails which first led Biermann[2] to deduce the presence of the solar wind.

Model Atmospheres for Central Stars of Planetary Nebulæ

The central stars of planetary nebulæ have effective temperatures[1-3], T_s, ranging from 3×10^4 ° K to about $2{\cdot}5\times10^5$ ° K. Such stars may therefore be much hotter than the hottest main sequence stars which have temperatures of about 4×10^4 ° K. To obtain a better understanding of the nature of very hot stars, a number of non-grey model atmospheres have been computed.

The three models of Table 1 have been calculated assuming a grey temperature distribution and a grey radiation pressure gradient and using a Rosseland mean absorption coefficient, $\overline{\varkappa+\sigma}$. Model I was calculated for comparison with earlier work[4,5], and good agreement was obtained. It is believed that models II and III are the first to be calculated for stars of effective temperature much greater than 4×10^4 ° K: in these models, the surface gravity, g, has been taken to be only slightly greater than the minimum value required for mechanically stable atmospheres. All three models have the same chemical composition, hydrogen : helium = 85 : 15 by numbers of atoms.

Table 1

	T_s (10^5 °K)	Log g
Model I	0·417	4·2
Model II	1·000	4·8
Model III	2·000	6·0

An important feature of these models is the large contribution of electron scattering, σ, to the opacity of the atmosphere, the ratio, $\sigma/\overline{(\varkappa+\sigma)}$, being about 0·95 for model II and about 0·99 for model III. The remaining contribution comes from continuous absorption by neutral hydrogen and singly ionized helium, the relative abundances of the ions being of the order $N_H{}^0/N_H \sim 10^{-8}$, $N_{He}{}^0/N_{He} \sim 10^{-15}$, and $N_{He}{}^+/N_{He} \sim 10^{-8}$.

The monochromatic source function for an atmosphere in which there is both continuous absorption and continuous scattering is given by the integral equation:

$$S_\nu(\tau_\nu) = \frac{\varkappa_\nu}{\varkappa_\nu+\sigma} B_\nu(T) + \frac{\sigma}{\varkappa_\nu+\sigma} J_\nu(\tau_\nu) \qquad (1)$$

where:

$$J_\nu(\tau_\nu) = \tfrac{1}{2}\int_0^\infty E_1(|\tau_\nu - t_\nu|) S_\nu(t_\nu)\,dt_\nu \qquad (2)$$

is the mean intensity. The condition of flux conservation may be written as :

$$\int_0^\infty \kappa_\nu J_\nu d\nu = \int_0^\infty \kappa_\nu B_\nu d\nu \quad (3)$$

or as

$$\int_0^\infty \kappa_\nu (\kappa_\nu + \sigma) S_\nu d\nu = \int_0^\infty \kappa_\nu (\kappa_\nu + \sigma) B_\nu d\nu \quad (4)$$

The expression for the emergent flux is

$$F_\nu(0) = 2\int_0^\infty E_2(t_\nu) S_\nu(t_\nu) dt_\nu \quad (5)$$

The usual techniques for solving equation (1) by iterative procedures in which S_ν is initially replaced by B_ν are no longer practicable when σ is large compared with κ_ν. In our method, therefore, the integral equation is replaced by a set of linear inhomogeneous equations and solved by matrix inversion. The integrated flux was found to be constant to within about 2 per cent.

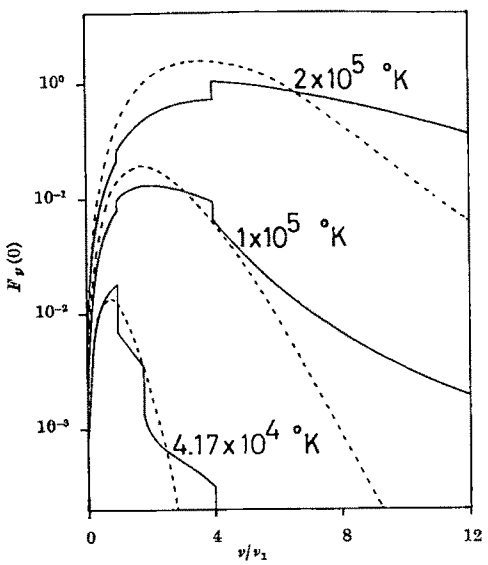

Fig. 1. The frequency distribution of the emergent flux for model atmospheres of effective temperatures, T_s = 4·17 × 10⁴ °K, 1·00 × 10⁵ °K and 2·00 × 10⁵ °K. The abscissa measures the frequency (in units of ν/ν_1, where ν_1 is the frequency of the H Lyman limit), and the ordinate measures the flux, F_ν (πF_ν in units of ergs cm^{-2} sec^{-1} per unit frequency interval where the unit of frequency is the cycle sec^{-1}). The black-body frequency distribution, B_ν (in the same units), for the same temperatures is given by the dashed curve

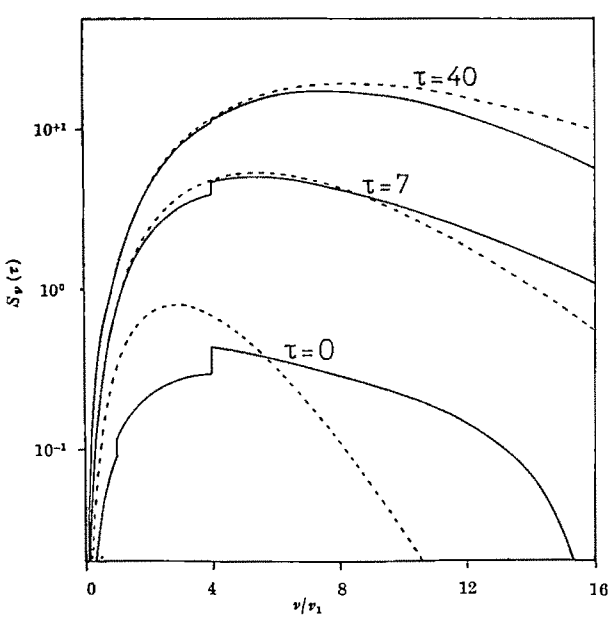

Fig. 2. The frequency distribution of the source function at optical depths, τ = 0, 7 and 40, for a model atmosphere of effective temperature 2·00 × 10⁵ °K. The abscissa measures the frequency (in units of ν/ν_1, where ν_1 is the frequency of the H Lyman limit), and the ordinate measures the source function, S_ν (in units of ergs cm^{-2} sec^{-1} sterad^{-1} per unit frequency interval where the unit of frequency is the cycle sec^{-1}). The black-body frequency distribution, B_ν (in the same units), for the corresponding temperatures is given by the dashed curve

Fig. 1 shows the distribution of emergent flux with frequency for each of the three models with the black-body distribution $B_\nu(T_s)$ plotted for comparison. For the lower temperature of model I, it will be noted that in regions of low opacity the stellar energy exceeds that of a black-body at the same effective temperature but that it drops sharply at the ionization limits of H, He, and He$^+$. For the hotter models, where the opacity is dominated by electron scattering, the behaviour is quite different. In model II, the stellar flux in the vicinity of the H Lyman limit is less than that given by the black-body curve and actually increases at the limit itself. The discontinuity being in emission, the series lines in this region will also be in emission. The discontinuity at the He I ionization limit has now disappeared, the ionization of He$^+$ being virtually complete. At the He II Lyman limit, the flux again drops as for the cooler star. For the still higher temperature of model III, the flux increases at both the H and He II limits.

In Fig. 2, the source function, together with the black-body curves, $B_\nu[T(\tau)]$, is plotted at three optical depths in model III. At high frequencies, S_ν is seen to be larger than B_ν due to the contribution to J_ν from hotter layers at greater depths. But to satisfy the conservation condition (equation 4), S_ν must then be less than B_ν at lower frequencies. At these frequencies, an increase in k_ν causes S_ν to increase towards B_ν and tends to produce an emission feature.

Whether an increase in κ_ν produces an absorption or an emission feature depends on two competing factors in equation (5). On the one hand, the exponential integral, E_2, will decrease rapidly with increasing depth so that the main contribution to the integral comes from the higher, cooler layers of the atmosphere where S_ν is relatively small: this will tend to reduce $F_\nu(0)$. On the other hand, at any given layer, S_ν itself may increase with increasing opacity, thus tending to increase $F_\nu(0)$. A related topic has been discussed in articles by Schuster[6] and Underhill[7] on the formation of emission lines in media with continuous absorption and continuous scattering.

RADIOPHYSICS

Extremely Low-frequency Radio Propagation in an Inhomogeneous Ionosphere

Experimental results[1] show that the attenuation rate of extremely-low frequency radio waves decreases with decreasing-frequency in the range from a few kc/s to about 70 c/s, below which it appears to increase again. The experimental results, however, are not yet fully confirmed. Moreover, theoretical work to date has given no indication that this behaviour would be expected. It has been suggested[1], however, that it might be possible to explain the observations by considering a stratified ionosphere consisting of three homogeneous layers having different conductivities. Although a two-layer model was

considered, no calculations have so far been given for the more complicated case.

It is the purpose of the present communication to show that the observed increase of attenuation rates as the frequency tends to sufficiently low values can be predicted on theoretical grounds using a relatively simple ionospheric model.

The propagation of vertically polarized waves in an isotropic, horizontally stratified medium can be represented by a Hertz vector which has a vertical, or z-component, only[2]. The z-wise variation of the Hertz vector is given by a factor $f(z)$ which satisfies a certain well-known differential equation[2]. It has recently been pointed out[3] that the equation has exact solutions for certain simple profiles of the refractive index. One of these cases, to be considered here, is that of an ionosphere having a linear variation of refractive index beginning at a height $z=h$ above a perfectly conducting earth at $z=0$.

The wave impedance, Z, is given in terms of f by the equation:

$$Z = -\frac{i\omega\mu_0}{k^2} \cdot \frac{1}{kf} \frac{\mathrm{d}(kf)}{\mathrm{d}z} . \qquad (1)$$

In this equation ω is the pulsatance, μ_0 is the permeability which is taken to have the free space value everywhere, and k is equal to the product of the plane wave propagation constant k_0 with the refractive index.

The boundary conditions require the surface impedance $Z_s = Z_{z=h}$ to be matched at the interface between two media. At the surface of a perfect conductor Z must vanish, so that in the air space:

$$f(z) = C\cos(gz),\ g^2 = k_0^2 - \gamma^2 \qquad (2)$$

where C is a constant and $\gamma = k_0 + iD$ is the propagation constant of the waves. The boundary condition at $z=h$ gives:

$$Z_s = \frac{i\omega\mu_0}{k_0^2}\, g\tan(gh) \qquad (3)$$

When $f(z)$ is known throughout the ionosphere equation (3), together with the condition on the fields at infinity, determines the eigen-values of g and hence of γ.

The conductivity parameter, ω_r, is determined by the ratio of the conductivity σ to the free space permittivity ε_0. It is much larger than ω for extremely low frequencies and in this case the ionosphere behaves like a good conductor. Attention will be restricted to the zero order mode which is dominant for frequencies in the ELF range. For this mode, with $\omega \ll \omega_r$, $|gh|$ is small. If also $|D| \ll 2k_0$ then equation (3) gives:

$$D = \frac{k_0}{2\,\omega\mu_0 h} Z_s \qquad (4)$$

For an ionosphere with a linear variation of refractive index[3]:

$$k(z) = \bar{k}(1+bz_1),\ z_1 = z - h \qquad (5)$$

and:

$$f(z) = \{\bar{k}(1+bz_1)\}^{-\frac{1}{2}} W_{\pm p,\,3/4}[\pm i\bar{k}(1+bz_1)^2/b] \qquad (6)$$

where $p = i\gamma^2/4\bar{k}b$ and $W_{p,m}$ is a Whittaker function. The bar above a symbol is used to denote its value at the lower face of the ionosphere.

Using equation (6) it can be shown that:

$$Z_s = \frac{\omega\mu_0}{\bar{k}}\left[-\frac{ib}{2\bar{k}} \pm \frac{2W'_{\pm p,3/4}(\pm i\bar{k}/b)}{W_{\pm p,3/4}(\pm i\bar{k}/b)}\right] \qquad (7)$$

where the dash on the Whittaker function denotes differentiation with respect to its argument. Provided $|b|$ is not too large the Whittaker functions may be replaced by their asymptotic expansions. Writing $\bar{k}^2 \doteqdot i\omega\,\mu_0\bar{\sigma}$ and neglecting $\gamma^2/\bar{k}^2$, a series for Z_s is obtained which, when combined with equation (4), gives:

$$D = \mp\frac{(1-i)}{2h}\left(\frac{\omega\varepsilon_0}{2\bar{\sigma}}\right)^{\frac{1}{2}} - \frac{b\varepsilon_0^{\frac{1}{2}}}{4h\mu_0^{\frac{1}{2}}\bar{\sigma}} \mp \frac{(1+i)5b^2\,\varepsilon_0^{\frac{1}{2}}}{8h\mu_0\omega^{\frac{1}{2}}(2\bar{\sigma})^{3/2}} + \qquad (8)$$

The real part of this formula gives the attenuation coefficient. The requirement that the wave amplitude decreases as the wave propagates resolves the ambiguity of sign in equation (8), the lower signs being taken.

When $b=0$ the ionosphere is homogeneous and only the first term remains, giving the result which is often quoted in this case[4]. When $b \neq 0$ the second term in (8) gives a constant shift, up or down, in the attenuation versus frequency curve. The third term varies as $\omega^{-\frac{1}{2}}$ and it is this and later terms which give rise to increasing attenuation as the frequency decreases to very low values. A similar behaviour results in the case of an exponential variation of refractive index when the exact solutions[3] are applied.

A much more complete investigation of these novel expansions for this and other profiles is at present being carried out and it is hoped to submit this work for publication at a later date.

Sudden Changes in Amplitude and Phase of 16 kc/s Very Low-frequency Signal received in New Zealand

In *Nature* of February 23, 1963, appears a report by P. Rohan, L. L. Anderson and D. J. Cooke on the anomalous behaviour of the radio signal received on 16 kc/s in South Australia.

We wish to confirm that very similar results, both in phase and amplitude, were obtained at Lower Hutt, New Zealand, on May 31 and June 25, 1962, at the times indicated in the report. Our records of *GBR* for June 11 and 12 may be among some sent overseas for investigation, so we are unable to examine them at present. However, a *GBR* receiver which we had operating in Wellington at the Time Service Observatory was observed by Mr. B. R. Gibson to give anomalous records on June 11 and 12. Our aerial was a bi-directional loop oriented to receive the maximum signal from *GBR*.

At the corresponding times on May 31, June 11 and June 12, the records of *NBA* 18 kc/s show nothing unusual. We do not have a record for June 25 of *NBA*.

From the Australian results and our own, we believe that it is likely that the anomalous signal on May 31 had a frequency of 4·5 ± 1 parts in 10^8 slow in respect to the 16 kc/s transmitted by *GBR*. On June 25 we have a record of 16 kc/s giving the sign and rate of change of phase and amplitude separately. The phase record during the disturbance is coherent although short, and indicates a frequency of 13 ± 3 parts in 10^8 fast with respect to the 16 kc/s transmitted by *GBR*.

The integrated amplitude of the anomalous signal received on May 31 and June 25 was about 4–5 times greater than the signal received from *GBR* when transmitting its normal duty cycle.

As no disturbance was observed on 18 kc/s there does not appear to have been a general disturbance of the ionosphere at the times in question. The unifo rm phase rate and the sudden cessation of the anomalous signal does not resemble a record obtained from a solar flare for instance. These disturbances were not observed by the British Post Office at Dollis Hill, so the signal transmitted

by *GBR* was normal. We believe that the National Bureau of Standards records also show no unusual occurrences.

As we are separated from Salisbury by about 3,200 km and as the National Bureau of Standards, Boulder, records were not affected, then presumably there is a powerful transmitter besides *GBR* able to operate on 16 kc/s relatively close to Australia and New Zealand.

This conclusion could be modified if the receiving aerials at the National Bureau of Standards are directional.

GEOPHYSICS

Radiogenic and Atmospheric Argon Content of Tektites

In previous publications it has been shown that tektites can be dated by the potassium/argon method[1-3]. The potassium/argon ages give the time of their formation and also show which tektite localities belong together. It has been found that tektites from North America, the moldavites and tektites from Indo-China, Indonesia and from Australia form three independent strewn fields. The size of the strewn fields is of crucial interest to all hypotheses concerned with the origin of tektites. Therefore, these experiments have been extended with improved techniques and with a larger variety of samples. The results are given in Table 1.

Table 1. Average Potassium/Argon Ages of the 4 Different Tektite Strewn Fields

Locality	Age (10^6y)
Georgia	34·0
Texas	34·2
Martha's Vineyard	33·7
Moldavites (results of 8 different localities)	14·6
Indo-China, Billiton, Java, Borneo and the Philippines (results of 12 specimens)	0·71
Australites (6 widespread localities)	0·72
Ivory Coast	1·3

Six specimens from different localities of Texas, two specimens from Georgia, and a fragment of the recently discovered Martha's Vineyard tektite gave the same age of $34{\cdot}2 \pm 2 \times 10^6$ y. The Texas tektites are found in the Jackson formation, which is late Eocene. The agreement with the potassium/argon age is quite good. The stratigraphy of the Georgia and Martha's Vineyard tektites is not well established. From the close agreement of the potassium/argon ages, one has to conclude that all North American tektites belong to one event.

Eight moldavites from different localities gave a potassium/argon age of $14{\cdot}6 \pm 0{\cdot}9 \times 10^6$ y. They form a distinctly different group. Their potassium/argon age is in reasonable agreement with their stratigraphic age, which is thought to be late Miocene.

Twelve samples from Indo-China and Indonesia, and six samples from Australia have been investigated. Although previously only one australite has been analysed, it was already indicated that all these tektites belong to one strewn field. For these reasons, more australites from widely spread locations throughout Australia have been selected. For all these specimens an age $0{\cdot}72 \pm 0{\cdot}6 \times 10^6$ y has been found, and, within the errors, no difference in the potassium/argon age of Indo-China, Indonesia, and Australia can be observed. This result has important consequences. While the tektite sites from Indo-China and Indonesia are thought to be of Middle Pleistocene age and agree within the uncertainties of the time scale with the potassium/argon ages, there seems to exist a discrepancy for the Australian tektites. Although no definite stratigraphic age exists for these finds, some authors believe that they can be only a few thousand years old[4,5]. Some of them were found 5 m deep in the clay drift of an old river course; others were lying at the surface and in recent soils. The fact that older material can always be transported in younger deposits makes an estimate of the age difficult. An underestimation of the age seems to be likely. It is suggested, instead, that the potassium/argon measurements be considered as a basis for the age discussion, and that confirming geological evidence be sought. There are also relations in the chemical composition among the whole group of these tektites. The aerodynamic structures of australites are no longer an outstanding feature since these structures are also found in samples from Flores, Java, and Billiton.

If the australites were really younger the potassium/argon values could only be understood if the australites were incompletely degassed. It is, however, extremely unlikely that the amount of inherited argon in the australites is exactly the same as the radiogenic argon content of the tektites from Indo-China and Indonesia.

From these results, it may be concluded, therefore, that all tektites from this area belong to a single event. The strewn field is of tremendous dimensions, and reaches 8,000 km from Indo-China to Australia. This fact has to be faced by all hypotheses about the origin of tektites.

Three tektite specimens from the Ivory Coast have also been investigated, and their age has been determined to be $1{\cdot}3 \times 10^6$ y. These tektite finds have to be considered as a fourth independent strewn field. A comparison with the stratigraphic age is, however, not possible, since more should be known about the geology of their sites.

Table 2. Argon Excess and Gas Pressure in Bubbles of some Gas Rich Specimens. The Isotopic Composition of Argon is the same as in Air Argon

Locality	Argon excess ($\times 10^{-6}$ c.c./g)	Gas pressure in bubbles (mm Hg)	$^{40}A/^{36}A$ ratio
Muong Nong	1,040	40	298
Hai Nan	380	—	305
Philippinite	83	1·3	294
Ivory Coast	7·8	—	295
Libyan Desert Glass	290	24	300
Darwin Glass	440	—	305
Atmospheric argon	—	—	296

In addition to the age determinations, bubble-rich specimens have been investigated for excess gases of other than radiogenic origin[6]. These have been found in the Muong Nong tektites, in the Darwin Glass and the Libyan Desert Glass, and also in the Ivory Coast tektites. In these samples the gases are homogeneously distributed. Excess gases have also been found in some philippinites from the Santa Mesa district, which had visible macroscopic bubbles. Nitrogen, argon, krypton and xenon have been measured; their abundance and the isotopic composition of argon are the same as in air. By cracking the samples in the ultra-high vacuum it was found that these gases are mainly included in the bubbles. The pressure in the bubbles, calculated from the amount of gases released and from the deviation of the densities, reaches values up to 40 mm mercury (Table 2). The characteristic value of the $^{40}A/^{36}A$ ratio in air is a conclusive criterion that these gases are of terrestrial origin. Since the gases in most of these samples are homogeneously distributed and the weight of the Muong Nong tektites amounts to kg, the inclusion of the air cannot have occurred through ablation in the atmosphere. The high pressure found in some bubbles also indicates that tektites were molten close to the surface of the Earth. These investigations, therefore, are considered as further support to the hypothesis that the tektite material itself is of terrestrial origin.

PHYSICS

Radioactivity of Air Dust, Rain Water and Turf Grass in Bandung, Java

During the period November 1961–December 1962 the radioactivity found in air dust, rain water and turf grass was determined in one single place in Bandung.

The air dust was collected once a month on a sheet of tracing paper, about 0·19 m², covered with a layer of 'Vaseline' (about 2 g per sheet). The paper sheet was fixed at a height of 1·5 m on the internal wall of an enclosed yard and protected from the rain by a concrete horizontal shade. (As comparison with paper sheets exposed in the open shows, the deposition of dust on the paper placed in the yard was independent of the direction of wind but dependent on the degree of turbulence of the air produced in the yard.) The paper sheets were exposed during the last 10 days of every month.

The weight of ash obtained after burning the paper sheets varied usually between 200 and 350 mg per sheet, probably depending on the variety of paper and on the slight variation of the conditions under which burning was carried out. Total error of the determination of the weight of obtained ash was + 13 ± 10 mg. Specific radioactivity of the ash varied between 20 and 90 pc./g with an error of measurement between 300 and 25 per cent.

The rain water was collected in enamelled wash-basins placed in the yard on a table (0·5 m high) under open sky. The basins were normally put out when the rain had already begun and removed after the rain had stopped. The volume of collected and evaporated rain water varied between 1 and 7 l. ± 1 cm³, depending on the intensity of rain.

The weight of sediment obtained after evaporation of the rain water varied, usually between 8 and 35 mg (in one exceptional ease, 62 mg) depending on the quantity of evaporated water and its dust content, which varied usually between 4 and 25 mg/l. The error of weighing of the sediment was ± 0·5 mg due to unavoidable handling of evaporation dishes. The error due to precipitation of the dust from the rain water while it was in the storage before evaporation was usually about + 5 ± 2 mg, depending upon the kind of dust contained in the rain water. The error of sedimentation on the walls of the beaker during the first stage of evaporation was about + 4 ± 1·5 mg. Both of these positive errors were taken into account. Specific radioactivity of the sediment varied between 416 and 11,400 pc/g with an error of measurement between 300 and 5 per cent.

The grass was collected at the end of every month from the same place. The quantity of grass put on the drying shelf varied between 720 ± 1 and 120 ± 1 g. The quantity of dry grass obtained varied correspondingly between 138 ± 1 and 37 ± 1 g. The quantity of dry grass taken for burning was always 30 ± 1 mg.

The quantity of ash obtained after burning of the dry grass varied usually between about 4 and 3 g. The total error in the determination of the weight of ash was + 13 ± 10 mg. Specific radioactivity of ash varied between 120 and 300 pc/g with an error of measurement between 33 and 4 per cent.

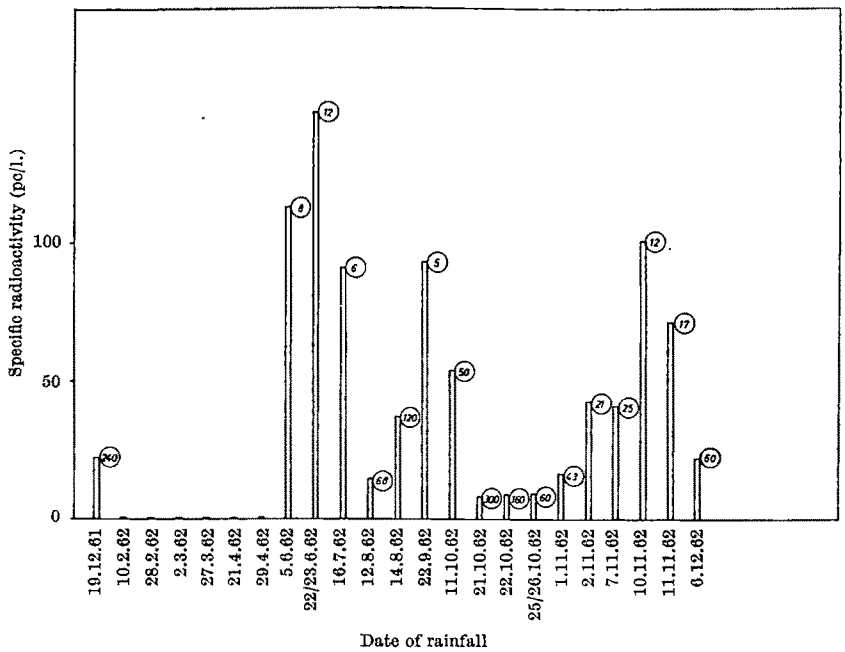

Fig. 1. Specific radioactivity of rainwater. Figures in circles indicate the relative errors of measurement (per cent)

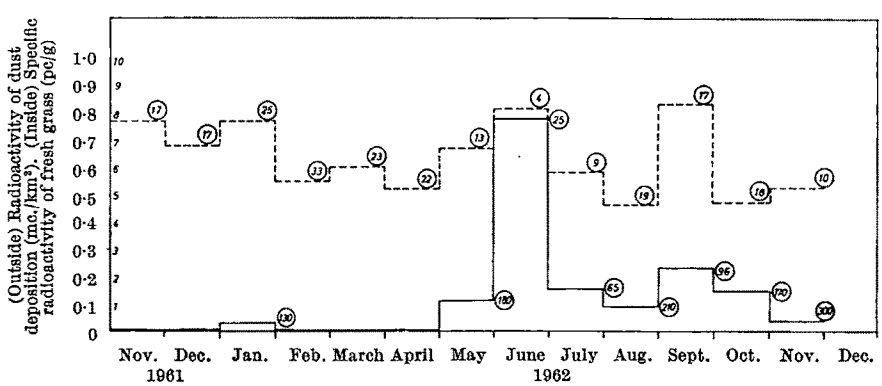

Fig. 2. —, Radioactivity of monthly dust deposition; – – –, radioactivity of monthly grass growth. Figures in circles indicate the relative errors of measurement (per cent)

The radioactivity of prepared ash probes was measured in the First Institute of Physics, University of Munich. The sensitivity of measuring equipment was 1 c.p.m. = 4·12 pc. The instrumental error was ± 3 c.p.m. (12·36 pc) and statistical error ± 0·4–0·6 c.p.m. Decrease of radioactivity due to decay during the delay of measurements was in all cases within error of measurement.

The radioactivity of air dust deposited per km², specific radioactivity of rain water and of fresh grass calculated from the obtained results of measurements are given in Figs. 1 and 2.

I thank Dr. Klaus Stierstadt of the First Institute of Physics, University of Munich, for measuring the radioactivity of ash probes.

Dislocations and Catalysis

CAUSAL connexions between dislocations and catalysis have been suggested by a number of workers over the past twenty years[1–6]. Conclusive evidence, however, has often been lacking because of surface contamination or other effects which could not be implicated as factors in catalysis. Recently an unusual amount of valuable results have been obtained on dislocations and mechanical properties of lithium fluoride crystals. Gilman[7–16], Forty[17] and Benson *et al.*[18] have determined the role of cleavage in nucleating dislocations in lithium fluoride and described the character of dislocations and stresses needed to produce them. This wealth of experimental results offers a fertile ground for exploring the role of dislocations in catalysis on this simple and well-documented crystalline substance. By using Gilman's[8,10,11,15] techniques for cleaving, etching, and stressing crystals it is possible to control the introduction of dislocations to a satisfactory degree and to identify them without spending a major effort on what could be a most illusory problem.

We are, therefore, examining dislocations and catalysis using this background on lithium fluoride and utilizing the reaction of dehydrogenation of ethyl alcohol. A precise reactor system similar to that described by Pozzi and Rase[19], but now made automatic and reduced greatly in size, is being used. Very pure (less than 1 p.p.m. impurities) grade lithium fluoride crystals obtained from the Harshaw Chemical Co. are cleaved into pieces approximately (1 mm × 2 mm × 2 mm) and tested in various ways.

A recent series of experiments has proved interesting as shown by the results in Fig. 1. Crystals of lithium fluoride were cleaved and treated in various ways in order to produce dislocation densities of different orders of magnitude (Table 1 outlines the history of each sample). The samples were then tested in the reactor at 260° C for acetaldehyde production. The differential-type reactor results enabled direct calculation of rates. These results represent the first quantitative representation of a correlation between catalytic activity and dislocation density.

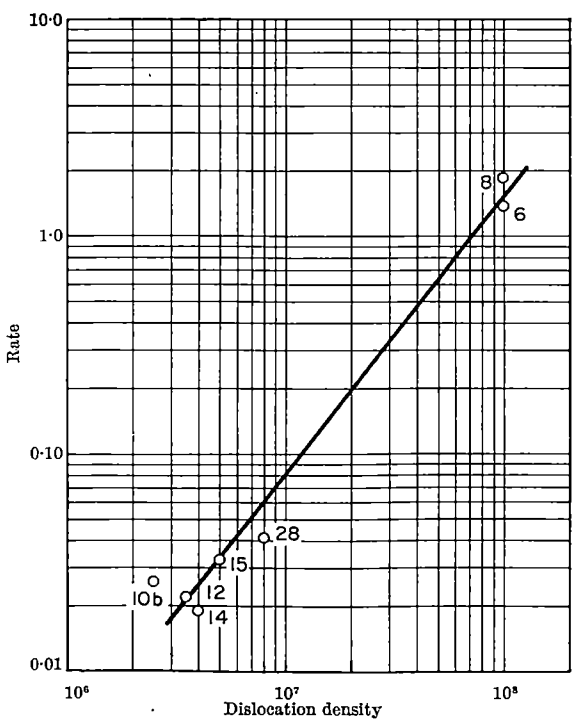

Fig. 1. Effect of dislocation density on catalytic activity of lithium fluoride crystals.

$$\text{Rate} = \frac{\left(\frac{\text{moles converted}}{\text{mole charged}}\right)\left(\frac{\text{c.c. ethanol}}{\text{h}}\right)}{\text{cm}^2 \text{ of surface.}}$$

Dislocation density = No. of dislocations per cm².

Table 1

Run No.	Treatment	Comments
6	As-cleaved	These samples exhibited unusually large numbers of dislocations when cleaved slowly
8	As-cleaved	
106	Cleaved, annealed and cooled rapidly	These samples showed moderate dislocation densities upon cleaving as shown in Fig. 1. Activity and dislocation density remained relatively constant before and after treatment
12	Cleaved, annealed and cooled rapidly	
14	Cleaved, annealed and cooled rapidly	
15	Cleaved, annealed and cooled rapidly and then each piece stressed	Prior to stressing no activity was observed
28	Annealed and cooled rapidly and then stressed prior to leaving	Samples of this material which had not been stressed showed no activity upon cleaving and testing. Dislocation densities in unstressed material were ~ 10^5

Equally as significant, however, is the rather dramatic production of activity in inactive and relatively dislocation-free crystals (for example, runs 15 and 28) by stressing annealed and rapidly cooled crystals. Gilman has shown that annealed and rapidly cooled lithium fluoride crystals are soft and moderate stresses can be applied to multiply dislocations profusely. We have observed this same phenomenon and seen the vastly increased numbers of dislocations on the etched crystals and the corresponding appearance of catalytic activity. Annealing and rapid cooling without stressing do not produce changes in dislocation density or catalytic activity.

Work is continuing to define these effects more precisely; but the value of the known techniques with lithium fluoride when applied to reaction studies has already been demonstrated, and the role of dislocations on catalytic activity of lithium fluoride has been demonstrated quantitatively.

We thank the National Science Foundation for supporting this work, and the Humble Oil and Refining Co. for a fellowship.

METALLURGY

Growth and Nucleation of the β→α Transformation in Uranium 0·45 per cent Chromium Alloy

THIS communication describes some experiments with uranium 0·45 per cent chromium, the purpose of which was to measure the growth and nucleation rates of α-uranium during the β → α transformation. To the best of our knowledge, these results are the first quantitative measurements of growth-rate of the β → α transformation.

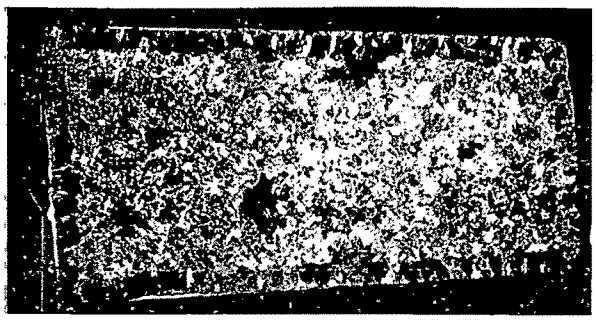

Fig. 1. Columnar growth in a uranium 0·45 per cent chromium specimen, solution treated at 720° C for 15 min followed by isothermal transformation at 625° C for 8 min (× *c.* 3·9)

The growth-rate G was established at four different temperatures by measuring the change in length of columnar grains after various transformation periods. In Fig. 1 the columnar grains formed isothermally at 625° C after 8 min can be seen clearly. The results of G are given in Table 1.

To calculate the rate of nucleation, $\dot{N}$, the relation $\dot{N} = G/D^4$ was used, where D is the mean macro grain size, measured after the completion of the transformation. The results of calculated $\dot{N}$ values are given in Table 2.

Table 1. Growth-rate as Function of Temperature

T (° C)	G cm/sec × 10^{+4}
630	0·47
625	1·00
615	1·30
605	1·78

Probable error ± 20 per cent.

Table 2. Rate of Nucleation as Function of Temperature

T (° C)	$\dot{N}$ $\frac{1}{\text{cm}^3\ \text{sec}}$
630	0·5
625	1·7
615	7·3
605	52

Further work is being conducted on various uranium alloys, and also attempts are being made to synthesize theoretical *TTT* curves from the measured G and calculated $\dot{N}$ values, and to compare them with experimental *TTT* curves.

MINERALOGY

Direct Electron-optical Resolution of Anti-phase Domains in a Silicate

In this communication the direct electron-optical resolution of anti-phase domain patterns in a plagioclase feldspar is recorded. (The specimen, from Frederiksvärn, Norway, was kindly provided by Dr. P. H. Ribbe. A partial chemical analysis, made by J. H. Scoon, yielded $KAlSi_3O_8$, 3·4 per cent; $NaAlSi_3O_8$, 45·2 per cent; $CaAl_2Si_2O_8$, 51·8 per cent by weight.)

Relevant X-ray diffraction data for material of this composition have been presented by Gay[1] and indicate that, in addition to primary Bragg maxima due to a triclinic unit cell (appropriate to this member of the solid-solution series albite-anorthite), additional maxima occur in pairs symmetrically disposed about the additional reciprocal lattice points due to a doubled unit cell (anorthite-type cell[2]). An electron diffraction photograph illustrating the character of these paired maxima is presented as Fig. 1*a*, where a single pair of the maxima have been ringed and the primary Bragg maxima have also been indicated, *B*.

In its essentials this distribution of intensity in reciprocal space can be compared directly with that observed by Glossop and Pashley[3] in the examination of anti-phase

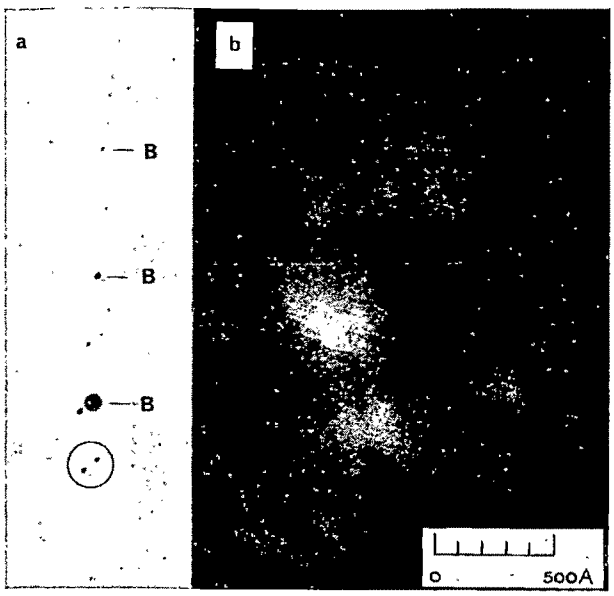

Fig. 1. *a*, Part of an electron diffraction photograph of the plagioclase studied. A pair of subsidiary intensity maxima have been ringed and the primary Bragg maxima have been indicated by letter *B*; *b*, part of the dark-field photograph obtained with a pair of diffraction maxima. The fringe pattern defines a distance of approximately 30 Å for the width of the individual domains

domains in an ordered copper–gold alloy; and implies, as suggested[4] in the case of nepheline where similar additional maxima are observed, that an antisymmetrical distribution in respect of a multiple cell is involved.

It has been possible in the feldspar, as in the alloys examined by Glossop and Pashley[3], to use the paired maxima for the direct electron optical resolution of the domain structure involved. This was done on finely crushed material mounted on a carbon film by selecting a single crystal orientated in such a way that a single pair of maxima, near the origin of the diffraction pattern, were in the reflecting position. The dark field image due to the pair of maxima was obtained by isolating them using a 25μ objective aperture but without introducing tilt in the direct beam. (The latter technique was used by Glossop and Pashley in order to obtain high resolution under dark field conditions.)

The anti-phase domains resolved during the present experiments were extremely regular and approximately 30 Å thick. The most striking feature of the anti-phase array (of which a small part is reproduced in Fig. 1*b*) was the absence of major dislocations in the pattern as studied in a semicircular area of 0·25μ radius.

The results of the present experiments were anticipated on the basis of a detailed thermodynamic analysis of anti-phase phenomena, as observed in several silicate systems, by one of us (J. D. C. McC.). This theoretical treatment, which will appear shortly, will deal with other aspects of the phenomena.

The present observations represent the first direct proof of the existence of anti-phase phenomena in crystalline solids other than the metal alloys. A model of similar character has recently been proposed for the plagioclase feldspars by Megaw[5].

The experiments described here were done on an *E.M.*6 which was kindly provided for the combined use of the Departments of Mineralogy and Geology at Cambridge by the Department of Scientific and Industrial Research.

CHEMISTRY

Dielectric Loss and Hydration of Sodium Chabazite

WE have measured the apparent permittivity, ε', and loss, ε'', of a sodium chabazite both anhydrous and partially hydrated. Powdered Bay of Fundy chabazite containing Na^+ and Ca^{++} in the approximate equivalent ratio 1 : 4 was cation exchanged to give a 95 per cent exchanged sodium chabazite. The powder was sieved through a 200-mesh sieve and packed in a concentric cylindrical cell described elsewhere[1]. It was then outgassed under vacuum for two days at 400° C. From the unit cell dimensions and the chemical analysis, the density of the anhydrous zeolite was calculated as 1·659, while the packing fraction of the powder in the cell was 0·445.

Measurements were then made of the apparent values of ε', ε'' and tan δ at 115°, 102°, 85°, 60°, 30° and −196° C, over a range of frequencies using apparatus already described[1]. From the apparent values of ε' and ε'', 'real' values ε_0' and ε_0'' were estimated from Bottcher's[2] approximate formula. Typical values are summarized in Table 1 for several temperatures. Both permittivity and loss are high and frequency dependent, although the limitations of Bottcher's formula means that accuracy in the figures may be rather low.

Table 1. 'REAL' DIELECTRIC CONSTANT AND LOSS FOR MASSIVE ANHYDROUS SODIUM CHABAZITE

Temperature (° C)		Frequency (kc/sec)					
		4	6	10	20	30	40
115	ε_0'	—	19·6	18·4	16·8	16·0	15·4
	ε_0''	—	5·54	5·47	5·72	6·01	5·53
102	ε_0'	18·0	17·0	15·5	13·6	12·6	11·9
	ε_0''	4·92	5·14	5·40	4·00	3·21	2·71
85	ε_0'	15·3	14·0	12·3	10·0	9·3	—
	ε_0''	4·49	4·80	4·40	2·44	2·03	—

As Fig. 1 shows, a loss peak was observed in curves of tan δ_{app} versus log f (f = frequency of a.c. field), at 115°, 102° and 85° C. The maximum moved to lower frequencies as the temperature was reduced and lay outside the practicable range of frequencies at 60°, 30° and −196° C. Even at the lower temperatures the zeolite was lossy, except at −196° C for the highest frequencies. At these temperatures, curves of log ε''_{app} versus log f had slopes differing from the value −1 which would correspond to d.c. conduction losses, except for a limited frequency range at −196° C.

Measurements were next made on the same specimen of sodium chabazite which had been allowed to take up first 4 per cent of zeolitic water and finally 11 per cent of water. The crystals when saturated sorb about 21 per cent by weight of water. In each of the partially hydrated states the loss peaks observed at 115°, 102° and 85° in the anhydrous state had moved out of the practicable frequency range as shown by the curves of ε''_{app} versus log f in Figs. 2*a* and *b*. Thus there is an interaction between water and the cause of the loss peaks.

The value of the activation energy for the process responsible for the loss peaks in Fig. 1, calculated by means of the Arrhenius equation from the temperature dependence of the frequency of maximum loss, is 7·5 ± 1 kcal per Avogadro number of unit loss processes. It has been established that, in other anhydrous zeolites at temperatures as low as these, the main charge transfer phenomena are due to cation movement[3]. Thus, at first sight it seems reasonable to ascribe the above value of the energy of activation to cation jumps within the crystal framework. It has been found that the self-diffusion of sodium and other monovalent cations in hydrated chabazites requires activation energies in the range 7–8 kcal per Avogadro number of unit diffusion processes[4], a value very close to that now observed for the dielectric loss process in

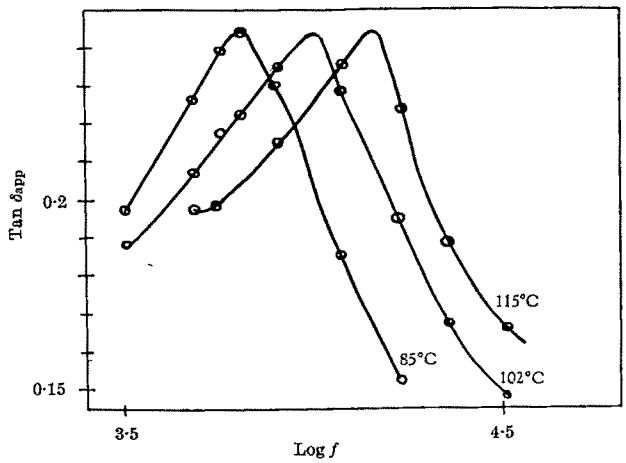

Fig. 1. Dielectric properties of anhydrous chabazite. tan δ_{app} versus log f

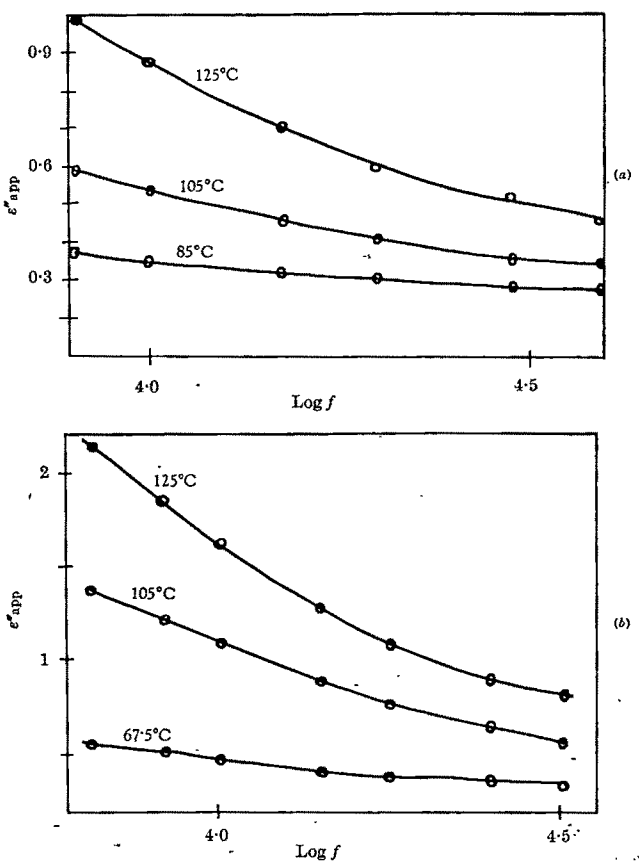

Fig. 2. Dielectric properties of partially hydrated chabazite. ε''_{app} versus log f. *a*, containing 4 per cent of zeolitic water; *b*, containing 11 per cent of zeolitic water

anhydrous sodium chabazite. On the other hand, for d.c. conductivity in anhydrous sodium-chabazite the larger energy of activation of 14–15 kcal was reported[5]. In another synthetic zeolite[3] it has also been found that the energy barriers for conduction differ considerably as between anhydrous and hydrated states, being larger in the anhydrous crystals. Thus, the loss peaks shown in Fig. 1 cannot with certainty be identified with intracrystalline d.c. cation jumps. Nevertheless, the interaction with water seems readily explained if the cause of the loss peaks is the sodium cations. It may, therefore, be that the loss peaks are due to sodium ion jumps in a partly hydrolysed surface skin on the sodium chabazite, or at dislocations or grain boundaries. It is interesting that

Ducros[6], in a hydrated calcium-rich chabazite containing a little sodium, found two kinds of loss peak associated with energy barriers of 16·1 and 8·0 kcal per Avogadro number of unit loss processes. The larger of these peaks was attributed to Ca^{++} and the smaller, possibly wrongly in view of ref. 4, was attributed to water. However, neither of the relaxation processes found by Ducros can be related to that which we have observed.

Mass Spectrometric Investigation of Reactions of Electronically Excited Neutral Particles with Alkali Metal Atoms

Recent development of radiation chemistry, gaseous electronics, plasma physics, and reaction kinetics in flames requires full understanding of elementary reactions occurring in highly energized systems. A substantial class of these reactions represent those between excited neutral particles and atoms or molecules (collisions of the second kind). However, knowledge of these processes is so far very limited, even though their important role, for example, in ionization phenomena in gaseous mixtures (Penning effect) has been known for a long time[1]. The need for further investigation became particularly apparent when collisions of the second kind were found, in which unexpected ions like $NeAr^+$, ArN_2^+, ArI^+, CH_4Xe^+, $C_2H_2Hg^+$ or N_2Hg^+ are formed[2–6].

We examined the reactions occurring in mixtures of noble gases and nitrogen with alkali metal vapours. The reactions occurred in an ordinary ionization chamber of the Nier type mass spectrometer[7]. The alkali metal vapour was introduced into the reaction region from a small furnace attached from one side to the ionization chamber. During experiments, the temperature of the furnace was controlled to ensure a constant pressure of the alkali metal vapour in the ionization chamber of the order of 10^{-5}–10^{-4} mm mercury. The total pressure of gaseous mixture varied up to 2×10^{-3} mm mercury. No special provision for homogenizing the electron energy was made.

The type of reaction and the nature of reacting particles were identified from the dependence of product ion current on the pressure of gaseous reactants, from appearance potentials of the ions formed, and from the shape of the molecular ion efficiency curves. The results are summarized in Table 1.

Table 1. Molecular Ions formed in Mixtures of Alkali Metal Vapour with Noble Gases and Nitrogen

Mixture	Product ion	Appearance potential (V)	Mixture	Product ion	Appearance potential (V)
He + Li	$HeLi^+$	19·3 ± 0·5	Kr + K	KrK^+	9·9 ± 0·5
Ne + K	NeK^+	16·7 ± 0·5	Kr + Cs	$KrCs^+$	9·8 ± 0·5
Ar + Li	$ArLi^+$	?	Xe + Na	$XeNa^+$	8·6 ± 0·5
Ar + Na	$ArNa^+$	11·3 ± 0·5	Xe + K	XeK^+	8·6 ± 0·5
Ar + K	ArK^+	12·0 ± 0·5	N_2 + Na	N_2Na^+	7·1 ± 0·5
Ar + Cs	$ArCs^+$	11·5 ± 0·5	N_2 + K	N_2K^+	7·3 ± 0·5
Kr + Na	$KrNa^+$	10·1 ± 0·5	N_2 + Cs	N_2Cs^+	6·8 ± 0·5

All the reactions found are of the same type

$$X^* + Me \rightarrow XMe^+ + e \qquad (1)$$

where X^* denotes an electronically excited atom (molecule) and Me an alkali metal atom. These reactions presumably occur together with concurring reactions leading to the ionizations of the metal atoms:

$$X^* + Me \rightarrow Me^+ + X + e \qquad (2)$$

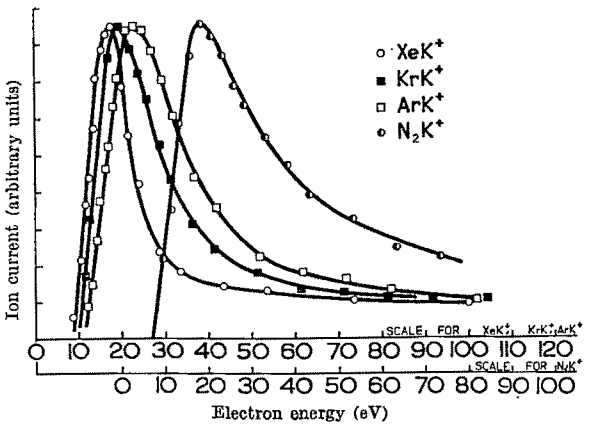

Fig. 1. Efficiency curves for ions XeK^+, KrK^+, ArK^+ and N_2K^+ (electron energy scale for N_2K^+ is shifted)

However, whereas the occurrence of reactions of type (2) can be *a priori* expected (ionization potential of Me is lower than the excitation energy of X), reactions (1) have not yet been reported. The formation of a molecular ion XMe^+ in reaction (1) is made possible by the fact that the electron released carries away the heat of reaction in the form of kinetic energy and stabilizes thus the molecular ion XMe^+.

In all mixtures with noble gases the appearance potentials of molecular ions XMe^+ correspond within experimental error to excitation potentials of the known metastable states of noble gas atoms (19·81 V for $He(2^3S)$, 16·61 V for $Ne(^3P_2)$, 11·54 V for $Ar(^3P_2)$, 9·91 V for $Kr(^3P_2)$ and 8·31 V for $Xe(^3P_2)$ (ref. 8). In mixtures with nitrogen the appearance potentials correspond to excitation potential of the metastable $A^3\Sigma_u^+$ state of N_2(7 V) (ref. 9). Reactions with molecules (atoms) in higher lying long-lived states cannot be excluded, but the measurement of appearance potentials of XMe^+ alone is not sufficient to decide the question.

The efficiency curves of XMe^+ ions exhibit in the case of reactions in noble gases a maximum at electron energies about 17–25 eV and decrease markedly with increasing energy. In the mixtures of alkali metals with nitrogen the maxima on efficiency curves are located at 18 eV (Fig. 1). The efficiency curves for various metals and the same gas coincide, within experimental error. The shape of the curves resembles that of the excitation functions of optically forbidden transitions. In our case, under the given pressure conditions, these curves reflect the abundance of excited metastable particles formed by electron impact both directly from the ground state via optically forbidden transitions and by cascade processes from higher lying excited states. The participation of meta-

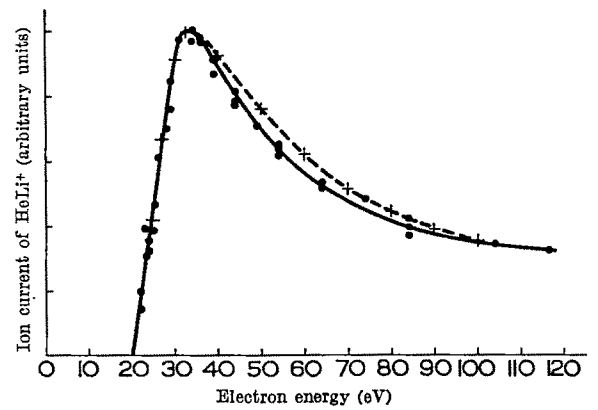

Fig. 2. Efficiency curve for $HeLi^+$ ion. Crosses and dashed line indicate the position of Dorrenstein's excitation curve for metastable helium atoms

stable particles in reactions (1) is supported also by the fact that the efficiency curve for $HeLi^+$ ion is practically identical with the electron excitation curve for metastable helium atoms which was obtained in a quite different way from secondary electron emission due to the arrival of separated metastable atoms at a metal surface[10] (Fig. 2).

The reaction cross-section may be at present only roughly estimated. Taking the mean path of the excited particle in the reaction zone $\approx 0{\cdot}25$ cm and the ratio of the corresponding excitation and ionization cross-sections (in the maximum of the excitation function) for argon $Q_e/Q_i \approx 0{\cdot}1$, the cross-sections for formation of $ArNa^+$, ArK^+ and $ArCs^+$ are $1{\cdot}5 \times 10^{-15}$ cm^2, 2×10^{-15} cm^2 and 5×10^{-15} cm^2, respectively. These results indicate that reactions (1) may effectively compete with ionization processes (2) for which a cross-section of the order of the gas kinetic cross-section may be expected.

It can be concluded that the formation of molecular ions in reactions with excited neutrals is a rather common process. Further investigation of these reactions promises to discover new ionic species, the knowledge of which may be of value in the aforementioned fields. Moreover, the formation of molecular ions may serve as a mean for the detection of excited molecular states. For example, if the molecular beam of metastable particles is used and the kinetic energy of the electron released in reaction (1) is measured, there may be obtained useful data on the energy levels of metastable biatomic and polyatomic molecules, data on the shape of excitation curves for intercombination transitions and an estimate of the bond strengths in new, unusual ions. Preliminary experiments in these directions have been commenced.

Equilibrium Coverage of Copper by Chemisorbed Hydrogen

Several instances have been given in the literature[1-3] in which copper will catalyse the *para-ortho* hydrogen conversion. This process requires the chemisorption of hydrogen, regardless of the reaction mechanism which may be prevailing.

Recently[4] the chemisorption of hydrogen by copper has been examined calorimetrically and volumetrically and the equilibrium surface coverage was found to be at a value of $\theta = 0{\cdot}15$, where the heat of adsorption was determined as 10 kcal/mole.

Confirmation of these values has been obtained in the course of a study of the kinetics of the *para-ortho* hydrogen conversion on evaporated metal films. It has been shown previously[3] that an investigation of the pressure dependency of the *para-ortho* hydrogen conversion enables a determination of the heat of adsorption to be made. In this manner the heat of adsorption of hydrogen on copper at equilibrium coverage was found to be 8·0 kcal/mole.

The Stevenson equation[5] has been used[6] to calculate a value for the heat of adsorption of hydrogen on copper, giving a value at zero surface coverage of $\Delta H_{\theta=0} = 25{\cdot}6$ kcal/mole. An experimental value of 28·0 kcal/mole has been reported[6] for silica-supported copper. The dipole moment of the hydrogen–copper bond may be calculated from the electronegativities of the elements as 0·73 Debye units, using Sanderson's[7] value for the electronegativity of hydrogen and calculating that for copper[6] from the work function as given by Michaelson[8].

The fall in the heat of adsorption with increasing surface coverage is related to the change in work function by the following equation[9]:

$$\delta(\Delta H) = e\Delta V \qquad (1)$$

where e is the electronic charge and ΔV the change in work function. The change in work function may be related to the surface coverage in the following manner:

$$\Delta V = 4\pi\sigma\mu\theta \qquad (2)$$

where σ is the number of surface sites per cm^2 and μ the dipole moment of the bond.

In the present case values of ΔH at equilibrium coverage of 10 kcal/mole and 8 kcal/mole were available, and the change in work function was calculated from equation 1. This value was substituted in equation 2 to obtain a value for the equilibrium surface coverage, θ. A value of σ for the 111 plane of copper was used. These calculations give, respectively, values of $\theta = 0{\cdot}17$ and $\theta = 0{\cdot}15$, which may be compared with the previously reported value of $\theta = 0{\cdot}15$.

The calculations assume no change in the dipole moment of the copper–hydrogen bond with increasing surface coverage. This seems reasonable as the surface of copper is sparsely populated and has been shown to be correct for hydrogen chemisorbed on nickel[10].

Behaviour of Polarons produced by the Action of Ionizing Radiation in Aqueous Media

It has been suggested[1,2] that the action of, for example, γ-rays on water leads primarily to the formation of radiation-produced electrons and the corresponding positive holes and that these electrons, and possibly also the holes, become self-trapped in the polar medium, water, leading to what should be regarded as 'polarons', in the sense of Landau, as discussed by Mott[3] and Pekar[4]. Afterwards, some definite experimental evidence was produced for the negative polaron[5,6]. This was based on its chemical reactions and reactivity, which in many cases (for example, with CO_2, leading to the formation of the CO_2^- radical ion[6]) were found to be different from hydrogen atoms which are known to be present in irradiated aqueous solutions under certain conditions. The chemical evidence concerning negative polarons has now been corroborated by the recent work using the methods of pulse radiolysis[7]. In pure water, the majority of the positive and negative polarons, $(H_2O)^+$ and $(H_2O)^-$, annihilate each other according to:

$$(H_2O)^+ + (H_2O)^- \rightarrow 2H_2O \qquad (1)$$

On the other hand, as suggested previously[1,2], the interaction of two polarons of the same species ('bipolarons') can lead to the 'molecular yield' processes. In the case of

the negative polarons, the formation of molecular hydrogen, according to:

$$(H_2O)^- + (H_2O)^- \rightarrow H_2 + 2OH^- \quad (2)$$

has now been confirmed by the recent pulse radiolysis work of Dorfman and Taub[8]. Formation of such bipolarons, even if rather short-lived, would be energetically favoured if the repulsion between the like charges is overcompensated by the increased polarization energy of the doubly charged species.

The theory of Pekar[4] allows to give an estimate of the region of optical absorption of the polaron or rather a relation between this and an effective mass of the electron (μ), according to the equation:

$$\hbar\omega_m \approx 0{\cdot}07\ \frac{\mu e^4 C^2}{\hbar^2} \quad (3)$$

where ω_m is the maximum (circular) frequency of absorption; $C = (\varepsilon_0^{-1} - \varepsilon_s^{-1})$, where $\varepsilon_0 = n^2$ is the optical dielectric constant and ε_s the static dielectric constant; $C \approx 0{\cdot}55$ for water at room temperature; the other symbols having their usual significance. In this theory the polar medium is regarded as a continuum and characterized by its optical and static dielectric constants; it is therefore applicable, in this approximation, not only to polar crystals but also to polar liquids.

Taking the observed maximum absorption of the negative polaron at $\lambda_{max} = 7000$ Å, one can obtain an estimate of the effective mass of the electron from equation (3) as $\mu \sim 3$, in units of the rest mass of the electron. A similar value can also be estimated from Feynman's theory[9].

The above value for the effective mass of the polaron leads to an estimate for its radius of the order of $r_p \sim 5$ Å, which means that the electron is not associated with a particular molecule but, corresponding to its de Broglie wave-length, is 'smeared out' over a number of water molecules (~ 10). These polarons could thus be written as $(H_2O)_n^+$ and $(H_2O)_n^-$; for the purpose of this and of our previous publications the subscript is omitted for simplicity.

It is clear from the above that it is more appropriate, therefore, to designate the self-trapped electron as a 'polaron' rather than as a 'hydrated electron', as the latter expression bears an obvious connotation to a hydrated ion, where the charge sits on a specific ion, with the water dipoles oriented around it.

Separation of Gases by Flow under Pressure through Porous Membranes

The separation of gases by permeation through membranes has been reviewed by several authors[1–4]. Since the observed separations do not always follow Graham's law, the mechanism is explained on the basis of solubility, diffusion and re-evaporation in the case of flow through 'non-porous' plastic films, and sorbed-flow through porous media.

The concept of preferential sorption at the gas-solid interface together with the flow of the interfacial fluid through capillary pores of size equal to, or less than, a critical diameter characteristic of the system offers a new approach[5]. The experimental technique consists simply in letting the gas mixture flow under pressure through an appropriate porous medium; the gas leaving the porous medium is enriched in the preferentially sorbed constituent. For a given separation problem, the physicochemical nature of the film material and the number of pores of appropriate size on the area of the film at the interface constitute the governing criteria for the development of films with superior separation and flow characteristics.

There is sufficient evidence in the literature to show that the physicochemical nature of the film surface affects the degree of separation of different gases[6]. Oxygen permeates faster than nitrogen in rubber and plastic films[7–9], and the reverse is true of flow through porous glass[10]. Different samples of the same type of film obtained from different sheets varied widely in their relative permeability values[9]; this is understandable since preferential sorption is a surface property.

Flow through microporous media has been discussed by Rutz and Kammermeyer[11]. For the mechanism of separation proposed here, gas flow through the films can still be laminar, and its rate can be increased, without affecting the degree of separation, by increasing the number of pores of appropriate size on the film surface. The effects of the different operating variables on the separation and flow characteristics may be expected to be similar to those discussed earlier with respect to liquid-solid systems[5].

A few experiments with air have recently been carried out to test the foregoing approach to gas separation. Porous cellulose acetate membranes (supplied by Schleicher and Schuell Co.) were initially shrunk in hot water, then dried and used. The film was held on a porous stainless steel backing plate suitably mounted on to a pressure chamber connected to a compressed air cylinder. The other side of the porous plate was open to the atmosphere. The experiments were carried out at laboratory temperature under static conditions of compressed air on the film surface. The compositions of the feed and permeated air were analysed using the mass spectrometer. The permeated gas was collected over water and its rate determined. A set of typical results is given in Table 1.

Table 1

Film No.	Operating pressure psig.	Flow-rate of permeated gas (c.c./min)	Composition of permeated gas* (%)		
			N_2	O_2	A
1	1,000	1·0	76·7	22·4	0·9
2	250	0·19	74·2	24·7	1·1
2	500	0·42	72·0	26·8	1·2
3	1,000	0·15	73·4	25·6	1·0
3	1,500	0·22	73·7	25·3	1·0
4	1,000	(not determined)	71·0	27·2	1·8

Area of film surface: 9·0 cm². Feed air composition* (per cent): nitrogen, 78·1; oxygen, 21·0; argon, 0·9.
* The feed air contained about 0·06 per cent carbon dioxide. The permeated gas showed an enrichment in carbon dioxide also. Since the analysis for carbon dioxide is not considered accurate in this investigation, the gas compositions here are given on carbon dioxide-free basis.

The permeated air was found to be enriched in oxygen, argon and carbon dioxide. The degree of separation increased with decrease in average pore size. Increase of operating pressure increased the rate of production of enriched gas almost proportionately without affecting the degree of separation. Even though the experimental conditions used here are far from ideal for the given separation problem, yet the results obtained are significant both with respect to the degree of separation and flow rate; they illustrate the essential validity of the new approach.

The foregoing technique is obviously applicable for the separation of vapours also[12]; in this case, the relative ease of condensibility of the vapour components under the

experimental conditions becomes an important additional factor affecting their separation and flow characteristics.

Thus, based on the concept of preferential sorption and capillary flow through critical and sub-critical pores, it seems possible to develop a general process for the separation of substances in gaseous, vapour or liquid solutions. It is clear that properly oriented researches on the precise physicochemical criteria of preferential sorption and the development of process techniques for making suitable high flow porous films can contribute much to the emergence of a new and versatile field of separation technology.

Calculation of Valence State Energies from Thermochemical Data

THE predictive power inherent in the concept of intrinsic bond energies has led to many attempts to calculate the energy of the hypothetical valence state of an atom in a molecule[1–7]. The intrinsic bond energy I can be defined[1] by the equation:

$$\Delta H_f = \Sigma V - \Sigma I \qquad (1)$$

where ΔH_f is the atomic heat of formation of a molecule, V is the energy of the valence state of an atom, and the summation is over all atoms and bonds in the molecule. The valence state of an atom in a molecule can be defined as the hypothetical state in which the free atom would find itself if the bond involved were broken without any change in the electronic configuration of the atom. Long has summarized the attempt to calculate the valence state energy of the tetrahedral carbon atom from thermochemical data[1]. He concluded that the probable limits for the energy of this state are approximately 60–70 kcal/mole. This value is quoted[6] as the only experimental value presently available for this quantity. (In several communications with people in this field it has been brought to our attention that this number is still widely quoted.)

One of the primary purposes of this communication is to point out that the limits for the valence state energy of the tetrahedral carbon atom given by Long were based on a value for the heat of atomization of graphite that is no longer accepted. Whereas Long used a value of 125 kcal/mole, it is now known that the heat of atomization of graphite is 171 kcal/mole[8–10]. Long himself stated that if the controversy over the value for the latter atomization energy were resolved in favour of the higher quantity, then his conclusions were invalid. As often happens in science these qualifications have been commonly ignored when the value of 60–70 kcal/mole is quoted for the tetrahedral valence state energy of the carbon atom. If Long's procedure is applied with atomic heats of formation based on presently accepted thermochemical data the lower limit becomes 6·8 and 0·8 kcal/mole instead of the previously reported 58·6 and 48·4 kcal/mole.

It is instructive to consider why Long's valence state energies become trivial when correct values for the thermochemical data are inserted in his procedure. He used equation 1 to set up simultaneous equations of the type:

$$\Delta H_{f,CH_4} = V - 4I$$
$$\Delta H_{f,CH_3} = V - 3I$$

based on the assumption that the valence state energies and intrinsic bond energies were essentially equivalent for CH_4 and CH_3. This is apparently unjustified. In point of fact the bond distances in CH_4 and CH_3 are 1·094 (ref. 8) and 1·066 Å (ref. 11), respectively, indicating that the C–H bond in CH_3 is stronger than in methane. This point is also verified by the respective overlap integrals, calculated from Mulliken's tables[12]. The overlap for $sp^2\,\sigma - 1s$ at 1·066 Å is greater than that for $sp^3\,\sigma - 1s$ at 1·094 Å; it is believed that CH_3 is planar with sp^2 hybridization of the carbon atom[13,14]. The stronger C–H bond in CH_3 compared to CH_4 requires consideration of appreciably larger intrinsic bond energies for the CH_3 molecule, compared to CH_4.

Successful application of equation (1) to the calculation of the various valence state energies of carbon from thermochemical data requires either prior knowledge of the intrinsic bond energies, or exact relationships between the intrinsic bond energies in a dissociation sequence such as CH_4, CH_3, CH_2 and CH. Such information is not available at present. Actually, the only system that might presently be solved satisfactorily by Long's procedure is that for BeH_2 and BeH. Since the ground-state of the beryllium atom has the $2s^2$ electronic configuration, the principle of minimum energy for molecules requires that the beryllium atom in both BeH_2 and BeH be essentially sp hybridized, assuming that these molecules are mostly covalent. For the latter reason the intrinsic bond energies in both of these hydrides should be essentially equivalent, and V identical for the sp beryllium atom in both molecules, since the valence state energy is based on isolated atoms. One can then solve the following equations to obtain V and I.

$$\Delta H_{f,BeH_2} = V - 2I$$
$$\Delta H_{f,BeH} = V - I$$

Unfortunately the atomic heat of formation for BeH_2 has not been experimentally determined. Using an empirically estimated value of $-153 \pm 3{\cdot}5$ kcal/mole (ref. 15) for this quantity with -53 ± 7 kcal/mole for BeH (refs. 8, 16) leads to $V = 47 \pm 17$ kcal/mole and $I = 100 \pm 10{\cdot}5$ kcal/mole. Better values for these energy quantities can be obtained only when better thermochemical data are available.

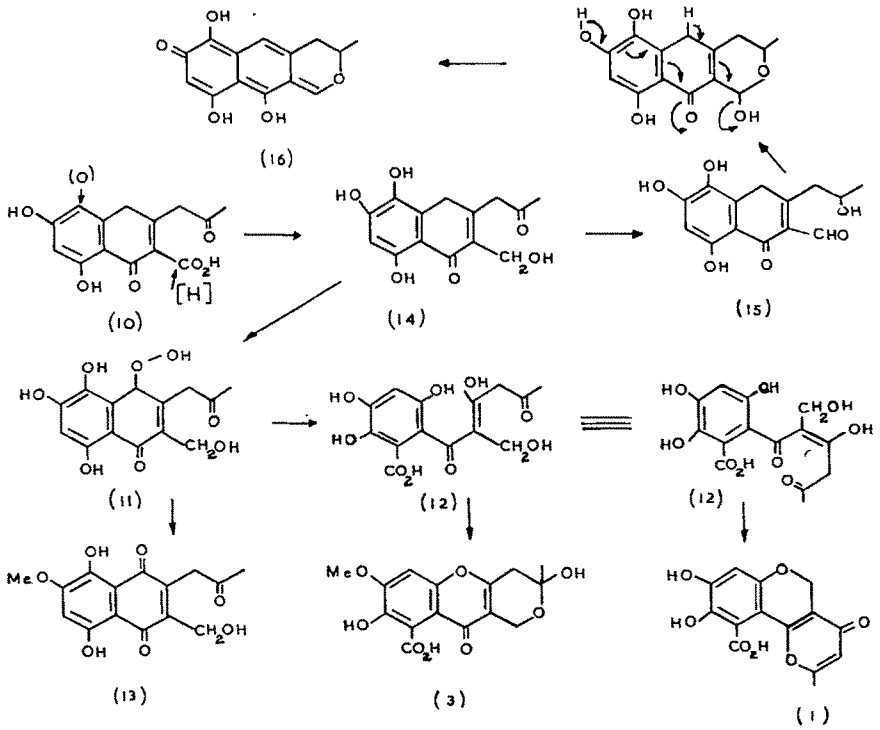
A Postulated Biosynthesis of Some 'Anomalous' Natural Phenolic Compounds



Considerable experimental evidence has been provided in recent years to substantiate Birch's biogenetic proposals[1] for the polyacetate derivation of a number of classes of naturally occurring phenolic compounds. However, certain phenolic substances are known which, although 'acetate-derived', cannot be formulated directly via a linear polyketide chain. Included in this 'anomalous' category are sulochrin (4), citromycetin (1), fulvic acid (3), and pinselic acid (2). To rationalize the structures of these compounds, Birch[1] and Thomas[2] have each postulated a branched polyketide precursor.

An alternative biogenetic pathway has been proposed[3] which involves an unelaborated 'oxidative cleavage' of well-known hydroxyanthraquinones. Thus, the structure of sulochrin and pinselic acid can be derived by application of this process to the anthraquinones emodin (6) and helminthosporin (5) respectively. These ideas are supported by the established co-occurrence of emodin 5-methyl ether and sulochrin[4]. It has further been suggested that citromycetin could be derived from oxyjavanicin (fusarubin) by a similar oxidative cleavage followed by cyclization[4,5].

It is proposed here that the oxidative cleavage reaction occurs at an earlier stage in the biosynthetic pathway by means of a rational mechanism based on plausible chemical analogies. Thus, in the case of sulochrin (4) the hypothesis envisages the initial formation of emodin anthrone by the usual cyclization of a linear polyketide chain, followed by oxygenation at the reactive meso-methylene position of the anthrone or anthranol to form the hydroperoxide (7). By the acceptable rearrangement mechanism shown, this hydroperoxide can be transformed to the sulochrin structure (for close chemical analogies see 6); the ready conversion of this intermediate to emodin is, of course, straightforward. In an exactly analogous manner pinselic acid (2) may be derived from helminthosporin anthrone (8) via fission of an intermediate hydroperoxide (9) followed by cyclization to produce the xanthone structure.

In the corresponding naphthalene series, cyclization of a linear polyketide chain in the usual manner would provide a naphthol tautomer (10), capable of transformation into the hydroperoxide (11). By the foregoing rearrangement this furnishes the intermediate (12), which possesses two

plausible modes of cyclization; the first leads to the structure established for fulvic acid (3) while the second produces citromycetin (1). Transformation of the hydroperoxide (11) without re-arrangement leads, of course, to oxyjavanicin (fusarubin) (13). It is also significant that the intermediate (14), without involving a change in oxidation state, can be transformed plausibly via (15) to the structure (16) already established for purpurogenone.

The ready oxidation of anthranols to hydroperoxyanthrones has indeed been demonstrated *in vitro* in these laboratories[7], and thus, practical precedent has been provided for the primary key-step in the above rationalizations. Further work is now in hand on these synthetic hydroperoxides to parallel the subsequent transformations.

RADIATION CHEMISTRY

Ultrasonic Effect on Neutron-irradiated Inorganic Solid Compounds

Intense ultrasonic waves are known to cause chemical effects in liquids and solutions similar to those caused by ionizing radiation. It is also well known that neutron-irradiated solid compounds can be annealed by heating (thermal annealing) as well as by treatment with ionizing radiation (radiation annealing) and, in some cases, by ultra-violet light (photochemical annealing). Therefore, it was of interest to see if it were possible to anneal neutron-irradiated solid compounds under the influence of intense ultrasonic waves. As model substances for this purpose potassium sulphate and ammonium sulphate were chosen because their thermal and photochemical annealing behaviour had recently been examined[1–4].

Samples of solid potassium sulphate and ammonium sulphate, both reagent-grade, were irradiated for 3 and 4 weeks respectively in the thermal column of the *Bepo*-pile, Harwell, at a thermal flux of 10^{10} n.s.$^{-1}$ cm^{-2}. As an ultrasonic source a quartz-oscillator with a frequency of 800 kc/s and an output power of 2 W/cm^2 was used. The samples of the neutron-irradiated material (about 500 mg) were kept in thin nylon bags in a suspension of water-free carbon tetrachloride. The bags were closed so that no air bubbles were present and then placed in a beaker, having a polished bottom, containing carbon tetrachloride. For a good join of the beaker to the oscillator glycerine was used. The duration of the ultrasonic treatment was varied from a few minutes up to 50 h and the temperature of the samples kept between 18° and 20° C by a water-cooling system.

Because of the recoil energy of the ^{35}S atom after the nuclear reaction $^{34}S(n, \gamma)^{35}S$, a part of the ^{35}S is present in form of sulphite. The separation of sulphate and sulphite as well as the separation of ^{32}P and ^{33}P, which are also produced ($^{32}S(n, p)^{32}P$, $^{33}S(n, p)^{33}P$), was achieved by using suitable inactive carriers and hold back-carriers, as described earlier[1,2]. The activity of ^{35}S of the sulphate and the sulphite was measured by a Geiger–Müller counter with a very thin window. The standard deviation was less than 1 per cent.

It was found with the neutron-irradiated potassium sulphate that the retention (ratio between ^{35}S activity in the sulphate form and the total ^{35}S activity) at first rises rapidly with duration of ultrasonic treatment, reaching a plateau of between 8 and 12 h, and then becomes successively smaller. Some typical results are shown in Table 1.

From these experimental results it can be assumed that ultrasound causes two processes in the neutron-irradiated potassium sulphate, namely, 'ultrasonic annealing' and

Table 1. Retention (*R* per cent) of Neutron-irradiated Potassium Sulphate as a Function of Time of Ultrasonic Treatment

Duration of ultrasonic treatment (h)	Without	2	8	12	25
% *R*	79·0	83·5	89·5	90·3	82·7

'ultrasonic damage' ('phonolysis'). In other words: the introduction of vibratory motion at ultrasonic frequencies into the neutron-irradiated potassium sulphate leads to a significant annealing process simultaneously with a damage effect. Only a small part of the fragments formed due to the recoil after the (n, γ)-process, possibly that which has a smaller activation energy, seem to be annealed under the given circumstances. As soon as this process has reached its plateau, phonolysis becomes more and more visible. Both processes, ultrasonic annealing and phonolysis, are supposed to take place simultaneously and to compete with one another.

From the neutron-irradiated ammonium sulphate the bigger crystals (corn size 1–2·5 mm) have been separated and the smaller ones ground to a corn size of 10^{-2} to 10^{-1} mm. The ground crystals showed under the influence of intense ultrasonic waves a small rise of retention in comparison with the selected rough crystals. Both parts, fine ground and rough crystals, have been treated separately in small portions by ultrasound as described above.

Table 2 shows some average results.

Table 2. Dependence of Retention (*R* per cent) of Neutron-irradiated Ammonium Sulphate on Duration of Ultrasonic Treatment

Duration of ultrasonic treatment (h)	Without	2	10	20
Rough crystals (1–2·5 mm) *R* %	59·6	61·8	57·0	54·6
Ground crystals (10^{-2}–10^{-1} mm) *R* %	61·2	60·5	52·2	46·7

It has been found that the effect of ultrasound on the ground crystals was much higher than in the rough ones. Obviously the displacements caused by the grinding-process of the fine crystals possess high absorption properties for ultrasound, which leads to more prominent chemical effects.

It was established recently[4] that hydrazine has been formed in solid ammonium sulphate under the influence of neutron irradiation. This can be explained due to both nuclear recoil and the chemical effect of the γ-radiation in the pile. Therefore, the amount of hydrazine produced depends on the dose of neutrons as well as on the dose of γ-radiation. Hydrazine formation was also observed when neutron-irradiated ammonium sulphate was post-irradiated with ultra-violet light[4].

Apart from the above it was found that small amounts of hydrazine were also produced by ultrasonic treatment of inactive finely ground ammonium sulphate. By ultrasonic treatment of neutron-irradiated ammonium sulphate an additional amount of hydrazine is found. Its yield in this case is a function of the duration of the ultrasonic treatment. The curve for the rough crystals shows a plateau, while it passes through a maximum in the case of the finely ground crystals. For the explanation of this fact one can assume that as a result of the higher ultrasonic absorption in the fine crystals, which leads to an increased formation of hydrazine, an increase of its diffusion is also achieved. Consequently the hydrazine can react more efficiently with the recoil fragments of the sulphate and reduce them to sulphite, and on the other hand, because of the small size of the crystals, the hydrazine can also diffuse out more easily. It is also very probable that simultaneously with these processes the effect of ultrasonic damage appears as with potassium sulphate. The hydrazine in all samples was determined after the method of Watt and Chrisp[5]. Table 3 shows some experimental results.

Table 3. Formation of Hydrazine in Solid Ammonium Sulphate by Neutron Irradiation and Ultrasonic Treatment

Duration of ultrasonic treatment (h)	Without	10	20	50
μg N_2H_4/mg $(NH_4)_2SO_4$ in ground crystals without neutron irradiation	0·0	0·003	0·004	0·006
μg N_2H_4/mg $(NH_4)_2SO_4$ in ground crystals neutron irradiated	0·275	0·370	0·361	0·348
μg N_2H_4/mg $(NH_4)_2SO_4$ in rough crystals neutron irradiated	0·275	0·310	0·326	0·334

Finally, it can be stated that by ultrasonic treatment of neutron-irradiated solid compounds, of the same type as potassium sulphate, two processes are in competition, namely, ultrasonic annealing and ultrasonic damage. In the case of neutron-irradiated solid ammonium salts an additional reducing process occurs, caused by the hydrazine, which can be formed due to the γ-radiation and recoil effects in the pile as well as because of the ultrasonic influence.

I thank Prof. B. Karlik for her advice, Prof. E. Schmid for the loan of an ultrasonic apparatus and for helpful assistance by Dr. D. Oelschlägel in carrying out the ultrasonic treatment. I also acknowledge the financial support awarded by Bundeskanzleramt of Republic Austria, Sektion IV, Verstaatlichte Betriebe.

Radiation Yield of Citraconic and Mesaconic Acids in Aqueous Solution

Experiments have been carried out in order to ascertain whether the double-bound radiolability of citraconic acid is different from that of its isomer mesaconic acid in aqueous solution. Mesaconic and citraconic acids were purchased from Fluka and were used without further purification. The water was prepared by distillation of de-ionized water from potassium permanganate. The solutions were irradiated with a cobalt-60 source at $(4{\cdot}20 \pm 0{\cdot}12) \times 10^{15}$ eV/(ml. × min). The source calibration was made with the Fricke dosimeter[1]. The determinations of mesaconic and citraconic acids were carried out spectrophotometrically at 220 mμ by a Beckman spectrophotometer model *DU*. When carboxylic group is conjugated with C=C, its absorption band in the ultra-violet regions is shifted to longer wave-lengths and the molecular extinction coefficient is increased at the same time by a factor of about 10^2 (ref. 2).

Therefore the decrease of optical densities of our irradiated solutions is due mainly to the opening of double bound. Indeed the solutions lose at the same time their strong absorption band and their ability to reduce potassium permanganate while their acidity is little reduced; for example, for a 5×10^{-2} M solution of irradiated citraconic acid the decrease of optical density was found to be 65·5 per cent and that of acidity was 2·7 per cent; for a 5×10^{-2} M solution of irradiated mesaconic acid the analogous data are 62·0 and 8·0 per cent.

Solutions of mesaconic and citraconic acids of the following molarities were irradiated in opened glass test

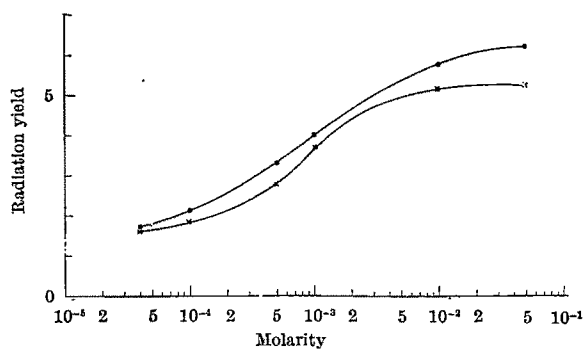

Fig. 1. ×, Citraconic acid; ●, mesaconic acid

tubes at room temperature: 4×10^{-5}; 10^{-4}; 5×10^{-4}; 10^{-3}; 10^{-2}; 5×10^{-2}. The G values (number of events for every 100 eV absorbed) were calculated at every concentration by least-squares method from the initial slope of the plot of destroyed molecules number against absorbed eV. The G values obtained are reported in Table 1 and plotted in Fig. 1.

Table 1

Initial molarity	G values Citraconic acid	Mesaconic acid
4×10^{-5}	1·56 ± 0·02	1·73 ± 0·06
10^{-4}	1·84 ± 0·02	2·13 ± 0·10
5×10^{-4}	2·76 ± 0·11	3·26 ± 0·12
10^{-3}	3·69 ± 0·09	3·99 ± 0·07
10^{-2}	5·15 ± 0·10	5·74 ± 0·04
5×10^{-2}	5·22 ± 0·06	6·19 ± 0·07

Table 2

Initial molarity	Maleic acid	Fumaric acid
$5{\cdot}00 \times 10^{-4}$	2·50 ± 0·02	2·54 ± 0·03
$5{\cdot}00 \times 10^{-4}$	3·64 ± 0·03	3·52 ± 0·02
$5{\cdot}00 \times 10^{-3}$	6·45 ± 0·08	6·01 ± 0·16
$1{\cdot}25 \times 10^{-2}$	8·87 ± 0·15	8·99 ± 0·05
$2{\cdot}5 \times 10^{-2}$	9·68 ± 0·14	10·75 ± 0·36

It can be seen that the radiation yields increase for both compounds with the concentrations of the solutions to attain almost a saturation value and that the radiation yields of the two isomers are different; particularly the radiation yields of *cis* form are lower than those of relative *trans* form. It is interesting to compare these results with those which we obtained[3] for the fumaric and maleic acids. They are summarized in Table 2. It can be observed that no difference exists between their G values in the range of experimental concentrations and that the substitution of a hydrogen atom of fumaric and maleic acids with a methyl group lowers the radiation yield of the double bound. This effect is more significant for the *cis* isomer. Therefore it seems that a steric factor plays a part in the double-bound stability of γ-ray-irradiated solutions of fumaric, maleic, citraconic and mesaconic acids.

Light Emission during the Neutralization Reaction in Presence of a Chemiluminescent Radical Indicator

Recent publications by Stauff *et al.*[1-3] of the results of experiments in which light emission during neutralization of sodium hydroxide with sulphuric acid was observed have prompted us to submit herewith the results of somewhat similar experiments of our own which were conducted some time ago.

In the course of experiments designed to determine whether the emission observed by Audubert[4] during neutralization extended into the visible wave-length, it was discovered that greater than expected yields of light were obtained. Since addition of chemiluminescent substances increased the yield without altering the characteristics of the light pulses the light was attributed to contamination of the solutions used with minute amounts of such substances. So far as we were then aware this type of 'activation' of chemiluminescence had not previously received attention. Since chemiluminescence of the phthalazdiones is observed as a result of reactions involving free radicals[5-8] some experiments were performed to try to determine whether in this case the flash of light emitted was the result of radical formation initiating an oxidation

Table 1. Magnitude of Light Flashes following Sequential Injection of 0·5 ml. Portions of Various Solutions into 5 ml. of 0·2 M Sodium Hydroxide containing Initially 0·15 μmole of Luminol

Substance added	Quantity (μmoles)	Maximum intensity * (galv. deflexion) (amp × 10^9)
None ('steady state')	—	1·0
'Versene' †	6	1·9
'Versene' †	6	0·09

Luminol	0·6	1·8
NaOH	400	1·8
HCl	100	2,800
CCl_3COOH	100	2,800
None ('steady state')	—	1·0
KNO_3	24	1·0
HCl	100	0·06

* A reading of approximately 3×10^{-9} amp is given by a blue light source emitting 10^8 quanta per second.
† Added as the tetrasodium salt.

of the luminol (5-amino-2,3-dihydro-1,4-phthalazinedione) used. The luminol was prepared by the method of Drew and Pearman[9], but commercially obtained material was also found to be effective.

Table 1 shows the effect of injection of 0·5 ml. portions of 0·2 M acid into 5 ml. of 0·2 M sodium hydroxide containing 0·15 μmole of luminol in front of a photomultiplier arrangement similar to that described by Cormier[10] and capable of easily measuring light emission from a source emitting about 10^7 quanta per second of blue light. Air was bubbled through the solutions throughout the experiments. Also shown is the effect of adding tetrasodium ethylenediamine tetraacetate, a substance the presence in solution of which improves the reproducibility of the results. Figs. 1 and 2 show characteristic recordings of results with and without the chelating agent. It may be noted from Table 1 that injections of potassium chloride or of demineralized water did not cause a light flash. The type of acid does not seem to be important as is shown by the response to trichloroacetic acid. Other acids tested which gave positive results were sulphuric, nitric, acetic, carbonic and succinic acid. The alkali may be replaced by sodium carbonate.

In order to test for radical involvement, additional luminol was injected (as shown in Table 1) until sufficient light intensity extending over a period of time was obtained. The addition of a small amount of potassium nitrite had no effect but the subsequent injection of acid brought the light emission to background at once instead of causing a flash. In the absence of more likely alternative explanations it may be assumed that production of NO during acid addition provided an effective radical trapping agent. Similarly, the addition of mercaptoethanol in quantities insufficient to remove the dissolved oxygen dimmed or abolished both the 'steady state'

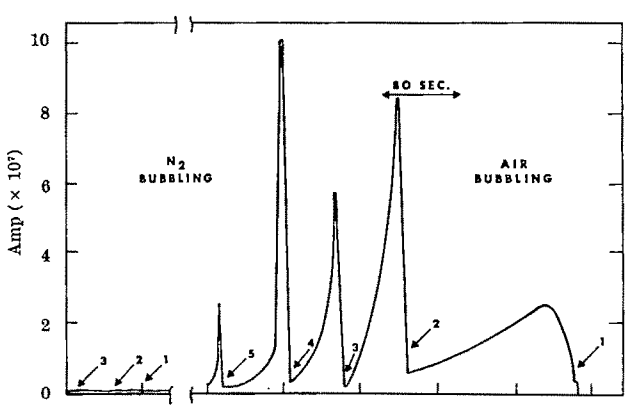

Fig. 1. Typical light pulses following injection of 0·5 ml. portions of 0·2 molar HCl into 5 ml. of 0·2 molar NaOH containing 0·15 μmole of luminol. The injections were made sequentially as indicated by the numbered arrows. Also shown is the effect of replacing air by nitrogen

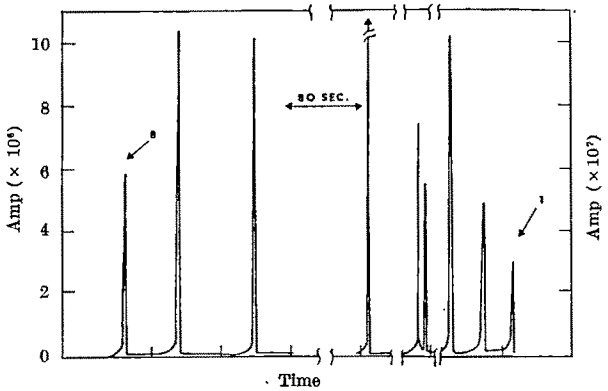

Fig. 2. Effect of versene on light pulses during neutralization in the presence of luminol. Conditions same as for Fig. 1 except that 6 μmoles of tetrasodium ethylenediamine tetraacetate were added. The fourth injection was divided and the full-scale deflexion is 3×10^{-6} amp

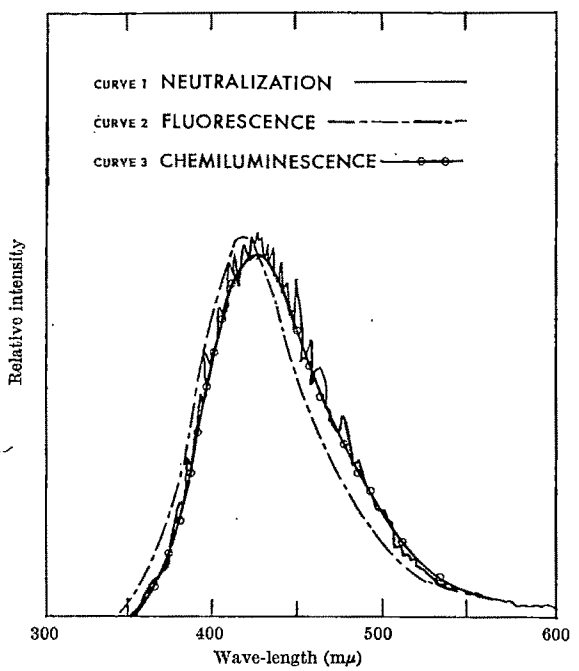

Fig. 3. Spectrum of light emitted during partial neutralization of 0·2 M NaOH with 0·2 M HCl in the presence of about 2×10^{-4} molar luminol compared with chemiluminescence spectrum and with fluorescence spectrum of luminol under similar *p*H conditions

emission and the neutralization flashes. Replacement of the air with nitrogen drastically reduced the intensity or abolished the flashes also (Fig. 1).

To show conclusively that the emission observed was that of the typical chemiluminescent oxidation of luminol an experiment was conducted in which 0·2 M hydrochloric acid was mixed with 0·2 M sodium hydroxide 3×10^{-4} M in luminol in a continuous-flow apparatus in such a manner that there always remained a slight excess of alkali. The mixing tube was placed in front of the slit of a monochromator (Aminco-Keirs spectrophosphorimeter) and the spectrum recorded during the mixing. The results of this experiment are shown in Fig. 3 (curve 1), together with the emission spectrum of the fluorescence of the sodium hydroxide solution of luminol excited by light of wavelength 350 mμ from the same tube placed in the same position (curve 2). The chemiluminescence emission spectrum was also taken by adding an excess of $K_2S_2O_8$ as a source of 'radicals' to the same tube. This is shown in curve 3. The results leave no doubt that the neutralization emission is due to chemiluminescence and not to fluorescence of luminol excited by some other means.

These results appear to suggest that hydroxyl radicals are present in not insignificant amounts during the formation of water in the neutralization reaction. The only alternative explanation that appears to us to have any probability is that the acid may change the state of some very effective catalyst present as a trace impurity. Such a catalyst might be expected to increase light emission in the presence of small amounts of peroxide. In this connexion freshly prepared luminol solutions were equally as effective as those which had stood for some days.

Whatever explanation is ultimately found to be the correct one, it is clear that neutralization may have unexpected effects on organic solutes. Even though quantitatively the effect may appear small when compared with the total chemical change, alterations in materials of high molecular weight might be profound. Should this phenomenon prove to be general, its importance in biological material may be highly significant, especially with respect to spontaneous mutation and to senescence.

BIOPHYSICS

Adsorption Chromatography of Direct Azo Dyes

Direct azo dyes contain in most cases a number of coloured by-products which may adversely influence the shade of the dye, its stability in light and distort its biological action. In view of the importance of direct azo dyes in industry as well as in biology and medicine a number of authors[1–10] worked on the problem of their purification. So far it has not been possible to separate these dyes completely (strong adsorption of dyes on cellulose in paper chromatography or electrophoresis, losses during crystallization, etc.). This communication describes a simple method of separation which excludes use of cellulose. Tests with agar electrophoresis, though there was some movement of dyes, did not lead to satisfactory separation. Therefore, I carried out adsorption chromatography on aluminium oxide. This method, though it has been frequently used for the separation of other dyes[11–15], has not been used in practice for direct azo dyes.

For preparation and analytical purposes the chromatography was carried out on columns 200 × 40 mm; for analytical purposes only, columns 150 × 10 mm were also used. In most cases a commercial aluminium oxide was used for chromatography (LACHEMA, Č.S.S.R.) which was not processed in any special way. On the column (200 × 40 mm) 0·01–1·00 g of dye was applied, dissolved in about 50 ml. 96–80 per cent ethanol, the concentration being dependent on the type of dye and on alkalinity of aluminium oxide. For elution the same solvent was used. When any fraction was eluted too slowly or not at all, I increased the proportion of water in the solvent up to 40

per cent. The fractions were collected by means of an automatic fraction collector and their absorption spectra were assessed. Thus we obtained from commercial congo red or congo red synthesized by myself two dyes, the first having an absorption maximum at 485 mμ, and a second one (real congo red) with a maximum at 498 mμ. The course of the absorption spectra of individual fractions is shown in Fig. 1. In a similar way from trypan blue (synthesized from commercial preparations of *o*-tolidine and 1 - amino - 8 - hydroxynaphthalene - 3,6 - disulphonic acid) three fractions were obtained: the first one with an absorption maximum (λ_{max}) of 560 mμ, a second with λ_{max} 610 mμ, and a third weak, and not closely defined fraction. Direct blue 2*B* (*C.I.* 406) was also separated into three fractions: one with λ_{max} 555 mμ, a second one with λ_{max} 590 mμ, and a third one with λ_{max} 600 mμ. From direct green *B* (*C.I.* 593) five dyes were isolated with the following absorption maxima: (1) 388 mμ; (2) 376 mμ, 644 mμ; (3) 384 mμ, 534 mμ; (4) 374 mμ, 640 mμ; (5) 382 mμ, 556 mμ.

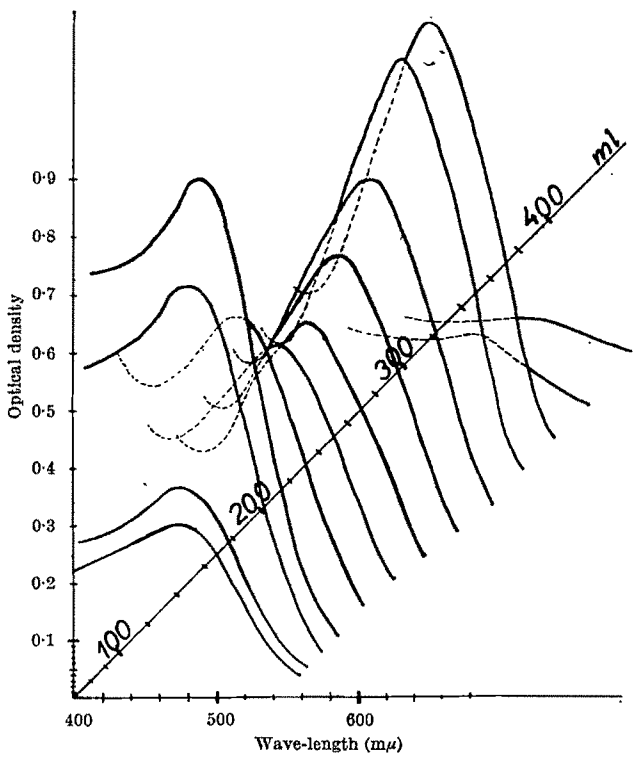

Fig. 1. Dependence of optical density on wave-length for fractions obtained from commercial congo red

I also used chromatography on thin layers of aluminium oxide with ethanol–water as a solvent, the ratio depending on the type of aluminium oxide and the dye. The dye was applied in the form of a 0·5 per cent solution in 50 per cent ethanol. By this method I was able to separate into their individual components congo red, trypan blue, direct blue 2*B*, direct green *B*, benzopurpurin, and direct red *F* (*C.I.* 419). Better separation of dyes was obtained as compared with paper chromatography (Whatman No. 1; 80 per cent ethanol or ethanol/ammonia/water (10 : 5 : 85) as a solvent).

As the commercial preparations of aluminium oxide are more or less alkaline and the degree of separation of dyes depends on the alkalinity of the aluminium oxide used, it is important to test the most suitable ratio of ethanol and water for every new type of aluminium oxide. This procedure is not required using neutral aluminium oxide prepared in a standard fashion. Moreover, ethanol with a higher water content may be used for elution, in which the dye is more easily soluble.

The importance of the purity of direct dyes in medicine and biology has often been demonstrated. The toxicity of non-purified preparation of congo red is much higher (LD_{50} 102 mg/kg) than in a preparation purified by crystallization (LD_{50} 320 mg/kg)[10]. In the case of Evans blue and trypan blue, which are used for estimation of the blood volume, other dyes present seemed to distort the results or give results which are not reproducible. A similar situation may develop when congo red is used in the diagnosis of amyloidosis. The importance of the purity of trypan blue was confirmed also by Beck, Spencer and Baxter[5]. The method of adsorption chromatography appears to be suitable for obtaining gram amounts of pure direct dyes as well as for assessing the content of coloured admixtures in commercial preparations of these dyes.

BIOCHEMISTRY

Effect of Phenolase on Anthocyanins

Several anthocyanin-decolorizing systems have been reported as present in leaves and fruits[1–4]. Although oxidizing enzymes are apparently involved, none has been isolated from these systems. In this communication the effect of a mushroom phenolase ('Tyrosinase', General Biochemicals, Inc.) on purified tart cherry anthocyanins is described. In view of the wide distribution and low specificity of phenolases, the testing of an enzyme not originating in the same tissue with the possible substrate seems justified, at least as a first step in the search for the enzyme responsible for the *in situ* reaction. Furthermore, phenolase activity has been detected in the cherries used here[5].

The anthocyanins were extracted from red, tart cherries (*Prunus cerasus*, var. Montmorency) with boiling ethanol, sorbed on 'Dowex 50W-*X*8' resin, eluted with methanol 0·3 N in hydrochloric acid, concentrated *in vacuo* and streaked on sheets of 3*MM* Whatman paper. After irrigating the paper ascendingly for 15–20 min with 1 M acetic acid solution, the two cherry anthocyanins appeared as well-separated zones. The pigment of each zone was eluted separately with methanol containing a trace of hydrochloric acid and the eluates were again concentrated *in vacuo* and further purified by zone electrophoresis on cellulose powder as described previously[6].

Before the enzymatic reaction was initiated, 3·0 ml. of a mixture of equal volumes of 0·1 M citric and 0·1 M phosphoric acids were mixed with 1·0 ml. of anthocyanin solution, 1·0 ml. of a catechol solution varying in concentration from 0 to 20 mM, varying volumes of 5 N sodium hydroxide solution, depending on the desired *p*H in the region 2·5–7·5, and water to make up a total volume of 6·8 ml. From this mixture, 0·5 ml. was transferred to a test tube containing 2·5 ml. of 1 M citrate buffer *p*H 2·0 and 0·1 ml. of 0·5 M potassium cyanide; another 0·5

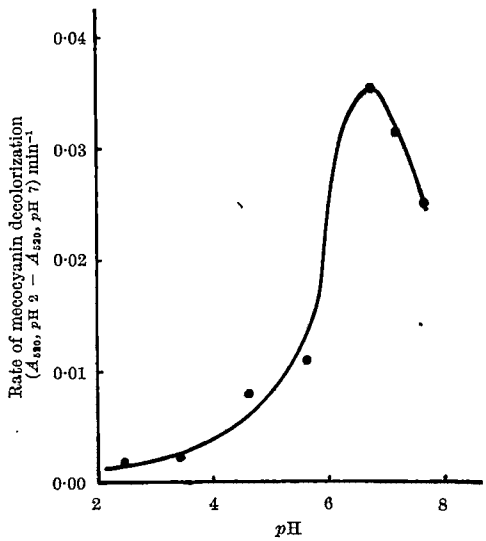

Fig. 1. Effect of *p*H on the mecocyanin decolorization by phenolase. 3·4 mg enzyme/100 ml. reaction mixture, 2·8 × 10^{-5} M catechol; 25° C

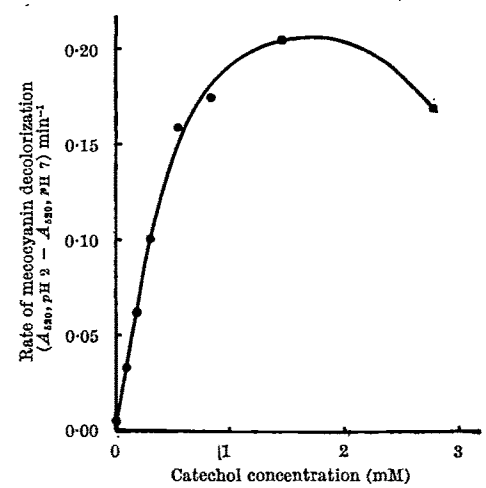

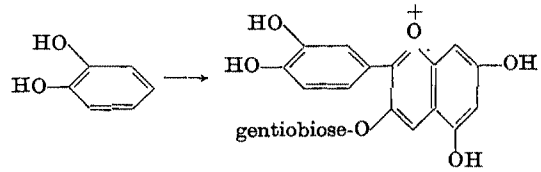

Fig. 2. Effect of catechol concentration on the mecocyanin decolorization by phenolase. 3·4 mg enzyme/100 ml. reaction mixture; *p*H 6·5; 25° C

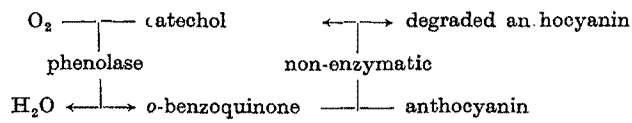
ml. of the mixture was transferred to a second tube containing 2·5 ml. of 1 M citrate buffer *p*H 7·0 and 0·1 ml. of 0·5 M potassium cyanide. These tubes served to obtain a measure of the zero time anthocyanin concentration.



To the remaining 5·8 ml. of anthocyanin–buffer–catechol mixture, 0·2 ml. of enzyme solution was added and at intervals of time as short as 30 sec two 0·5 ml. aliquots of reaction mixture were transferred to citrate–cyanide solutions similar to those used for the zero time anthocyanin determination. The reaction mixture was kept under vigorous magnetic stirring to ensure air incorporation. Fifteen min after each transfer the absorbancy of the tube contents was measured in a Beckman *DU* spectrophotometer at 520 mμ for the mecocyanin (cyanidin-3-gentiobioside) and 515 mμ for the antirrhinin (cyanidin-3-rhamnoglucoside) of the cherries. The difference in absorbancy at *p*H 2·0 and 7·0 has been found a better measure of anthocyanin concentration than the absorbancy at one *p*H, because of the interference of the concurrent browning[7]. The reaction rates are given here as decrease in this differential absorbancy per min and are based on the first few min during which the reaction was of zero-order.

The effect of *p*H on the degradation of mecocyanin by phenolase is illustrated in Fig. 1. A *p*H optimum of about 6·5 is apparent.

The effect of catechol concentration on the reaction rate is shown in Fig. 2. It is obvious that in the absence of catechol the reaction is very slow, although mecocyanin can be considered a benzopyrylium derivative of catechol.

In the presence of catechol the rate of mecocyanin decolorization increases rapidly with catechol concentration. Excessive catechol, however, inhibits the reaction. The probable mechanism of the phenolase–catechol–anthocyanin reaction is as follows:

An attempt will be made to support this scheme by using free *o*-benzoquinone.

The effect of temperature was also examined using 3·4 mg of enzyme per 100 ml. reaction mixture, 2·8 × 10^{-5} M catechol, and *p*H 6·5. The reaction rate increased as the temperature was raised from 5° to 50° C; at higher temperature it rapidly declined.

When the amount of enzyme was varied at *p*H 6·5, 2·8 × 10^{-5} M catechol and 25° C, the typical linear rise of reaction rate with enzyme concentration was observed. Above 3 mg of enzyme per 100 ml. reaction mixture the rate levelled off.

The results obtained with antirrhinin were very similar to those of mecocyanin.

It is concluded that anthocyanins, of the cyanidin types at least, are poor phenolase substrates; but they are readily decolorized by this enzyme in the prosence of a better substrate, such as catechol.

This research was supported in part by the National Institutes of Health grant, *RG*-9025.

Effect of Puromycin on Cholinesterase Activity of Embryonic Chick Intestine in Organ Culture

The acetylcholinesterase (AChE) activity of a number of chick embryo tissues cultured *in vitro* can be influenced by the presence of acetylcholine (ACh) or other substrates in the nutrient media[1–4]. For example, in the presence of 0·02 M ACh, the AChE activity of primary explants of chick embryo lung increased 3–7-fold over a period of four days[3]. It would seem that a case of enzyme induction had been demonstrated. However, no direct evidence has been provided which would support this hypothesis. This report presents evidence that certain changes in AChE and cholinesterase (ChE) activity of chick embryo intestine maintained *in vitro* are due to changes in protein synthesis, a finding that is compatible

with the hypothesis that the synthesis of AChE can be induced.

When fragments of chick embryo small intestine were maintained in organ culture for 48 h using Waymouth's synthetic medium, *MB* 752/1, the AChE activity of the tissue medium usually caused no further increase. However, when medium No. 199 was used instead of Waymouth's medium, no 'spontaneous' increase in enzyme activity was observed, and addition of ACh to the 199 caused an increase in AChE activity of the cultured intestine. These observations with 199 are similar to those published previously[1–3]. Although the exact reasons for the differences in results with the two culture media are unknown, Waymouth's medium is superior to 199 in the maintenance of the tissue. Also, the choline concentration in Waymouth's medium is 250 mg/l. compared with 0·5 mg/l. in mixture 199. This may be important since choline is a precursor in the biosynthesis of ACh. The 'spontaneous' increase in enzyme activity occurring when using Waymouth's medium is much like that recently reported for cultured chick skeletal muscle by Goodwin and Sizer[4]. One question raised by all these studies is whether the increase in enzyme activity is due to increased synthesis of enzyme protein. This problem was approached by studying the effects of puromycin, a known inhibitor of protein synthesis[6,7].

Fragments of small intestine from 16-day-old chick embryo were maintained in organ culture for 48 h, using Waymouth's defined medium containing puromycin. The fragments were then homogenized and the colorimetric method of Ellman *et al.*[8] was used to determine enzyme activity. Both acetylthiocholine and butyryl thiocholine were used as substrates, and enzyme activity was based upon both wet weight and protein content. The results are shown in Table 1.

Table 1. CHOLINESTERASE ACTIVITY OF EMBRYONIC CHICK INTESTINE

	μM/g tissue/min	% of control	μM/g protein/min	% of control
Acetylthiocholine hydrolysis				
Control (not cultured)	2·06*	100	33·7	100
Cultured 48 h	3·56	173	57·6	171
Cultured 48 h + 5×10^{-5} M puromycin	0·42	21	10·4	31
Cultured 48 h + 5×10^{-6} M puromycin	1·74	84	31·4	93
Butyrylthiocholine hydrolysis				
Control (not cultured)	0·93	100	15·2	100
Cultured 48 h	1·13	121	18·0	118
Cultured 48 h + 5×10^{-5} M puromycin	0·01	1	0·1	0·07
Cultured 48 h + 5×10^{-6} M puromycin	1·15	123	22·1	146

* Each number is the average of three independent determinations.

Addition of 5×10^{-5} M puromycin not only blocked the 'spontaneous' increase of AChE activity (reflected by acetylthiocholine hydrolysis) but decreased it to less than control levels. ChE activity (butyrylthiocholine hydrolysis) was virtually abolished by this concentration of puromycin. At 5×10^{-6} M, puromycin blocked the increase in acetylthiocholine hydrolysis without decreasing butyrylthiocholine hydrolysis. These effects of puromycin were not due to enzyme inhibition since addition of the same concentrations of puromycin to the enzyme assay system had no effect on the hydrolysis of either acetylthiocholine or butyrylthiocholine. 5×10^{-5} M puromycin caused a 30 per cent decrease in the average protein content of the cultured tissue. This decrease was statistically significant ($P < 0{\cdot}01$). The small decrease in protein content (16 per cent) caused by 5×10^{-6} M puromycin was not statistically significant.

The mechanism of the 'spontaneous' increase, or of the ACh induced increase in AChE activity of these embryonic tissues is not known. The results with puromycin indicate that, at least for the 'spontaneous' increase, protein synthesis is involved and that the increased activity probably reflects an increase in synthesis of enzyme protein. Further studies are required to clarify the biochemical mechanisms, and to determine the physiological significance of these observations since both ACh and AChE are involved in cholinergic synaptic transmission, and histochemical localization of the AChE in embryonic chick intestine revealed that this enzyme was almost exclusively located in the Meissner's and Auerbach's plexi of the intestine[5].

I thank Sally Hegeman for assistance and Dr. Ofengand for the puromycin.

Possible Turnover of DNA with an Increased 6-Methylaminopurine Content

THE 6-methylaminopurine content of the DNA of a thymine-requiring mutant of *E. coli* strain 15, normally 2·1 per cent of the adenine, increases when 5-aminouracil is added to a logarithmically growing culture[1]. We have previously reported that the 6-methylaminopurine content of the DNA of a culture of a similar strain (strain *I*) continues to increase after net DNA synthesis ceases[2]. We have also shown that this increase could not be attributed to additions to the ends of DNA molecules since 6-methylaminopurine was not localized at these ends[2].

The increase in the 6-methylaminopurine content of DNA in the absence of net DNA synthesis can be explained by any of the following three proposals.

(1) The adenine in polymeric DNA is methylated[2–5].

(2) DNA molecules (possibly only one strand of the two) are degraded and replaced by new ones having an increased 6-methylaminopurine content (DNA-turnover). Although DNA-turnover in bacteria is not an established phenomenon, it has been indicated in the case of another abnormal DNA, that is, DNA containing 5-bromouracil[6]. In addition, incorporation of thymidine-2-^{14}C into DNA in the absence of net DNA synthesis has been reported in bacteria treated with alkylating agents[7]. It should be pointed out that DNA breakdown and resynthesis could also be effected by cell turnover, that is, the breakdown of old cells and the concomitant formation of new cells. However, normal cells of *E. coli* do not lyse easily in 24 h (refs. 6 and 8). Cell turnover, therefore, is an unlikely explanation unless the condition of the cells with respect to lysis in the presence of 5-aminouracil is very different from normal; this cannot be rigorously excluded since such cells are abnormal in shape[2].

(3) There may be net synthesis of DNA involving a small, undetectable fraction of DNA with a high 6-methylaminopurine content. The existence of small fractions of DNA of unusual base composition (but not involving 6-methylaminopurine) has been reported[9].

It is to be noted that these three proposals are not mutually exclusive. For example, the proposals (2) and (3) do not preclude the possibility that methylation of polymeric DNA is the mechanism by which 6-methylaminopurine appears in DNA.

The experiments reported here concern the incorporation of thymine-2-^{14}C into DNA during the period when

net DNA synthesis has ceased but the 6-methylaminopurine content increases. Under our conditions, the final 6-methylaminopurine content was 6 moles per 100 moles of adenine. The bacterial strain and the methods used have been discussed in a previous publication[2]. A small amount of radioactive thymine (14·8 μc./μmole was added to cultures containing 5-aminouracil and to control cultures without 5-aminouracil, after cessation of net DNA synthesis. (This represents the beginning of the stationary phase (culture about 17 h old).) The incubation was continued until the termination of the increase in the 6-methylaminopurine content of DNA (2 h)[2]. During the incubation with radioactive thymine the DNA content of the cells (determined by a micro-modification of the diphenylamine test[10]) remained constant. (μg of DNA per ml. of culture: with 5-aminouracil 10·0 ± 0·6; without 5-aminouracil 11·3 ± 1·0; the error is expressed as the standard deviation among samples removed from the medium at different time intervals.)

Table 1. Specific Activity of Thymine in DNA of Thymine-requiring Strain *I* of *E. coli*

(Exposed to thymine-2-^{14}C for 2 h after cessation of net DNA synthesis)

Experiment No.	Specific activity of thymine in DNA: Culture with 5-aminouracil (c.p.m./μmole) × 10^{-4}	Control* (c.p.m./μmole × 10^{-4})
1	9·5 ± 0·9	3·8 ± 0·3
2	5·5 ± 0·4	2·5 ± 0·2
3	5·6 ± 0·4	4·0 ± 0·2
Average	6·9	3·4

* One half of the culture, without 5-aminouracil, served as the control. The error is expressed as the standard deviation of four thymine samples isolated and counted independently.

The specific activity of thymine in DNA is presented in Table 1. Although the thymine in DNA of the control is radioactive, the amount of thymine actually incorporated (about 6–10 per cent of total thymine calculated using specific activity of thymine in the medium as 100 per cent) during the period under investigation is low enough to be attributed to a small amount of cell division and/or DNA synthesis undetected by our methods. However, the specific activity of thymine in the DNA with an increased 6-methylaminopurine content (culture grown in the presence of 5-aminouracil) is consistently higher than the control (on the average, twice that of the control).

These results do not allow one to rule out completely any of the three proposals already presented here. However, the proposal concerning the synthesis of a small fraction of DNA with a very unusual base composition appears unlikely; if the incorporation of thymine were due to net synthesis of DNA, the increase in DNA, as indicated by the specific activity of DNA thymine, should have been detectable. The results given here indicate a possibility of DNA turnover; thus, experiments designed to demonstrate methylation of polymeric DNA in this system must be interpreted with caution.

Incorporation of Propionic Acid into a Branched-chain Fatty Acid of the Preen Gland of the Goose

Murray[1] has recently isolated the two main acids of the secretion of the preen gland of the goose and has shown that they are 2,4,6,8-tetramethyldecanoic (I) and 2,4,6,8-tetramethylundecanoic acids (II).

(I)

(II)

In view of the mounting evidence of the role of propionic acid in branched chain synthesis[2–6], Murray has suggested that the C_{14} acid (I) is derived from one acetate and four propionate units, and the C_{15} acid (II) from five propionate units. The present investigation was undertaken to test this hypothesis by tracer technique.

Recently, Lennarz *et al.*[7] have demonstrated that the synthesis of tuberculostearic acid (10-methylstearic acid) occurs via addition of a 'C_1 unit' from methionine on to oleic acid. Hence, parallel experiments with methionine-$^{14}CH_3$ were conducted here for the purpose of comparison.

Fifty μc. each of sodium propionate-3-^{14}C (0·025 m/moles) and L-methionine-$^{14}CH_3$ (0·010 m/moles) (purchased from the New England Nuclear Corp., Boston, Mass.) dissolved in 0·5 ml. of physiological saline were injected directly into the preen gland of each of two adult geese. Five h later the fowls were killed and their preen glands dissected out entirely. The glands were washed with water, cut open and the waxy contents removed by gentle scraping with a spatula.

Fatty acids (average yield = 820 mg) were isolated according to methods previously used in the examination of mycobacterial lipids[8]. The fatty acids obtained from the methionine-$^{14}CH_3$ experiment were found to contain no detectable radioactivity, whereas the propionate-3-^{14}C fatty acids showed incorporation of tracer to the extent of 19 c.p.m./mg (^{14}C-activity determined in a Geiger–Müller counter operating at 6 per cent efficiency) (Table 1).

Table 1. Radioactivity of Total Fatty Acids of Preen Gland after Administration of Radioactive Precursors

	Activity (c.p.m.)	Background (c.p.m.)	Activity—background (c.p.m.)	Weight fatty acids (mg)	C.p.m./mg fatty acids
Methionine-$^{14}CH_3$ fatty acids	38	37	1	31·1	~0
Propionate-3-^{14}C fatty acids	779	37	742	37·7	~19

The propionate-3-^{14}C fatty acids were esterified with diazomethane and chromatographed on a 30 per cent 'Apiezon *L*'/'Chromosorb *P*' column, using an F and M vapour phase chromatograph. The fraction corresponding chromatographically to the methyl ester of 2,4,6,8-tetramethyldecanoic acid (I) (The identity and the structure of I were verified by mass spectrographic analysis by Dr. W. Vetter. Acid II was present only in small quantity. Meanwhile, Prof. E. Stenhagen (Göteborg) has informed us that he too has confirmed the structure of I proposed by Murray using mass spectrometry), as described by Murray[1], was collected and found to be radioactive to the extent of 22 c.p.m./mg. Kuhn–Roth degradation[9] of this compound resulted in 24 per cent recovery of the original radioactivity in the formed acetic acid. (The low yield obtained is due to the loss of acetic acid during the course of the degradation. One millimole of carrier acetate was added at the termination of the reaction.) The acetic acid was purified[10], counted on a proportional gas phase counter and further degraded by the Schmidt

method[11] to determine activity of each carbon atom. The degradation data, showing the exclusive presence of radioactivity in the methyl group (Table 2), provide further evidence that propionic acid is indeed incorporated into 2,4,6,8-tetramethyldecanoic acid (I) in the predicted manner.

Table 2. SCHMIDT DEGRADATION OF ACETIC ACID FORMED FROM KUHN–ROTH DEGRADATION OF 2,4,6,8-TETRAMETHYLDECANOIC ACID OBTAINED FROM PROPIONATE-3-^{14}C EXPERIMENT

Activity of CH_3COOH (c.p.m./mM*)	Activity of CH_3-group (c.p.m./mM*)	Activity of —COOH group (c.p.m./mM*)
1,756	1,725 (99%)	22 (1%)

* ^{14}C activity determined in a proportional gas phase counter operating at 90% efficiency.

The incorporation of propionic acid into branched-chain aliphatic compounds has already been proved for bacterial products: erythromycin[2,3], methymycin[4], mycocerosic acid[5,6] and phthiocerol[6]. In the animal kingdom, Saz and Weil[12] have shown that in the *Ascaris* 2-methyl-butyric acid is synthesized *in vivo* from one molecule of acetic and one molecule of propionic acid and that 2-methyl-valeric acid is formed in a similar way from two molecules of propionic acid.

This work seems to prove that propionic acid can also be used by vertebrates to produce branched-chain compounds.

An Inverse Relationship of the Effects of Oxygen and Iron on the Production of Fluorescin and Cytochrome *c* by *Pseudomonas fluorescens*

IT has been suggested by Burton *et al.* that fluorescin, a yellow-green fluorescent bacterial pigment, is related to respiratory enzymes. Observations from this laboratory on the control of cytochrome c production in *Pseudomonas fluorescens*[2–4] are in general accord with Burton's hypothesis, and suggest that fluorescin is an alternative product of porphyrin metabolism.

Burton *et al.*[1] and Totter and Mosley[5] demonstrated that production of fluorescin by *Ps. aeruginosa* is inversely related to the amount of iron present in the media. Using *Ps. fluorescens*, Koepsall[6] reported that medium obtained from cultures grown without iron "contains sufficient pigment of a fluorescent nature to give a marked greenish yellow colour, while the pigment is almost absent in fermentations containing iron".

In the experiments illustrated in Fig. 1, *Ps. fluorescens* grown at a high oxygen tension in the absence of iron produced large amounts of fluorescin while less than 0·1 per cent of the protein in the cells was accountable as cytochrome *c*. Conversely, when the organism was grown at a low oxygen tension in the presence of iron, 3·5 per cent of the soluble proteins of the cell consisted of cytochrome *c* while scarcely any fluorescin was produced. These results, in agreement with Burton, suggest that in the absence of iron and at high oxygen tensions *Ps. fluorescens* cannot make cytochrome *c*; the accumulated metabolic precursors of the porphyrin, therefore, might be metabolized to yield fluorescin.

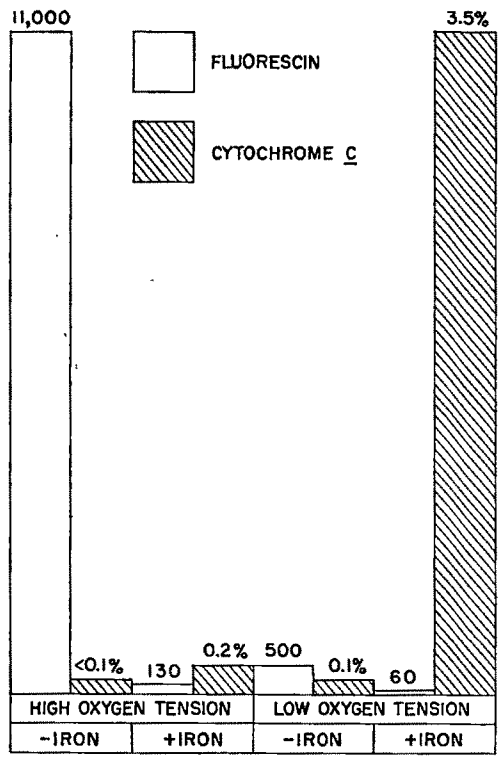

Fig. 1. A comparison of the effects of oxygen and iron on the production of fluorescin and cytochrome *c* by *Pseudomonas fluorescens*. *Pseudomonas fluorescens* was grown at conditions of high oxygen tensions (shaking) and low oxygen tensions (non-shaken) in media with or without iron prepared as previously described[3]. A unit of fluorescin is described as the reading of 1 ml. of the clear media as measured by the Coleman fluorimeter equipped with *B*–1 and *PC*–1 filters. The cytochrome *c* is expressed as the percentage of the soluble protein of the bacterial extract[2]

If Burton's postulate is true, then it might seem likely that the 'respiratory precursor' of fluorescin is also fluorescent. Indications to this effect are shown by examining washed cells of *Ps. fluorescens* previously grown at a low oxygen tension in the presence of iron (10^{-5} M or greater ferric chloride). Suspensions and aqueous extracts of these cells fluoresced red. The extract fluoresced red, however, only when the cytochrome *c* was in the reduced state. If the cytochrome *c* were oxidized, the extract fluoresced yellow. Extracts of cells grown so that no observable cytochrome *c* was present did not fluoresce either in the presence or absence of oxidizing or reducing agents. Furthermore, in contrast to the red fluorescing cultures, similar cells grown at low oxygen tensions containing less than 8×10^{-6} M ferric chloride fluoresced blue, while a trace of fluorescin was excreted into the medium.

Fluorescin has been considered to be a flavinic pigment[7,8]. However, my observations (see also refs. 4, 9) and consideration of its empirical formula as determined by Turfitt[10], $C_4H_9O_2N$, rather suggest that fluorescin might be a derivative of either pyrolle or pyrollidine.

I thank Dr. Nathan O. Kaplan and Dr. D. J. D. Nicholas for their advice and criticism.

Purine Catabolism, a Source of Endogenously Formed Urea in Homogenates of Amphibian Kidney

CLASSICAL thinking holds that the bulk of urea formed in the body is derived from reactions of the Krebs–Henseleit cycle[1] occurring in the liver of mammals and of amphibia[2]. Although the cycle is incomplete in mammalian kidney due to a relative lack of ornithine transcarbamylase and of carbamyl phosphate synthetase[3], the enzymatically catalysed pathway, citrulline + aspartate ⇌ arginine ⇌ urea + ornithine provides a potential source of urea in kidney cells.

Recent results have suggested the existence of alternative chemical pathways for urea production in mammalian liver and in amphibian kidney.

Cedrangolo *et al.*[4] injected rats with α-D-L-methyl aspartate (α-MA), a potent inhibitor of arginino-succinate synthetase in liver homogenates[5]. Even though the Krebs–Henseleit cycle was completely blocked in liver slices of rats treated with α-MA, the daily excretion of urea in treated was the same as that in untreated rats. We[6] have demonstrated that urea production of bull-frog kidney was not inhibited by lysine, a well-known inhibitor of arginase activity.

This communication, an investigation of the source of urea produced by homogenates of amphibian kidney, involved testing for the activity of three possible reaction paths—that from citrulline to arginine to urea; that from protein to arginine to urea; and that from uric acid to urea.

Kidneys of 10–20 frogs (*Rana catesbiana*) were homogenized together with 3–10 volumes of diluent solution, 60 mM sodium chloride plus 60 mM potassium chloride. Aliquots of diluted homogenate were boiled for determination of pre-incubation levels of urea. Other aliquots of the same homogenate were incubated in a Dubnoff shaker at 23° C. for varying times after which they were boiled for determination of post-incubation levels of urea. Tissues, incubated with or without exogenously added substrates, were buffered to a *p*H of 7·3. Analyses, performed routinely on supernatant fluids of boiled homogenates before and after incubation, were those of urea and ammonia[7]. In some instances, arginine was measured enzymatically. No free ammonia was detected in more than 30 pools of frog kidney homogenate under present conditions. All exogenous materials added to homogenates were tested for their effects on urease and arginase activity in synthetic systems.

Table 1 presents results on concentration of exogenously added substances and on urea production by homogenates of bull-frog kidneys. No extra urea production was induced by addition of citrulline or of arginino-succinate, suggesting that neither arginino-succinate synthetase nor arginino-succinase was active in homogenates. Extra urea production was induced by indicating the presence of some a frog kidney.

e ultracentrifuge, the 'Lusteroid'
sucrose gradient is placed in the
'Perspex' block (Fig. 1), from which the upper screw has been removed. This screw carries a rubber washer and a fine stainless steel tube through which the gradient will be extruded. Underneath the 'Lusteroid' tube is a No. 18 gauge hypodermic needle, sheathed by a rubber bung and connected by a fine polythene lead to a syringe which can be driven by a synchronous motor. The needle and syringe are filled with a sucrose solution of a density greater than the maximum used in preparing the gradient. When the upper screw is replaced the washer seals the top of the centrifuge tube and the needle penetrates the bottom, the compression of the rubber bung effectively preventing any leakage from the point of entry. The syringe motor is then started and the contents of the tube are steadily floated upwards on the denser sucrose, through a short polythene lead, and into a specially designed micro flow-cell (Fig. 2). The cell is held in a detachable mounting that is fixed to the edge of the platform in the sample compartment of the spectrophotometer. Four screws in the mounting permit accurate adjustment of the position of the flow-cell so that it contains the slit image (Fig. 3). A polythene lead is taken from the top of the flow-cell out through a special lid to the cell compart-

‡ Carried out by Dr. A. Schrumpf, St. J Norway, using the method of Killander[3].
Solutions of pigment I were sterilized by fil

It is seen from Table 1 that pigment I has virtually no activity for *Ochromonas malhamensis* and *Lactobacillus leichmannii*. For *Euglena gracilis* a small activity is found. Bioautography with the *E. coli* mutant (*M* 200) of a chromatogram of 25 μg of pigment I run in the solvent system described showed no growth-promoting properties. The chromatogram indicated traces of vitamin B_{12} and Factor *B*, both of which were present in quantities less than 0·01 per cent of pigment I. (This experiment was kindly carried out by Dr. E. Lester Smith, Glaxo Laboratories, Greenford, England.)

Pigment I has been given intramuscularly as a single dose with no apparent side-effects to 9 patients with megaloblastic marrow and histamine fast achlorhydria typical for pernicious anæmia. The reticulocyte responses are shown in Table 2. The administration of 30–50 μg of pigment I gave some response. Subsequent administration of vitamin B_{12} or liver extract gave an increased response in all but one case (patient 4). When 100 μg of pigment I was injected, subsequent injection of 1 mg and 5 mg of vitamin B_{12} in patients 5 and 6 respectively did not produce additional reticulocyte responses. The time required for maximum reticulocyte response following injection of pigment I is longer (6–9 days) than is usual with vitamin B_{12}. The increase in red blood cells over a period of 15 days following the injection of 100 μg of pigment I is seen in Table 3. Using the formula of Ungley[4], who found that the increase in red blood cells was linear to the logarithm of the dose of vitamin B_{12}, it can be calculated that the activity of pigment I in man corresponds to 8 per cent (by weight) of that of vitamin B_{12}.

Table 2. Reticulocyte Response of Patients receiving Pigment I

Patient No.	Reticulocytes before treatment per cent	Dose (μg)	Maximum of reticulocyte response Per cent	Day
1	0·8	30	4·0	7*
2	0·5	50	2·0	4†
3	1·0	50	4·2	9‡
4	1·0	50	11·7	6§
5	0·1	100	5·8	8¶
6	0·8	100	13·1	7‖
7	0·8	100	15·5	6
8	2·0	100	15·8	9
9	1·5	100	10·8	8

Reticulocytes were counted using a wet method with nile blue.

* 1 mg of vitamin B_{12} on the 14th day gave a second reticulocyte response of 8 per cent on the 20th day.
† 5 ml. of Pernami, Nyegaard and Co. *A/S*, on the 11th day gave a second reticulocyte response of 7 per cent on the 15th day.
‡ 10 ml. of Pernami on the 12th day gave a second reticulocyte response of 8·3 per cent on the 21st day.
§ 10 ml. of Pernami on the 12th day gave a second reticulocyte response of 5 per cent on the 18th day.
¶ 1 mg vitamin B_{12} on the 18th day gave no additional reticulocyte response.
‖ 5 mg vitamin B_{12} on the 10th day gave no additional reticulocyte response.

Table 3. Number of Red Blood Cells after Administration of Pigment I

	Days after injection			
	0	5	10	15
Patients No.*	No. of red cells (millions)			
7	1·6	1·9	2·3	2·8
8	1·8	2·1	2·4	2·8
9	1·9	2·0	2·4	3·0

* See Table 2.

It appears from these results that pigment I produces in patients with pernicious anæmia a hæmatological response typical for vitamin B_{12}. Maintenance therapy has not been attempted.

A number of B_{12}-analogues differing in the nucleotide portion of the molecule have in the past been examined for biological activity in micro-organisms and in man[5]. Certain of these analogues exhibit activity in man. The results so far indicate that all the substances which are active in pernicious anæmia patients also exhibit microbiological activity. Pigment I, being active in man, shows a different pattern as no activity was found with *E. coli*, *L. leichmannii*, *O. malhamensis* and only slight activity with *E. gracilis*.

The activity of pigment I in man is most likely explained by assuming that part of the pigment injected is converted to a biologically active substance. Its negligible microbiological activity makes it unlikely that the unchanged molecule should have any effect.

The structure of pigment I is not known. It has recently been suggested by Hill, Pratt and Williams[6] that pigment I may have an additional group on one of the methene bridges. Whether man is capable of converting such a structure to a biologically active substance is not known.

This work was supported by the Rockefeller Foundation and Nansenfondet. We also thank Glaxo Laboratories, Ltd., for a gift of vitamin B_{12}.

Aromatic Acids of Fermented Cacao

A resinous material with a 'balsamic' or 'honey-like' aroma can be recovered from chloroform-extracts of fermented cacao; it has been regarded as an important component of chocolate flavour[1]. Paper- and gas-liquid chromatography have now revealed in this material several aromatic acids, some of which have been identified.

Fermented and dried cacao beans (*CPA* brand) were homogenized and defatted with petroleum solvent (b.p. 80°–100°). The fat-free residue was acidified with N sulphuric acid (20 ml. per 100 g) and extracted with chloroform in a Soxhlet apparatus. Acids were extracted from the chloroform solution with 5 per cent sodium bicarbonate solution and taken into chloroform again after acidification of the bicarbonate solution. The chloroform solution was reduced to small volume and used for chromatography.

On paper chromatograms five main spots are revealed with diazotized *p*-nitroaniline after pre-treatment with ammonia[2]. A sixth spot is detected by its fluorescence in ultra-violet light. The R_F, colour reactions and tentative identifications are given in Table 1.

Table 1

Spot No.	Solv. *A*	Solv. *B*	Solv. *C*	Colour	Identification
1	0·51	0·71	0·78	mauve	*o*-hydroxyphenyl-acetic acid
2	0·43	0·89	0·77	red	phenylacetic acid
3	0·20	0·60	0·79	violet	*p*-hydroxyphenyl-acetic acid
4	0·12	0·61	0·60	brownish-red	*p*-hydroxybenzoic acid
5	0·09	0·82	0·57	violet	vanillic acid

Solvent *A*, *sec* butanol–conc. ammonia–water (8 : 1 : 1).
Solvent *B*, chloroform–acetic acid–water (34 : 15 : 1).
Solvent *C*, 2 per cent aqueous acetic acid.

Only short runs (5 in.) were routinely used and there was some variation in R_F, but the identifications were checked by eluting the individual components of the extract from large one-dimensional chromatograms of rows of spots and co-chromatographing the isolated component with the pure compound it was thought to be. Further corroboration of the identifications was obtained from gas-liquid chromatography.

A portion of the chloroform solution was evaporated. The residue was treated with diazomethane in ether and reaction allowed to continue until methylation was

complete ($K_3Fe(CN)_6/FeCl_3$ reaction for phenolic groups negative). Evaporation of the ether left a brown oily residue which was analysed by gas chromatography on polyethylene glycol adipate at 150° C. Methyl phenylacetate was readily detected as a major constituent, and methyl veratrate was also present. The methyl esters of *p*-methoxyphenylacetic acid and *o*-methoxyphenylacetic acid and/or *p*-methoxybenzoic acid were present in small amount. The principal constituents of the mixture appeared to be methyl esters of the fatty acids C_{14} upwards. The relevant known compounds were prepared by treatment of the acids in the table with diazomethane.

Phenylacetic and vanillic acids are both strongly odorous but are not alone responsible for the honey-like aroma. Carbonyl compounds also present probably contribute to this.

PHYSIOLOGY

Aortic Wall as a 'Two-phase' Material

Comparison of the orientation of the collagen and elastin components of the rabbit aorta at various distending pressures indicates that the media functions as a 'two-phase' material. At physiological pressures, collagen fibres of high tensile strength and relatively high modulus of elasticity bear most of the stressing force; an intricate network of elastin lamellæ and fibrils of relatively low modulus of elasticity distributes stressing forces uniformly.

The microscopic arrangement and interrelation of collagen and elastin fibres was examined in 40 rabbit aortæ each of which was fixed while distended by a constant intra-luminal pressure. In each instance a 5-cm segment of abdominal aorta was cannulated at both ends and restored to *in vivo* length on an adjustable frame. During 2–4 h of fixation in 10 per cent formalin or 2 per cent osmic acid intra-luminal pressures ranging from 0 to 200 mm mercury were maintained by a constant pressure perfusion apparatus. For light microscopy sections of formalin-fixed material embedded in paraffin were stained with Weigert and Van Gieson stains for elastin and collagen. For electron microscopy, osmium-fixed tissues were embedded in 'Epon' or 'Araldite'; phosphotungstic acid or uranyl acetate stains were used. Microscopic measurements included vessel diameter and wall thickness, thickness of elastin lamellæ and distances between elastin lamellæ.

The relation of vessel radius, vessel wall thickness and total tangential tension to distending pressure is shown in Fig. 1. As intra-luminal pressure increased, the radius of the aorta increased and thickness of the wall decreased. The differences between radii and wall thicknesses were large below physiological pressures. However, differences between radii and wall thicknesses were small at physiological distending pressures between 80 and 120 mm mercury and remained small at higher pressures up to 200 mm mercury. The wall tension is related to both the intra-luminal pressure and the radius (according to

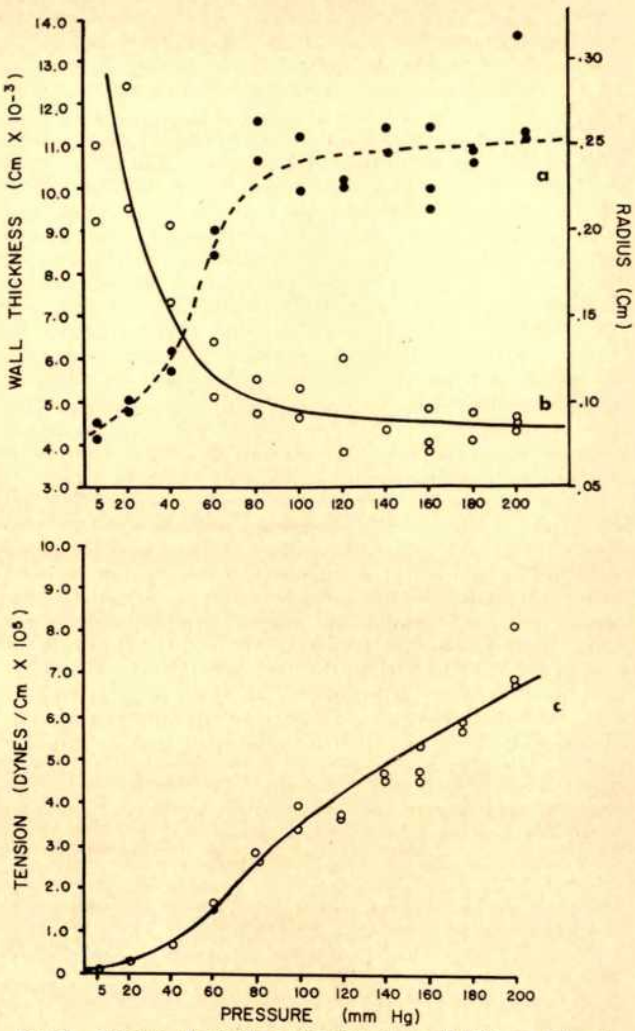

Fig. 1. Relation of rabbit aortic radius (*a*), wall thickness (*b*) and wall tension (*c*) to distending pressure

Laplace's law, as applied to blood vessels, $T = Pr$, where T is the total tangential tension (dynes/cm), P is the intra-luminal pressure (dynes/cm²), and r is the radius (cm) of the vessel). Since there is relatively little change in radius at and above physiological pressures, the tension in this range was almost entirely a function of pressure. These findings, based on measurements of many fixed aortæ, are in essential agreement with those of investi-

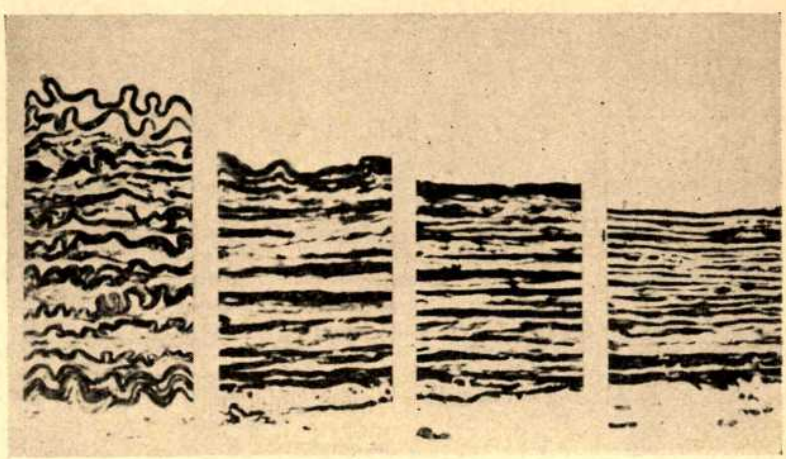

Fig. 2. Transverse sections of rabbit aortæ at distending pressures of 40, 60, 80 and 100 mm mercury, left to right. Weigert–Van Gieson stain (× *c.* 470)

gators who have measured the relation of volume or diameter to intra-luminal pressure or wall tension in individual fresh specimens[1,2]. The modulus of elasticity of the aortic wall is relatively high at and above physiological pressures.

The appearance of the concentric elastin lamellæ of the rabbit aortic wall at distending pressures of 40, 60, 80 and 100 mm mercury is shown in Fig. 2. At pressures below 80 mm mercury cross-sections of the lamellæ were wavy and crumpled; and above physiological pressures the lamellæ were straight. The media appeared to function as a whole, for the orientation of each of the lamellæ throughout the thickness of the wall changed with each increase in distending pressure. With increasing pressures below physiological values straightening of the lamellæ was uniform throughout the wall; interlamellar distances decreased uniformly and markedly; lamellar thicknesses decreased uniformly but very much less than interlamellar distances. Tangential and oblique sections revealed an abundant network of fine elastin fibrils which connected the thicker tubular elastin lamellæ (Fig. 3). At and above pressures of 60 mm mercury, the fine elastin fibrils between adjacent thick lamellæ were nearly parallel and arranged obliquely with respect to both the circumferential and longitudinal directions of the vessel. Thus, at physiological pressures lamellæ were straight, interlamellar distances were uniform and the extensive fine elastin net connecting lamellæ had a distinct orientation.

Electron photomicrographs revealed the orientation of the abundant collagen fibres within the media of the distended aorta. Below physiological pressures with elastin lamellæ and fibrils wavy and crumpled, collagen fibres showed no consistent arrangement. At and above physiological pressures collagen fibres appeared to be dispersed uniformly and arranged very nearly circumferentially. In transverse sections through the vessel wall most of the collagen was seen as long fibres. In longitudinal sections through the wall the collagen was seen as round or oval cross-sections of the fibres (Fig. 4).

Materials consisting of 2 components of different tensile strength and elastic modulus have been called 'two-phase' materials. Some of the advantageous properties of these systems have been described[3,4]. In a 'two phase' material

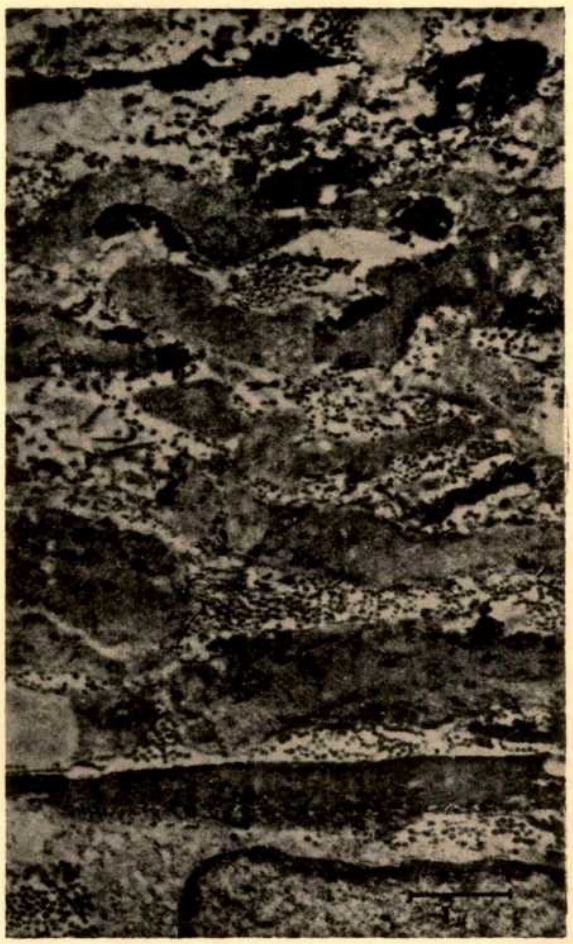

Fig. 4. Electron photomicrograph of a longitudinal section of a portion of the media of a rabbit aorta fixed while the vessel was distended by an intra-luminal pressure of 150 mm mercury (× *c.* 13,500). Most of the collagen fibres are seen in cross-section as small round and oval osmophilic spots

Fig. 3. Oblique section of a rabbit aorta fixed while the vessel was distended by an intra-luminal pressure of 60 mm mercury. Weigert–Van Gieson stain (× *c.* 620). The fine elastin fibrils are almost parallel and arranged obliquely between adjacent thick lamellæ

the elastic modulus is less than that of the highly elastic component but greater than that of the less elastic components; the absolute value of the modulus is related to the cross-sectional area occupied by each component. Substances of high tensile strength may yield at much less than intermolecular binding forces because of structural defects; a 'two-phase' material may have an actual tensile strength greater than that of the stronger component alone. This occurs because the more extensible (less elastic) component distributes the stressing forces uniformly; stresses about flaws are transferred to other parts of the stronger component, preventing the extension of structural defects and permitting the tensile strength to approach the theoretical value. Glass fibres embedded in plastic and laminated metals are examples of industrial 'two-phase' materials. The usefulness of bamboo and other woods with special properties is attributable to the presence of oriented cellulose fibres dispersed in lignin[3]. The strength of felted fur results from the intimate admixture of fibres of different composition[5]. Currey has recently discussed bone as a 'two-phase' system of collagen and apatite crystals[6].

Collagen and elastin are suitable components for a 'two-phase' material. Collagen has a high tensile strength and a modulus of elasticity of about 1×10^9 dynes/cm^2; elastin has a relatively low tensile strength and a modulus of elasticity of about 3×10^6 dynes/cm^2 (ref. 2). Though the relative quantities of elastin and collagen may vary somewhat in different segments of an aorta[7], the aortic wall has an elastic modulus approximating that of elastin at.

low intraluminal pressures and increasing markedly at and above physiological pressures[1,2,3]. Although distensibility is comparatively low at and above physiological pressures, the wall rarely breaks despite rapid fluctuations in distending pressure and numerous irregularities of composition and structure which increase in size and number with age. Thus, under usual conditions of distention at physiological pressures, the elastic modulus is relatively high as the oriented collagen fibres bear most of the stressing force; elastin fibrils serve to distribute the stressing forces uniformly. The mechanical properties of the wall at low, non-physiological pressures of 0 to 80 mm mercury, associated with the straightening of the wavy elastin lamellæ and the aligning of the disarrayed collagen fibres, may be only indirectly related to normal vessel function.

Attempts to assess the role of pressure and tension gradients in the aortic wall in disease processes must take into account the special mechanical features of this 'two-phase' material. The role of local defects and zonal strain may be relatively insignificant.

'Rebound Effect' of Ovulation-inhibiting Steroid in Rats

While interpreting the results of studies in women and the dual role of 'Norethynodrel', Rock describes it as 'rebound effect' possibly on the pituitary gland[1]. It has been shown that syntheses of gonadotrophins are affected by administration of 'Norethynodrel'[2,3]. Our recent experiments on this rebound effect phenomenon and the results obtained have brought forth some new thoughts on the role of anterior pituitary gland in gonadotrophic hormone elaboration.

In the test animals (adult rats, Holtzman strain) which received 'Norethynodrel' over a period of 100 days, a marked decrease in ovarian weight was observed; but no other major differences were from our control animal experiments (Table 1). Structural changes in the anterior pituitary of test animals were not significant, and the variations were negligible. Somewhat similar observation has been recently reported[4]. In a second group of experimental animals the drug was administered for 100 days and the animals killed 50 days later. Salient differences in the number of corpora lutea and eggs (recovered from tubes at autopsy) were noticed in the test groups. Average number of corpora lutea were 6·4 per ovary in controls and 9·2 per ovary in test animals; the number of eggs 4·4 per tube in controls and 7·2 per tube in test animals, indicating a definite increase in the number of eggs in 'Norethynodrel' treated (1·0 mg/day)–recovered individuals. No other highly significant differences were noticed in the organs of test groups from controls, except slight variation in the weight of kidneys (Table 2). Microscopically the uterine cells which line the lumen in the treated group appeared more columnar than in the controls. This is possibly due to direct effect of steroid on the uterus, and this observation, to a certain extent, lends support to Rock's interpretation of expansion of womb in his post-medication subjects with progestins. We were a little surprised to see microscopically no outstanding differences in the pituitary glands of treated, treated–recovered and control groups.

Ever since the pioneering work of Bayliss and Starling[5], it is believed that a hormonal homeostatic mechanism exists in a normal individual depending on age and sex. They suggested that secretions of the pituitary gland are regulated by the needs of the body. Zuckerman gives a good review of earlier workers regarding this aspect[6]. It has already been reported that imbalance of ratio of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) results in anovulation[7,8]; the former seems to be more potential than the latter, since it is believed that twice the dose of suppressants is required for FSH inhibition than for LH in the pituitary gland (W. O. Nelson in discussion in *Control of Ovulation*, Pergamon, 1961, 243). As such the exact mode of action of pituitary gonadotrophin suppressants is not completely understood. However, it is assumed that exogenous steroids affect the pituitary gland in the synthesis and release of gonadotrophins[9]. Also the steroids can act as augmenting agents along with pituitary hormones in frog ovulation[10]. There is a common and perhaps important resemblance between endocrine glands and the brain. Both essentially control the vital processes occurring in the body. Whether the hormones affect changes by acting directly on the enzyme systems, or by modifying the permeability of cells and thus making particular substrate available, or some other method, remains to be explored.

The pituitary gonadotrophic hormone possibly unites with some receptor of the cells of the ovary, resulting directly or indirectly in the formation of a new biochemical entity which becomes potent to trigger some metabolic reaction to result in liberation of the egg. Hence, it seems that reproductive function is not merely a hormone to hormone relationship but involves an intricate system of glandular production, neural stimulation and vascular transportation. In the investigation recorded here it is noticed, in spite of no structural variations in the pituitary glands of treated animals, the ovaries were very small and did not show any grown follicles, indicating cessation of ovulation. Therefore, it may not be incorrect to assume that 'Norethynodrel' exerts its primary effect on the neurohumoral system which in turn affects the adenohypophyseal secretions.

There are many unanswered questions concerning hormonal activity and there are many aspects of total reproductive function as affected by hormones that are not completely understood. The role of the hypothalamus in reproduction presents a relatively new field of study, promising to answer many questions when its role is better understood. A series of experiments regarding the effect of 'Norethynodrel' in hypophysectomized and gonadectomized rats and changes in the hypothalamic nuclei, in correlation with normal intact ones, are in progress.

In the investigation recorded here it is noticed that the action of 'Norethynodrel' is not directly on the pituitary gland so far as basophil changes go. However, the depletion of gonadotrophins is not ruled out as it is known that synthesis is affected for administration of 'Norethynodrel'[2,3]. In the treated animals it is clearly seen that ovaries are highly reduced in size and weight, and with underdeveloped follicles. 'Norethynodrel' seems to exert its primary effect on the neurohumoral system which in turn affects the hypothalamo-hypophyseal complex to decelerate the secretion of gonadotrophins. This observation could lend support to Harris's interpretation of pituitary control by neural mechanisms[11] through a neurohumoral system. The pituitary gland plays a secondary part in the elaboration of trophic hormones but certainly not a dispensable one.

The 'rebound effect' seems to result in increase of number of eggs in rats; although at this juncture we are

Table 1

Organ weights are calculated in mg/100 g body-weight. Six animals in each group, except group 5 with four. Groups 3, 4, 5, and 6 killed 12 h after initiation of œstrus.

unable to say whether this increase in number of eggs in the recovered animals is transitory or a permanent one. The structure of anterior lobe of pituitary gland in treated, recovered and control groups did not show any significant microscopic differences, indicating that 'Norethynodrel', in the doses used in this experiment, does not significantly alter the morphology of the pituitary gland. Further experiments to elucidate the pathways are continuing and others planned for the future.

We thank G. D. Searle and Co. for the supply of 'Norethynodrel'.

Biochemical and Physiological Function of Thiamine in Nervous Tissue

A considerable amount of evidence has been accumulated, primarily as a result of studies by von Muralt *et al.*[1], to suggest that thiamine may play a vital part in peripheral neurophysiology that is independent of its classical role as a coenzyme. Experiments in our laboratory suggest that thiamine may function as a neurohumour in the central nervous system, and, in addition, may be involved with sodium transport.

The spinal cord of a large pithed frog (*Rana catesbiana*) was stimulated via the sciatic nerve at a frequency of 1 pulse/sec; the amplitude of each stimulus was 6–12 V and its duration was 1 msec. At the conclusion of the stimulation period (15–60 min), the frog and a control (unstimulated) frog were decapitated and the spinal cords dissected out and extracted with either acid-alcohol (50 per cent ethanol; 0·1 N hydrochloric acid) or 5 per cent trichloroacetic acid. Using the procedure of Burch[2], the thiamine-content of an aliquot of the deproteinized extract was determined; the remainder of the extract was dried, taken up in a small volume of 50 per cent alcohol and chromatographed on either Whatman No. 3 *MM* or No. 4 paper using a solvent system composed of propanol : ammonium formate solution (2 M; *p*H 5) : water (65 : 15 : 25). Reference standards were thiamine, thiamine monophosphate (TMP), thiamine pyrophosphate (TPP), α-hydroxyethylthiamine (HET), and α-hydroxyethylthiamine pyrophosphate (HETPP). After chromatography, either the spots were visualized by spraying with alkaline ferricyanide or the paper was arbitrarily sectioned into 0·5-in. strips which were eluted and the eluates assayed by the procedure of Burch.

Table 1. Release of Thiamine from Spinal Cord Thiamine μg/g Spinal Cord

Exp.	Control	Stimulated	Increase (%)
1	3·33	4·25	27·6
2	7·30	9·85	34·9
3	4·56	6·35	39·1
4	2·09	3·81	82·3
5	3·07	8·02	160·0

Values are expressed in terms of thiamine. Details on experimental procedures are given in the text. Exps. 1–3 are *in vivo*, experiments 4 and 5 are *in vitro*.

As shown in Table 1, stimulation of the spinal cord caused the appearance of an increased amount of thiamine compounds in extracts of the tissue, as compared with those of unstimulated control frogs. Exps. 1, 2 and 3 were performed as already indicated; Exps. 4 and 5 were done on isolated spinal cords (*in vitro*); some cords were kept as controls, while the others were stimulated as described above. Using the perfusion method of Angelucci[3], similar results were obtained with perfusates of the spinal cord of the frog. These results, which suggest that thiamine or its metabolites are released from a bound form on stimulation of the cord, are in agreement with those obtained by Minz[4] and von Muralt[5] with isolated peripheral nerves of the ox, frog, and rat. Since the thiamine assay of Burch does not distinguish between free thiamine and its various naturally occurring forms, paper chromatography of the spinal cord extracts was used for identifying the thiamine compound which is released on excitation of the tissue. The qualitative results obtained so far have indicated that both free thiamine and TMP appear to be responsible for the increase; in one experiment a trace of HETPP appeared to be present in the extract of the stimulated cord, but not in that of the control animal. Reliable and reproducible quantifications of the thiamine metabolites are difficult to obtain with this procedure because of the lability of the coenzyme forms of the vitamin.

For this reason these techniques do not permit a conclusion concerning the form of the vitamin that is released during the initial response to electrical stimulation. Although the neurophysiological activity of thiamine and its antimetabolites has been well documented by Kunz[6], von Muralt[1] and Petropulos[7], no direct evidence is available to separate this role from the metabolic role of TPP in carbohydrate metabolism. Enough indirect evidence has accumulated[8–10], nevertheless, to suggest that thiamine may have dual functions in the body.

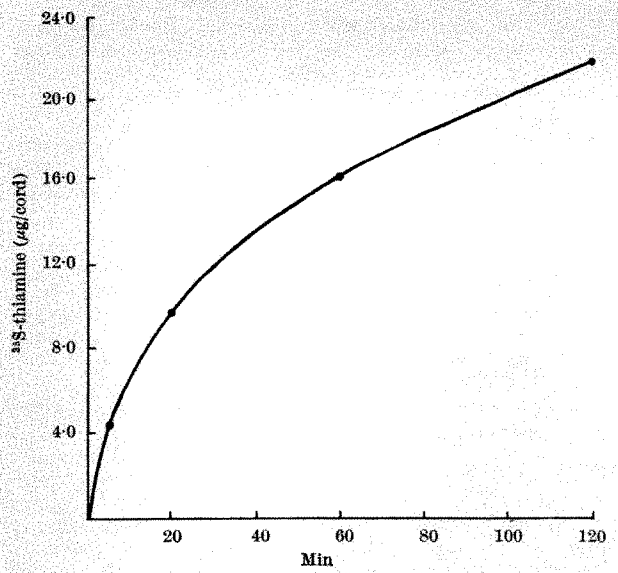

Fig. 1. Intact spinal cords of frogs were individually pre-incubated in 1 ml. of frog Ringer solution for 10 min at room temperature with oxygen as the gas phase. After the pre-incubation period, 300 μg of ^{35}S-labelled thiamine was added to each beaker and the incubation continued. At various times, the spinal cords were removed, rinsed quickly in cold Ringer's solution, blotted, and homogenized with 2 ml. of 5 per cent trichloroacetic acid. After centrifugation an aliquot of the supernatant solution was plated and the radioactivity determined in a gas-flow counter. In Fig. 1, the radioactivity measurement has been converted to μg of thiamine

That the neurophysiological activity is not mediated by thiamine *per se* is suggested by observations showing that large amounts of the vitamin are required to elicit a neurophysiological response. Although thiamine is a cationic molecule which contains a quaternary nitrogen atom, and it might be assumed that it does not readily penetrate lipoidal membranes, this explanation is untenable in the light of our findings; thus, when thiamine labelled with sulphur-35 was incubated with intact spinal cords, a rapid uptake of the vitamin occurred (Fig. 1). The radioactivity in the spinal cord was shown by paper chromatography to be unchanged thiamine; it is probable, however, that the neurophysiologically active form of the vitamin is some derivative of thiamine. Both pyrithiamine and oxythiamine produce signs of thiamine deficiency, but only pyrithiamine causes polyneuritis[10]. Since pyrithiamine, again in contradistinction to oxythiamine, inhibits the phosphorylation of thiamine, it might be inferred that the aforementioned active form of the vitamin is a phosphorylated derivative.

Present investigations in this laboratory[11] on the possible cation requirements of pyruvic oxidase in heart and brain have shown that in both tissues this enzyme complex is specifically activated by sodium ions (Table 2). In some preliminary experiments, a marked accumulation of HETPP (the primary intermediate in the oxidation of pyruvate by this enzyme system)[12,13] occurred when sodium ions were included in the incubation mixture.

It is tempting to speculate that the following sequence of reactions may occur during excitation of nervous tissue. The influx of sodium ions into the cell activates pyruvic oxidase, which then causes the rapid formation of HETPP The HETPP may itself initiate a response which is terminated by the hydrolysis of HETPP to another form of the vitamin, or it may, under appropriate conditions, lead to the rapid synthesis of acetylcholine, which then initiates the response. Although the foregoing hypothesis is highly speculative, experiments by von Muralt[5] and by Kunz[6] with the thiamine-binding extract of ferns, as well as with pyrithiamine, have indicated a relationship between the sodium transport system and thiamine.

A critical evaluation of this hypothesis is at present under investigation in this laboratory.

We thank Dr. H. Holtzer for a sample of HETPP, Dr. J. M. Sprague for the HET and Hoffmann-LaRoche for ^{35}S-labelled thiamine. We also thank Dr. L. O. Krampitz for details concerning the preparation of HETPP.

Table 2. Sodium Ion Activation of Pyruvic Oxidase

Cation in medium	Citrate formed (μmoles) Beef heart	Pig brain
K^+	1·89	1·35
Na^+	2·75	2·57
Increase in activity with Na^+	45·5%	90·5%

The incubation medium contained, in a volume of 2 ml., the following: phosphate buffer, *p*H 7·4, 100 μmoles; pyruvate, 20 μmoles; oxaloacetate, 10 μmoles; $MnCl_2$, 2·5 μmoles; cysteine HCl, 10 μmoles; coenzyme A, 100 μg; NMN, 2·1 μmoles; thiamine pyrophosphate, 1 μmole; lactic dehydrogenase (Worthington), 40 μg; condensing enzyme (ref. 14), 50 μg; pyruvic oxidase preparation from beef heart, 3·8 μg, or from pig brain, 3·9 μg. Incubation was carried out at 30° in a nitrogen atmosphere for 1 h and the mixture was deproteinized with trichloroacetic acid. Citrate was determined by the method of Stern (ref. 15).

HÆMATOLOGY

Role of Platelets in Dissolution of Blood Clots

Venous blood (1 vol.) diluted with 0·05 M phosphate buffer, *p*H 7·4 (9 vol.), and clotted with bovine thrombin (Parke, Davis and Co.; 1 unit per ml.) will afterwards dissolve in 2–8 h at 37° C if the diluted blood is handled in siliconized glassware and kept at 0° C for 30 min after the addition of thrombin[1]. The time required for the clot to dissolve is 12–24 h when the diluted blood is centrifuged at 1,800*g* for 10 min (4° C) and the supernatant alone is clotted. If the supernatant and infranatant are mixed and then clotted with thrombin, the clot will again dissolve in 2–8 h. Centrifugation at 1,800*g* for 10 min would be expected to remove only the cellular components from the supernatant.

Red blood cell and platelet counts on the supernatant (Table 1) show that the red blood cell count approaches zero before the dissolving time of the clotted supernatant increases. Only as the blood platelet count drops to $1{\cdot}0 \times 10^3$ per ml. does the dissolving time of the clot increase to 12–24 h. It therefore appears that blood

Table 1. Relationship of Red Blood Cell and Platelet Counts to Clot Dissolving Time*

	Supernatant alone (h)	Remixed samples (h)	Platelet count/mm³ (× 10³)†	Red blood cells/mm³ (× 10⁶)
0	4·3	4·3	25·0	513·3
200	4·1	4·3	18·2	0·26
1,200	4·6	4·3	8·1	0·29
1,800	> 12 < 24	4·3	1·1	0·05

* Average values from studies on five healthy adults at 9 a.m.
† Platelet counts carried out with a phase microscope (ref. 3).

platelets are required for short dissolving times of clots in the assay system used in this work. In investigations of blood from a patient with leukæmia and thrombocytopænia, Van Creveld and Mochtar[2] found that the dissolving times of clots were related to the level of circulating platelets. Apparently the dissolving time of clots will be prolonged if the platelet concentration is lowered by *in vitro* centrifugation or *in vivo*.

PHARMACOLOGY

Pharmacological Characteristics of Neurohypophysial Hormones in Lungfish and Amphibians

THE morphological similarity between the neurohypophysis of lungfishes and amphibians[1] suggested a comparison of the neurohypophysial hormones of these groups of vertebrates. When extracts of the neural lobe of *Protopterus aethiopicus* Owen were chromatographed and pharmacologically characterized, we[2] found that they contained one active principle (8-arginine oxytocin, vasotocin) common to both teleosts and amphibians. The other oxytocic peptide found differed pharmacologically from the second hormone in teleost glands, that is, from ichthyotocin[3], which has now been identified as 4-serine 8-isoleucine oxytocin[4,5].

Further investigations of the unidentified oxytocic principle obtained from the African lungfish (*Protopterus*) and the Australian lungfish (*Neoceratodus* sp.) showed that it behaved in many ways like oxytocin: its R_F in the solvent system *n*-butanol/acetic acid/water (4 : 1 : 5) could not be distinguished from that of oxytocin. When assayed against oxytocin on the isolated rat uterus with or without magnesium in the suspending solution, the mean potency ratio (R_m = with Mg^{++}/no Mg^{++}) was 1·00 ± 0·08 for *Protopterus* and 1·19 ± 0·12 for *Neoceratodus*. Similar ratios (0·97 ± 0·16 for *Protopterus*, 1·06 ± 0·05 for *Neoceratodus*) were obtained by comparing milk ejection activity in the guinea pig with oxytocic action on the rat uterus (no Mg^{++}).

A difference from oxytocin was observed when the lungfish extracts were assayed on the blood pressure of the chicken. By definition the ratio of avian vasodepressor potency to rat uterus (no Mg^{++}) activity ($=R_a$) should have been unity had the eluates contained oxytocin alone. However, significantly higher values were consistently obtained (Table 1).

The active principles in amphibian neurohypophyses were investigated in the same manner. Extracts of frog (*Rana esculenta*) and toad (*Xenopus laevis*) glands were used. The characteristics of one of the hormones found were again compatible with the presence of vasotocin. The pharmacological properties of eluates from the other active region of the chromatograms resembled those of the unidentified oxytocic peptide in lungfish glands: the potency ratios in oxytocic assays with and without magnesium and in galactobolic assays were again near unity. The results of avian vasodepressor assays differed somewhat in *Rana* and *Xenopus*. The values of R_a in thirteen assays from three batches of *Xenopus* neurohypophyses varied from 1·64 to 2·30; assays on eluates from frog pituitaries (nine assays, four batches of glands) gave lower figures, varying from 1·18 to 1·58.

In order to obtain a measure of the precision of R_a, control experiments with mammalian oxytocin were performed. Oxytocin was prepared from pig neural lobes by the same method as the eluates from amphibian or lungfish glands. It was then assayed against synthetic oxytocin on the isolated rat uterus (no Mg^{++}) and by the avian depressor method.

Table 1 shows the mean values for R_a obtained in the species investigated. It also gives values for mammalian oxytocin and a synthetic analogue of oxytocin the pharmacological characteristics of which are similar to those of the eluates under discussion.

The high values for the ratio R_a obtained in lungfish and amphibians pose the following questions:

(1) Since R_a for vasotocin is much greater than unity (3·1 ± 0·14), could the high values found be due to contamination of the 'oxytocic' region of the chromatograms with vasotocin? In 26 out of 32 assays on lungfish and amphibian eluates R_a was greater than 1·4. To yield such a ratio, 20 per cent of the rat uterus activity would have to be due to vasotocin. A contamination of this magnitude is unlikely since it would have become apparent in rat pressor assays. Moreover the potency ratio R_m (rat uterus with Mg^{++}/rat uterus without Mg^{++}) would also have been raised whereas in all experiments it was not significantly different from unity. The fact that the African lungfish extracts contained little vasotocin should be added.

Table 1. MEAN POTENCY RATIOS AVIAN DEPRESSOR ACTIVITY TO RAT UTERUS ACTIVITY WITHOUT MAGNESIUM (R_a)

Material	No. of assays*		R_a ± S.E.†	P for difference from oxytocin
	No Mg	Chick B.P.		
Oxytocin	7	9	0·98 ± 0·07	—
8-Ileu oxytocin	6	6	1·56 ± 0·08	< 0·001
Protopterus	9	8	1·48 ± 0·13	< 0·01
Neoceratodus	3	2	1·81 ± 0·06	< 0·001
R. esculenta	13	9	1·40 ± 0·10	< 0·005
Xenopus	16	13	1·95 ± 0·13	< 0·001

* Each assay consisted of four (2 + 2) blocks.
† The potency ratios were calculated according to Sawyer, Munsick and van Dyke (ref. 6).

(2) Are the high values for R_a due to the presence of an as yet unidentified neurohypophysial hormone or to a mixture of several active peptides, including perhaps oxytocin? The activities present in the eluates could indeed be due to a single hormone, for a synthetic analogue of oxytocin, namely, 8-isoleucine oxytocin, is known the pharmacological spectrum of which resembles closely those of the eluates under discussion. Thus in rat uterus assays with and without magnesium and in milk ejection assays the potency ratios for 8-ileu-oxytocin are not significantly different from unity[7,8]. However, R_a for 8-ileu-oxytocin is considerably higher than 1·0; it is 1·67 according to Berde and Konzett[7] and was 1·56 ± 0·08 according to our own findings. 8-isoleucine oxytocin is intermediate in structure between the 'oxytocic' hormone of bony fishes (4-serine 8-isoleucine oxytocin) and oxytocin, the hormone of higher vertebrates. Its occurrence would therefore be in keeping with the intermediate phyletic position of dipnoans and amphibians. However, the possibility that the eluates contained more than one active principle cannot be excluded. The results of Maetz, Morel, Acher, Chauvet and Lenci[9] with neurohypophysial extracts of *Rana esculenta* are compatible with the presence of two active peptides in addition to vasotocin. A high natriferic activity was associated with one of these peptides whereas in our experiments the natriferic activity of eluates from *Protopterus*, *Rana esculenta* and *Xenopus* was low, and not different from that of oxytocin.

These results confirm the findings of Follett and Heller[2] that, besides vasotocin, lungfish glands contain an oxytocic principle different from that of bony fishes and similar to that of amphibians. They show, however, that the pharmacological spectrum of this oxytocic hormone (or mixture of oxytocic hormones) in the Amphibia and Dipnoi investigated differs from that of mammalian oxytocin. The occurrence of yet another neurohypophysial hormone, in addition to the five already identified, may thus have to be envisaged.

We thank Profs. A. H. Ennor and F. W. Landgrebe for supplying us with *Neoceratodus* and *Xenopus*.

Anti-coccidial Activity of Halogenonitrobenzamides

In the course of a search for new anti-coccidial compounds we have prepared and examined the prophylactic activity of a number of halogenonitrobenzamides against *Eimeria tenella*.

The compounds, mixed in the food at 0·01 or 0·02 per cent w/w, were fed to young chicks for 8 days, starting one day before inoculation with sporulated oocysts. The criteria of activity were comparisons of deaths, blood in the droppings, and cæcal lesions.

Several compounds showed good prophylactic activity in these preliminary tests (Table 1), but after more detailed examination (Table 2) one of these, 2-chloro-4-nitrobenzamide[1] ('M and B 5921'), was selected for further investigation both alone and in association with sulphaquinoxaline. In particular, a mixture composed of 3 parts 'M and B 5921' and 2 parts sulphaquinoxaline showed good activity against experimental *E. tenella*, *E. necatrix* and

Medication from 1 day before until 7 days after infection when results were determined
* Numerator = No. of survivors; denominator = No. of chicks infected.
† By Abbott's formula (ref. 5).
‡ Dose which saved 50 per cent of chicks obtained graphically using de Beer's method[6].
§ 'M and B 5888' = 3-chloro-5-nitrobenzamide.
¶ 'M and B 5889' = 3-iodo-5-nitrobenzamide.
‖ Results of two comparative tests added together.

E. acervulina infections when fed at 0·02 per cent w/w. The nitrobenzamide appeared to be less effective than sulphaquinoxaline against *E. acervulina*, but more effective against the other two species.

The mixture affected the development of the second generation schizonts of *E. tenella* and inhibited the early developmental stages of *E. acervulina*.

Detailed comparisons of activity against different laboratory strains of *E. tenella* have shown interesting variations.

The halogenonitrobenzamides are analogous to the active dinitrobenzamides[2,3] in which one nitro-group has been replaced by halogen. Hepworth[4] similarly found that replacement of one of the nitro-groups in 4,4′-dinitrocarbanilide by halogen gave a compound which retained anti-coccidial activity.

A full account of the biological investigations will be submitted for publication in due course.

PATHOLOGY

Calcification in the Intervertebral Disk

The human intervertebral disk is a structure in which degenerative changes are very common, often appearing as early as the third decade. Consequently it is not surprising that foci of calcification are frequently found in the intervertebral disks of apparently normal subjects. However, little information is available on the exact nature of the mineral phases and the possible significance that these may bear in relation to the underlying changes in the matrix. At present X-ray diffraction is the most sensitive method for identification of the various calcium compounds which can occur in the body.

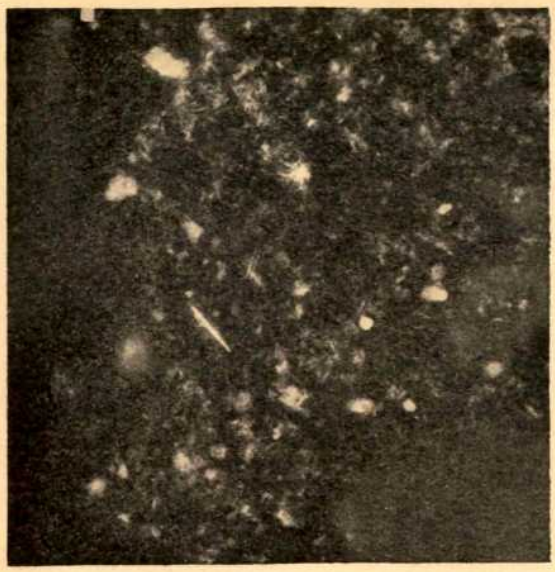

Fig. 1. Electron microscope photograph of prolapsed calcified thoracic intervertebral disk tissue showing crystallites of variable size on a very degraded matrix (× 9,000)

In an X-ray diffraction examination of intervertebral disk tissue which has been carried out by one of us (T. K. F. T.) hydroxyapatite diffraction patterns, similar to those obtained from bones, have been recorded from small calcified deposits at all spinal levels. However, when larger deposits have been examined, the crystallite size, as judged from the degree of broadening of the major reflexions, was larger than that which is usually recorded from pathological calcifications. When prolapse of a thoracic intervertebral disk occurs the extruded tissue is usually highly calcified and the dominant inorganic phase is hydroxyapatite. X-ray diffraction and electron microscope studies of such tissue have shown that although there is a variation in the crystallite size the majority of the crystallites are very large, approaching the size of those present in normal dental enamel. In the electron microscope the large crystallites have been observed in those areas devoid of living cells and fibrillar elements in the matrix (Fig. 1). This suggests that cell activity, in some as yet unexplained way, may be associated with the factors which regulate the size of the hydroxyapatite crystallites in a calcifying focus.

Hydroxyapatite is usually the dominant mineral constituent of pathological calcifications in the human body, but X-ray diffraction patterns of calcite, as a separate phase, have frequently been obtained from post-mortem and prolapsed disk tissue examined by us. It thus appears that calcium carbonate is a common inorganic component of the intervertebral disk. On twelve occasions (eleven of them when examining prolapsed tissue) the diffraction pattern shown in Fig. 2 has been recorded. The spacings do not correspond to those characterizing any compound yet described; the two strongest reflexions are 3·88 Å and 2·62 Å ± 0·05 Å. However, as water was eliminated (a matter of hours) the diffraction pattern changed to that of calcite. It is tentatively suggested that in this tissue the calcium carbonate, or a proportion of it, exists in a metastable form. On numerous occasions when calcium carbonate had not been found in disk tissue dried at room temperature the inorganic residue contained calcium oxide after heating to 950° C for 1 h. It is well known that mineralized tissues in the body contain 5–10 per cent carbonate, and this lack of separation as an independent phase is the normal finding[1].

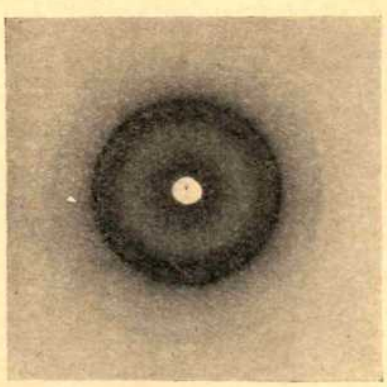

Fig. 2. Fibre X-ray diffraction pattern of prolapsed intervertebral disk tissue: Copper $K\alpha$ radiation of wave-length 1·54 Å, specimen to film distance ≈ 3 cm. The collagen diagram shows orientation with arching of the 2·86 Å reflexion. Two further rings are present, one at 3·88 Å (strong) and the other at 2·62 Å

X-ray diffraction patterns of whitlockite have been recorded from a substantial proportion of samples of air-dried disk tissue from subjects of more than sixty years of age. Preliminary measurements have indicated that the alterations in the lattice constants of this phase are compatible with a high atomic percentage of magnesium. In those subjects whose intervertebral disks contained whitlockite, it has been found that the cartilaginous tissues of the nasal septum, trachea, epiglottis and the wall of the abdominal aorta occasionally gave similar whitlockite diffraction patterns. The fact that whitlockite was not found in an extensive survey of the mineral phases in the bones of elderly people[1] suggests that the changes in the above tissues favouring the pathological deposition of whitlockite are due, at least in part, to local factors. Whitlockite diffraction patterns have not been recorded from a large number of specimens of prolapsed lumbar disk tissue dried at room temperature, and in this respect, as well as in some of the appearances of cells and matrix[2], prolapsed lumbar disk tissue differs from other disk tissue in the older age groups. A fuller account of this work and of other inorganic constituents of the intervertebral disk will be presented at a later date.

This work was carried out while one of us (T. K. F. T.) has been in receipt of a Nuffield Dominions Clinical Assistantship in Orthopædic Surgery at the University of Oxford. We thank Dr. J. Thewlis for his advice on the interpretation of some of the X-ray diffraction patterns.

Carcinogenic Action of *N*-hydroxy-4-acetylaminostilbene

Recent investigations[1,2] have indicated that 2-acetylaminofluorene and 4-acetylaminobiphenyl are metabolized to *N*-hydroxy derivatives in the rat and these metabolites are more carcinogenic than the parent amides. Thus, *N*-hydroxy-4-acetylaminobiphenyl was as active as the parent amide as a mammary carcinogen and in addition induced a higher incidence of ear-duct carcinomata and forestomach papillomata[2].

The urinary excretion of *N*-hydroxy-4-acetylaminostilbene following oral administration of 4-dimethylaminostilbene or 4-acetylaminostilbene to rats has been demonstrated[3]. Furthermore, *N*-hydroxylation of 4-acetylaminostilbene has been observed in an *in vitro* system with rat liver homogenate or the mitochondrial supernatant fraction in the presence of oxygen and $NADPH_2$ (ref. 3). The carcinogenicity of *N*-hydroxy-4-acetylaminostilbene has

been examined, therefore, to assess further the importance of *N*-hydroxylation in amine carcinogenesis.

N-hydroxy-4-acetylaminostilbene was prepared by aluminium amalgam reduction of an ethereal solution of 4-nitrostilbene followed by direct acetylation of the reaction mixture with acetic anhydride. The *N*-hydroxy derivative was then extracted into alkali, re-extracted into ether/ethanol/acetone (3 : 1 : 1) from neutral solution and crystallized several times from benzene (m.p. 200° C).

The carcinogenic activity of this compound as well as that of the parent amide and 4-dimethylaminostilbene was assessed following oral administration to rats in a low protein diet[4]. The concentration of each compound in this diet was 40 mg/kg so that the daily intake of carcinogen per rat was approximately 0·5 mg. The *N*-hydroxy derivative proved to be highly toxic for female rats at this dose-level, as evidenced by marked weight losses after prolonged feeding. This toxicity was also manifested by a high mortality and only 10 rats (62 per cent) survived the period of treatment (22 weeks; total dose, 75 mg/rat). Toxic effects were less pronounced in male rats and all but two survived feeding with the *N*-hydroxy compound for 32 weeks (total dose, 112 mg/rat). Survival in rats fed either 4-acetylaminostilbene or 4-dimethylaminostilbene was good and these compounds were fed for 22 weeks or 32 weeks in female and male rats, respectively.

Following completion of carcinogen treatment, rats were maintained on the basal low protein diet until the experiments were terminated (50–60 weeks).

Ear duct tumours first became detectable after 20 weeks of feeding these compounds and, as shown in Table 1, the final tumour incidence in rats receiving *N*-hydroxy-4-acetylaminostilbene was almost identical to that obtained with the parent amide. In contrast, the incidence of ear-duct tumours in rats fed 4-dimethylaminostilbene was somewhat lower, while with this compound female rats were almost twice as susceptible as male rats.

Table 1. Carcinogenicity of Aminostilbenes following Oral Administration to Rats

Compound	Initial No. of rats	Sex	No. at risk*	Incidence of ear-duct carcinomata percentage
4-Dimethylaminostilbene	16	M	16	55
	16	F	11	55
4-Acetylaminostilbene	16	M	16	88
	16	F	13	85
N-Hydroxy-4-acetylaminostilbene	16	M	14	86
	16	F	6	83

* Tumour incidences calculated from number of rats alive when tumours were first observed.

Histologically the ear-duct tumours induced with the aminostilbene compounds were all squamous carcinomata. They were well differentiated with plentiful cell nest formation and often showed keratin-filled cysts. Polymorph infiltration going on to abscess formation was a frequent finding, and in the larger tumours central necrotic areas were present.

No other tumours were observed in rats fed either 4-acetylaminostilbene or 4-dimethylaminostilbene. In rats fed the *N*-hydroxy derivative, one had an abdominal fibrosarcoma and another had an intestinal adenocarcinoma.

The carcinogenicity of *N*-hydroxy-4-acetylaminostilbene has been observed also by Andersen *et al.*[5]. In confirmation of the present findings, they found that the *N*-hydroxy derivative was as active as the parent amide in inducing ear-duct carcinomata in the rat. In addition, however, they also found that the *N*-hydroxy derivative, but not the parent amide, induced tumours at other sites, particularly in the forestomach.

In considering possible mechanisms of the carcinogenic action of *N*-hydroxy-4-acetylaminostilbene, the high reactivity generally observed with arylhydroxylamines[6] may be relevant, since these compounds will be capable of undergoing a variety of interactions *in vivo* with intracellular components such as protein and nucleic acid. Thus, for example, hydroxylamine itself is a mutagen in *T4* phage[7] with a high degree of specificity of action and the genetic damage is produced, it is thought, through direct action on cytosine in DNA. Furthermore, hydroxylamine has been shown to induce chromosomal damage in mammalian cells grown *in vitro*[8].

Differential Behaviour of Transplanted Mouse Lymphoma Lines in Genetically Compatible Homozygous and F_1 Hybrid Mice

Tumours induced in F_1 hybrids between two isogenic resistant mouse strains, differing at the histocompatibility-2 locus, occasionally give variant lines, compatible with one or the other of the parental strains, entering the F_1 cross[1,2]. Such variants have irreversibly lost the histocompatibility-2 antigens, determined by one of the parents. The mechanism of variant formation has been tentatively attributed to somatic crossing-over, even if deletion of a terminal chromosome segment cannot be excluded[1–4].

During further analysis of variant formation, variant sub-lines, compatible with one parental strain, were compared with the unselected F_1 tumour line, from which they have been derived, with regard to their ability to grow in mice of the original F_1 genotype. The results obtained were rather unexpected: the variant lines grew less well in the F_1 hybrids than the unselected lines.

A lymphoma designated *LNSF* was used. It originated in an *A/Sn* × *A.SW* F_1 hybrid and had been carried by serial subcutaneous transplantation in adult *A* × *A.SW* F_1 hybrids during 23 passages prior to the experiments recorded here. Four variant sub-lines were isolated, compatible with the *A.SW* strain, and two sub-lines, compatible with *A/Sn*. They were true variants, according to serological and transplantation experiments, performed as previously described[2], as judged by the loss of the histocompatibility-2 antigenic complex specific for *A* and *A.SW*, respectively.

Two *A.SW* variants were used for the tests recorded here immediately after one passage in the *A.SW* mouse where they were selected, while the other variants were carried for 1–3 transfers in the selective parental strain, followed by 1–2 passages in *A* × *A.SW* F_1 hybrids. Mechanically prepared cell suspensions of the variants or the F_1 line, *LNSF*, containing 60–80 per cent eosin unstained cells[5], were inoculated subcutaneously in a volume of 0·1 ml. containing 10^3 living cells to mice weighing 16–18 g. Approximately the same proportion of males and females was used in the majority of experiments. The mice were inspected every third day after inoculation, and the time required for the appearance of a tumour was recorded.

As exemplified in Fig. 1*A*, the variants grew less well in *A* × *A.SW* F_1 hybrids than the original unselected line, as judged by a more prolonged latency period and a slightly lower total frequency of takes. This was true for all variants tested, and particularly striking for the two *A*-variants. No differences were found between the sub-line tested directly after one passage in the selective

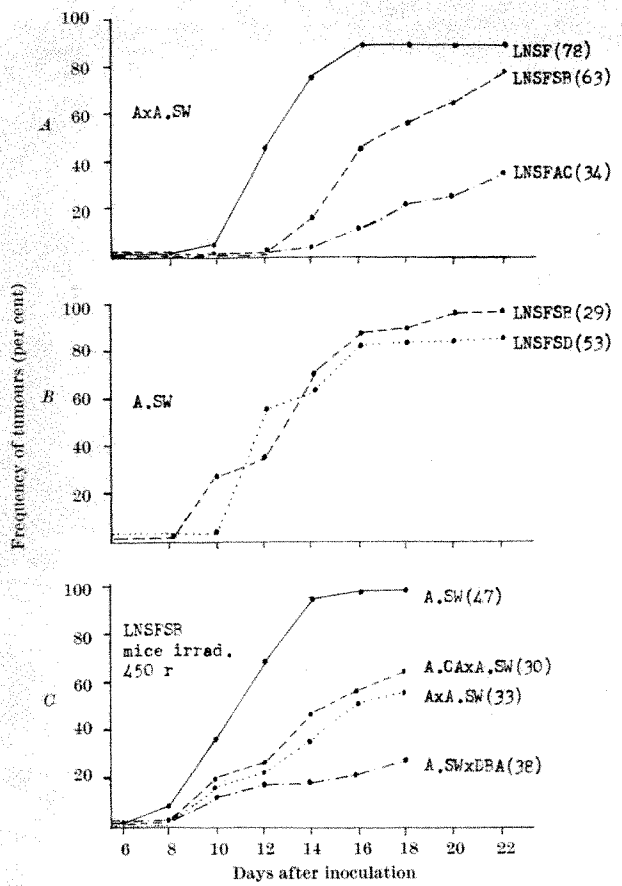

Fig. 1. *A*, Inoculation to *A/Sn* × *A.SW* F_1 hybrids of *LNSF* (unselected line in *A* × *A.SW*), *LNSFSB* (selected during two transfers in *A.SW*, followed by two transfers in *A* × *A.SW* prior to the current test) and *LNSFAC* (selected during two transfers in *A*, followed by one transfer in *A* × *A.SW* prior to the test). The numbers of mice inoculated in each group is shown within parentheses. *B*, Inoculation to *A.SW* of *LNSFSB* and of *LNSFSD* (tested directly after selection in *A.SW*). *C*, Inoculation of *LNSFSB* to *A.SW*, *A* × *A.SW*, *A.CA* × *A.SW* and *A.SW* × *DBA* F_1 hybrids. The mice had been pre-irradiated with 450 r. the day before inoculation

A.SW host or after subsequent serial passage in *A* × *A.SW* F_1. The difference between variants and the F_1 line disappeared when 10^6 cells were inoculated.

In order to test whether the differences between selected variant sub-lines and unselected F_1 hybrid lines with regard to their growth in the common F_1 hybrid recipient are related to the antigenic differential between the F_1 recipient and the variant cell, that is, the lack of certain histocompatibility-2 antigens in the latter, the variant cells were tested in an analogous way in the parental strain, where they had been selected and where no antigenic differential was known to exist. When 10^3 variant cells were tested in this way, they grew better than in F_1 hybrids and as well as the unselected lines grew in *A* × *A.SW* (Fig. 1*A* and *B*).

When 10^3 variant cells, compatible with *A.SW*, were tested in different F_1 hybrids other than the type of origin but containing *A.SW* as one contributor to the cross, it was found that they grew poorly in *A.SW* × *DBA*, slightly better in *A.SW* × *C3H* and still better in *A.SW* × *A.CA*, which was behaving similarly to *A* × *A.SW* F_1. The differences between the growth of *A.SW* variants in *A.SW* and in F_1 hybrids was not abrogated by irradiation of the hosts with 450 r. one day before grafting, in experiments with three variants and a minimum of 10 mice of each genotype tested for each variant. Analogous results were obtained with two *A*-variants, compared in untreated and irradiated *A* × *A.SW* and *A* × *A.CA* F_1. Fig. 1*C* exemplifies the growth of an *A.SW* variant in pre-irradiated mice of various genotypes. It may be of interest that pre-irradiated *A.SW* × *DBA* F_1 hybrids, while still showing relatively poor growth of 10^3 variant cells, nevertheless accepted an inoculum of 10^6 cells from a genetically incompatible (*A/Sn*) tumour, which did not grow in unirradiated hosts of this type, indicating that irradiation was efficient in abolishing the host versus graft reaction.

The mechanism of the phenomenon remains to be clarified. Two possible explanations may be considered:

A host-versus-graft reaction directed against antigens present in the variants and their parental strain hosts but absent from the F_1 hybrids could be postulated by assuming the existence of recessive antigens, determined by genes on the ninth chromosome and coming into expression in the variants as a result of somatic crossing-over (or, possibly, deletion of a chromosome segment). The fact that recessiveness to transplantation antigens has not, so far, been conclusively demonstrated by a variety of methods used and the finding that pre-irradiation does not abrogate the relative resistance of the F_1 hybrid hosts weakens this possibility. This latter finding also weakens the possibility that the results are due to antigenic differences between *A.SW* and *A* other than histocompatibility-2 or to the slight heterozygosity of the *A.SW* strain, detectable by skin transplantation techniques[6]. Furthermore, it would be difficult to explain on the basis of such a hypothesis that the unselected *LNSF* tumour grew as well in *A* × *A.SW* F_1 mice as the variants in the strain where they have been selected and both grew better than the variants in the F_1 hybrids.

These results may be more akin to a graft-versus-host reaction than a host-versus-graft response. The variant cells may recognize the host cells as antigenically different, and an intercellular reaction based on such recognition would be in line with the results obtained, although direct experimental confirmation is lacking. Alternatively, the mere exposition of the variant cells to the foreign antigens of the host may inhibit their growth. Both phenomena might act as homeostatic mechanisms, counteracting the appearance of antigenically deficient cells.

The results described appear to be similar to findings mentioned by Snell, obtained with homozygous lymphomas[7,8], which have been fully confirmed in (unpublished) experiments with two lymphomas of *A/Sn* origin, one lymphoma of *C57 B1* origin and one lymphoma of *A.SW* origin: they all grew better in the strain of origin than in various F_1 hybrids. The possible influence of recessive antigens or, for example, endocrine or metabolic differences may be more difficult to exclude in such situations, however, than when comparing tumour lines of a common origin, as presently described. It needs to be worked out whether similar findings can be made even with carcinomas and sarcomas.

The findings may suggest possibilities for the selection of cells having certain antigens from a large population of cells lacking them. Model experiments of that type are in progress. If successful, they might be of value for genetic investigations, trying to concentrate rare variants, resulting from, for example, fusion[9].

RADIOBIOLOGY

Effects of X-rays on Electrical Activity in the Eye of the Cockroach *Blaberus giganteus*

Significant changes in electroretinograms (ERG) and in spontaneous electrical activity recorded from the compound eyes of cockroaches have been found here during investigations of the effects of radiation on insects. These electrical discharges, although similar to the activity recorded from the optic nerve of *Limulus*[1], do not exhibit as marked a change in frequency with light stimulation. In this communication, we present the results of preliminary studies of the effects of X-rays on both the ERG and the spontaneous electrical discharges in the eye of the cockroach *B. giganteus*.

Whole adult insects, wrapped in polythene, were fastened to a wax platform. Fine platinum wire electrodes were inserted into the eye and into the head capsule by means of a semi-micromanipulator. Most consistent results were obtained when the reference electrode was located immediately posterior to the margin of the eye. Electrical activity, displayed on a dual-beam 'Tecktronix' oscilloscope, was recorded with a 'Brush' pen recorder. The insects were irradiated with a 150 kV X-ray machine (inherent filtration 3 mm beryllium; target-specimen distance 20 cm) at a dose rate of 2,000 r./min. The source of light was fluorescent room-lights giving an illumination of approximately 4 ft.-candles. All experimental animals were light-adapted.

Fig. 1, tracing *A* shows the typical spontaneous electrical activity prior to irradiation. With irradiation, this activity gradually decreased and, at a total dose of approximately 120 kr, all activity had virtually disappeared (Fig. 1, *B*). Partial recovery from this effect occurred during a one-hour rest period without X-rays (Fig. 1, *C*). Subsequent irradiation-and-rest cycles showed that suppression and recovery would occur several times, although less radiation and shorter rest periods were required for succeeding cycles of irradiation and rest. The amplitude and frequency of the electrical activity never returned to the pre-irradiation values.

B. giganteus reacted to changes in light intensity with the typical 'on-off' response (Fig. 2, *A*) of some insects as described by Roeder[2]. Exposure to X-rays decreased the amplitude of the 'on' response to light, but no change in amplitude was observed in the 'off' response. The reduction in the 'on' response was small, reaching a maximum of 15 per cent only after an exposure of 60 kr. Recovery from this effect was rapid, occurring in approximately 30 sec after the cessation of exposure to X-rays. After short rest periods of about 5 min following irradiation, this decrease in amplitude could be produced with very small doses (about 300 r.). No attempt was made to measure latent periods in these preliminary tests. It was interesting that an 'on-off' response was also found with X-rays (Fig. 2, *B*).

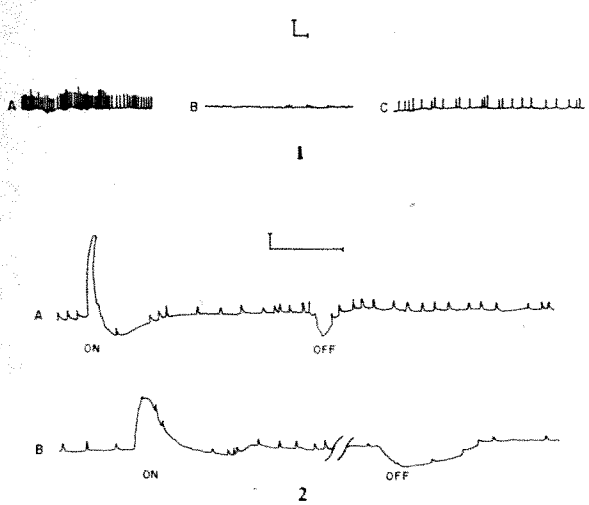

Fig. 1. Spontaneous electrical activity in the eye of *B. giganteus*. (*A*) Normal activity prior to X-rays. (*B*) after 120 kr; (*C*) recovery after a rest period of 45 min. Calibration values 275 μV and 1 sec

Fig. 2. 'On-off' response to (*A*) light and (*B*) X-rays. (Note that in tracing *B* a time lapse of 15 min occurred between the 'on' and 'off' responses.) Calibration values 200 μV and 1 sec

This work has demonstrated a marked effect of large doses of radiation in reducing the amplitude and frequency of the electrical activity recorded from the eye of *B. giganteus*. Also, an effect of X-rays was found in the 'on' response to light. Recovery from the effect occurred in both responses, but at very different rates. Further work will involve the study of recovery from radiation damage in these two systems.

BIOLOGY

Species Identification of Animal Cell Strains by Immunofluorescence

Animal cells cultivated *in vitro* can be readily identified with respect to their species of origin by several immunologic procedures, including: hæmagglutination[1], and mixed cell agglutination[2], both involving detection of species antigens common to erythrocytes and cultured cells, and an immunofluorescence method[3], which provides direct visualization of species-specific antigen–antibody reactions on cell surfaces. By means of these procedures, a number of established cell lines have been shown to be of a species other than that originally claimed[4,5], a finding obviously due to heterologous cell contamination and overgrowth or other laboratory errors.

This communication describes the use of the immunofluorescence procedure to detect individual cells of different species within mixed cell populations (as occurs in contamination, especially in early phases), as well as its use in species identification of a number of established cell lines and sub-lines from various laboratories.

Antisera against verified prototype strains (human: Detroit-6, HeLa; monkey: *LLC-MK*$_2$; mouse: *L-M*, *S*-180; Chinese hamster) and/or primary kidney cultures of various animal species (human, monkey, mouse, rat, rabbit) were prepared by immunizing guinea pigs or rabbits with washed cells scraped from monolayers cultured in Eagle's medium supplemented with 5 or 10 per cent human or calf serum as previously described[3]. Antisera were heated at 56° C for 30 min and the globulins precipitated in 18 per cent sodium sulphate (1 vol. serum/2 vol. 27 per cent sodium sulphate) at 37° C for 16 h. Following dialysis, the resulting globulin solutions, adjusted to *p*H 9, were conjugated with fluorescein isothiocyanate (FITC) by adding them directly to a dry mixture of 1 part FITC (0·025 mg. FITC/mg protein) and 9 parts cellulose powder ('Celite') and shaken for 5 min[6]. The 'Celite' was removed by centrifugation and the unbound dye by 'Sephadex' gel filtration.

Cells to be tested were obtained by trypsinizing monolayer cultures to yield $3–4 \times 10^6$ cells per ml. After 3 washes in buffered saline (*p*H 7·5), 0·1 ml. of cell suspension was mixed with 0·1 ml. labelled antibody, agitated for 30 min, again washed 3 times, and a drop of the final sediment sealed under a coverslip and observed by fluorescence microscopy[3]. Specific staining reactions

head and the region containing the graft, were fixed in sublimated Bouin–Hollande[8]. The thyroid was studied in 5μ sections stained with a modified Masson technique[9], with periodic acid–Schiff (PAS), Cleveland–Wolfe (trichrome) and hæmalum-eosin. The pituitary grafts were recovered in 4μ or 5μ serial sections of the tail region and stained with Cleveland–Wolfe and various histochemical procedures[8]. The heads of the hypophysectomized fish were sectioned at 10μ to verify the absence of pituitary fragments.

As in most teleosts, the thyroid gland in *M. formosa* is not encapsulated, but consists of follicles scattered in the gular region associated with the inferior jugular veins and the ventral aorta, and contained in a mass of loose connective tissue into which the gland expands when strongly stimulated. In some fish, both intact and hypophysectomized, a few thyroid follicles have been found also in the region between the heart and the œsophagus. This region in grafted-hypophysectomized fish has not been examined.

Histological features of the thyroid in the three groups of fish are summarized in Table 1, and typical glands are illustrated in Fig. 1. It is clear that the transplanted pituitary maintained the thyroid in a more active state, by histological criteria, than the gland in the hypophysectomized controls. Furthermore, in six of the grafted-hypophysectomized fish, the thyroid was more strongly stimulated than in any of the intact controls, with marked hyperplasia in which epithelial cells and follicles filled nearly all the thyroid area and invaded the bases of the gill-arches.

Table 1. Summary of Histological Characteristics of the Thyroid Glands. Figures show the Number of Fish in which the Listed Characters were Predominant

	Intact	Hypophysectomized	Grafted-hypophysectomized
No. of fish	14	17	13

Granulated	10	0	9
Resorption vacuoles			
Many	9	0	8
Few	5	12	4
None	0	5	1
Hyperplasia of thyroid	4	0	8

In work now in progress we have identified the pituitary thyrotrophs in *Mollienesia* as PAS+ and AF+ cells in the proximal pars distalis (meso-adenohypophysis). In the eight grafts we have so far examined, there were large numbers of these cells, displaying signs of great secretory activity. All the grafts were healthy and well-vascularized, and besides the thyrotrophs contained many acidophils of the rostral pars distalis (pro-adenohypophysis), corticotrophs, inactive gonadotrophs, very few putative somatotrophs, and cells of the pars intermedia (meta-adenohypophysis). In two grafted-hypophysectomized fish which were kept for seven months, the grafts contained many active thyrotrophs and the thyroid glands were markedly stimulated and hyperplastic with extensive invasions of the gill-arches: evidence that function can continue in the transplanted pituitary for a considerable time.

These results indicate that TSH can be secreted at a greater rate by the transplanted pituitary than by the gland in its normal situation. The simplest explanation of this finding would be that the hypothalamus normally inhibits TSH-secretion, as suggested by other workers to account for enhanced TSH-output by heterotopic pituitary transplants in *Ambystoma*[4]. We have made no direct measurements of thyroid hormone (TH)-levels in the blood of these fish, but two lines of evidence suggest that the histological hyperactivity in the thyroid of grafted-hypophysectomized fish was accompanied by physiological activity and was not a false appearance analogous to the state of the thyroid after anti-thyroid drugs. First, the slight growth displayed by the grafted-hypophysectomized fish[11] suggests the presence of TH as well as small amounts of growth-hormone. Secondly, the state of the skin of these fish indicated at least normal blood TH-levels. In the hypophysectomized group, the skin was dull and poorly reflecting, due presumably to loss of guanine, but the grafted-hypophysectomized fish retained the silvery skin of the intact controls. In *M. latipinna* the dull skin of hypophysectomized fish is restored to the normal silvery state by treatment with thyroxine[10]. These observations indicate that the blood-levels of TH in the grafted hypophysectomized fish must have been at least as high as in the intact controls.

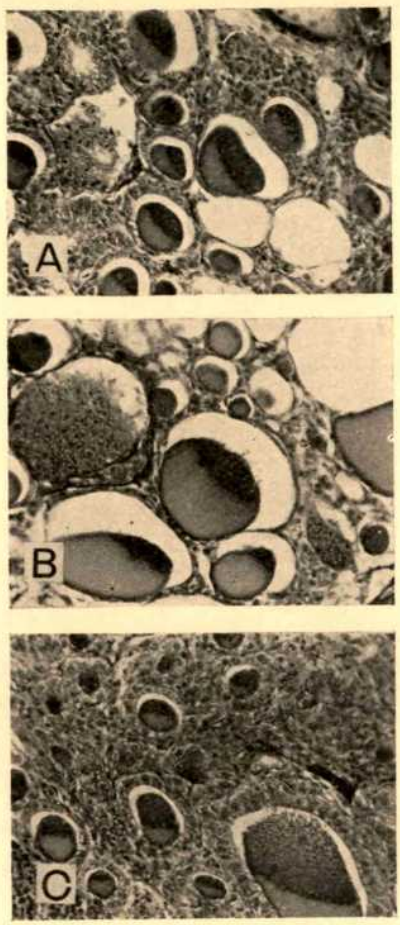

Fig. 1. Thyroid gland of *M. formosa* (× 230). *A*, Intact control; *B*, hypophysectomized control; *C*, hypophysectomized fish bearing pituitary transplant in caudal musculature

We have evidence, from the thyroidal response of intact *M. latipinna* to thiourea treatment[10], that negative feed-back operates between TH and TSH in these fish as in mammals. Thus we have to account for continuously elevated rates of TSH-production by the transplanted pituitary in the presence of normal (or even supra-normal) TH-levels in the blood. It may be that TH in the intact animal suppresses TSH-production by acting on the hypothalamus and reinforcing the hypothalamic inhibitory influence on TSH-secretion. Alternatively, TH may directly inhibit the activity of the thyrotrophs, the hypothalamus normally modifying this control by lowering the threshold for suppression of TSH-output by TH.

In conclusion, our results show decisively that the ability to secrete considerable amounts of TSH can be

retained by the teleost pituitary gland when removed from its normal connexion with the hypothalamus, and suggest that the teleost hypothalamo-hypophysial relationship with respect to TSH may differ considerably from that in mammals.

Phototaxis and Green Rods in Urodeles

Many Amphibia are strongly phototactic, and it is generally found that this behaviour is more readily released by blue light than by light of any other colour[1]. It is reasonable to suppose that the green rod underlies such phototaxis, since this receptor has been shown to be strongly sensitive to blue light[2]. Although all anurans are said to have green rods, not all urodeles possess them, so that if this hypothesis is correct we should expect those urodeles which lack green rods also to fail to show any marked sensitivity to blue light when their phototactic behaviour is tested. In experiments recorded here two urodeles were tested, one of which has green rods (*Triturus cristatus*), and one of which lacks them (*Salamandra salamandra*)[3].

The experimental arrangement for testing phototaxis has previously been described in detail[4]. Animals were tested in a dark room in a *Y*-maze of black 'Perspex', in which they chose between two 4 in. × 4 in. translucent windows illuminated by means of Wratten filters and 500 W projectors. The average half band-width of the filters was 30 mμ, and the energy reaching the windows was approximately 23 μW/cm². Six filters were used, giving seven possible stimuli, for the windows could be illuminated by six different colours, or remain dark. These seven stimuli were presented on the windows in all 21 possible pairs, and the stimulus chosen by the animal noted in each case. In this way spectral response curves were obtained, which could be tested for statistical significance by means of Kendall's coefficient of agreement[5].

Twelve *Salamandra* and 14 *Triturus* were used. Eight of the *Salamandra* received two trials on each of the 21 possible pairs of stimuli; the other four only received one trial on each pair. All 14 *Triturus* received one trial each pair. Each individual received all its trials on one day,

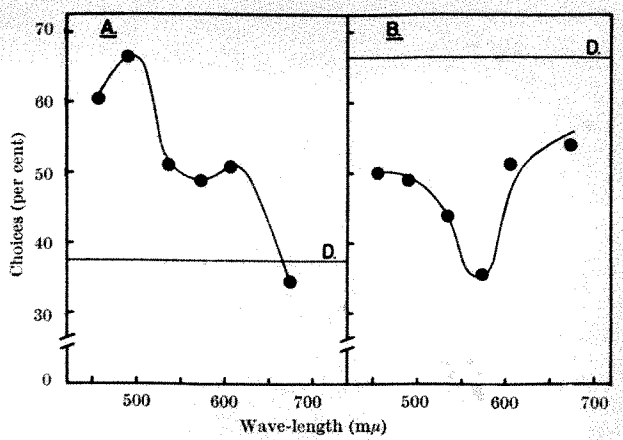

Fig. 1. *A*, Spectral response curve for *Triturus*; *B*, spectral response curve for *Salamandra*. The line labelled *D* shows the percentage of occasions on which darkness was chosen in each case

except for those animals which saw each pair of stimuli twice: these received one trial on all possible pairs on one day, and a second trial on all pairs a day later.

The spectral response curves thus obtained are shown in Fig. 1. The coefficient of agreement was in each case significant at considerably better than the 0·1 per cent level of confidence. It can be seen that the behaviour of the two species differed markedly. *Triturus* is positively phototactic, and responds to blue more often than to any other colour. The responsiveness to blue is less marked than it is in the frog[4], and the response curve also differs in having the maximum in the blue and the minimum in the green both shifted somewhat towards the longer wavelengths. The latter is presumably a consequence of the newt having visual pigments based on vitamin A_2 as opposed to vitamin A_1 like the frog. *Salamandra*, on the other hand, is negatively phototactic, choosing darkness more often than any other stimulus. The animal is maximally sensitive at about 570 mμ, and the spectral sensitivity curve is in line with the photopic sensitivity that would be expected for this animal[6].

The results therefore support the view that the green rod is involved in amphibian phototaxis. Previous results, however, show that other receptors must be involved as well[4].

This work forms part of a project on stimulus analysing mechanisms jointly supported by the U.S. Office of Naval Research (contract No. *N*62558–2453) and the U.K. Nuffield Foundation.

Movements and Co-ordination of the Ciliary Comb Plates of the Ctenophores *Beroe* and *Pleurobrachia*

Investigations by Afzelius[1,2] on the comb plates of *Mnemiopsis* showed that these plates are compound structures built up from several hundred thousand cilia of somewhat modified structure, the shafts of which are apparently cemented together in long rows. The comb plates of the smaller ctenophores used in this work contain fewer cilia, but even here many thousands of cilia must be incorporated in each plate.

Figures for parameters of ciliary beating published previously[3] refer to measurements made on a detached

Table 1. Some Parameters of Ciliary Activity in Ctenophores (Temperature, 19°–20° C)

	Pleurobrachia	*Beroe*
Length of comb plate cilia	1·1 mm	0·8 mm
Angular velocity of beat in effective stroke	6,100°/sec	5,750°/sec
Rate of propagation of the contraction wave	11·1 mm/sec	9·7 mm/sec
Time for one cycle of beat (approx.)	0·1 sec	0·085 sec
Metachronal wave velocity	72·9 mm/sec	40·6 mm/sec
Number of comb plates excited per sec	197	185
Separation of comb plates	0·37 mm	0·22 mm
Overall length of animal	6·3 mm	4·2 mm

Table 2. Parameters of the Metachronism of Four Animals

	Paramecium[3]	*Stentor*[3]	*Beroe*	*Pleurobrachia*
Metachronal wave velocity (μ/sec)	712	657	40,600	72,900
Cilia excited per sec	228	173	185	197
Interciliary distance (μ)	3·1	3·8	220	370
Time interval between excitation of adjacent cilia (msec)	4·4	5·8	5·4	5·1

comb row of *Pleurobrachia*, and are shown by the present investigation to be quite different from values measured on an intact animal. Data obtained from cinematograph films taken at 64 frames/sec are shown in Table 1; it is not appropriate to use a stroboscope or quote the frequency of beat since the cilia rest frequently between beats.

The rate of movement of these compound cilia in the effective stroke is not abnormally fast (the angular velocity is little more than half that in *Stentor*), probably because of the large viscous resistance offered to the extensive surface area of the comb plates. However, the propagation of the contraction wave up the cilium in the recovery part of the beat is much faster than in any other example described. In simple cilia the rate of propagation is usually below ½ mm/sec, and this rate rises as the number of cilia in each compound cilium is increased, so that it approaches 1 mm/sec in *Stentor* membranelles containing 60–75 component cilia, and rises further to around 10 mm/sec in these ctenophores where many thousands of cilia are present. It seems reasonable to suggest a correlation between the contractile force that can be exerted and the rate of propagation of the contraction.

The antiplectic metachronism of comb plates appears from preliminary experiments on the effects of viscosity to be of the neuroid type found in *Stentor*[4]. The rates of movement of the metachronal waves in these two types of ctenophore differ considerably from one another and are both much greater than the fastest recorded from other types of animal (0·6–0·7 mm/sec). However, the comb plates are very much farther apart than normal cilia, and the number of cilia excited per second is of the same order in both ctenophores as it is in *Stentor* membranelles and *Paramecium* vestibular cilia at similar temperatures (Table 2). The interval between the excitation of adjacent cilia in ciliary tracts from these four animals appears to be fairly constant at about 4–6 msec, although the distances between the cilia may differ by a factor of 100. This is in agreement with the suggestion[4] that the neuroid type of conduction of metachronal waves involves two steps, a rapid interciliary conduction and a slower build-up of excitation within the cilium.

It is clear from the cinematograph records that the form of beat of ctenophore comb plates resembles that of *Stentor* membranelles[5] in that the cycle of beat cannot be rigidly separated into two parts. The contraction wave responsible for the recovery phase of the beat has clearly started to move up the shaft of the compound cilium before the effective stroke has been completed.

ENTOMOLOGY

Central Nervous Control of the Mechanical Properties of the Cuticle in *Rhodnius prolixus*

In the course of experiments carried out to examine the mechanism of neurohumoral regulation of water economy, tonus modifications in the cuticle of the abdominal wall conditioned by the nervous system were observed. Such modifications in the mechanical properties of the cuticle were reported in a previous communication[1] as "peripheral inhibition of central origin". Cottrell[2] describes similar changes in the blowfly, *Calliphora erythrocephala*, and interprets them on the basis of the sclerotization process. Certain evidence obtained in the fifth-stage larvæ of *Rhodnius prolixus* during feeding leads to the postulation of a nervous control of these properties of the cuticle.

Fifth-stage larvæ of *Rhodnius prolixus* during feeding may take an amount of blood 10 times higher than their fasting weight (35 mg). This enormous increase in volume is accompanied by a distension of the abdominal cuticle. The distended cuticle may even become transparent, thus allowing details of tracheæ and internal organs to be observed.

If the nerves corresponding to one side of the abdomen (for example, the left side) have been previously severed, during feeding the distension of the abdominal wall occurs asymmetrically, being larger on the intact side (Fig. 1). This asymmetry in distension is permanent and manifests itself whether feeding occurs immediately after neurotomy or one month later.

As abdominal distension progresses during intake of blood in these animals with partial lateral neurotomy, the asymmetry of abdominal distension disappears gradually, and on reaching maximum distension no differences are apparent with normal animals, except for slight changes in the shape of the abdomen. However, the cuticle of the operated animals shows, when observed in polarized light under the microscope, differences in the orientation of the birefringent micelles between the left and the right side. If total abdominal neurotomy is performed at the mesothoracic fused ganglionic mass, there is no asymmetry of distension at feeding, but the distended abdomen has a more nearly spherical shape than in normal animals. Furthermore, the cuticle so distended shows distinct modifications of its physical properties: (1) it has nacreous reflexions and the surface is smoother and more brilliant; (2) it loses elasticity and becomes friable (it tears upon slight external pressure).

The same result is obtained in animals which have suffered neurotomy of the connectives between the prothoracic ganglion and the mesothoracic fused ganglionic mass.

Preliminary observations show that the internal pressure in the abdomen immediately after feeding is not

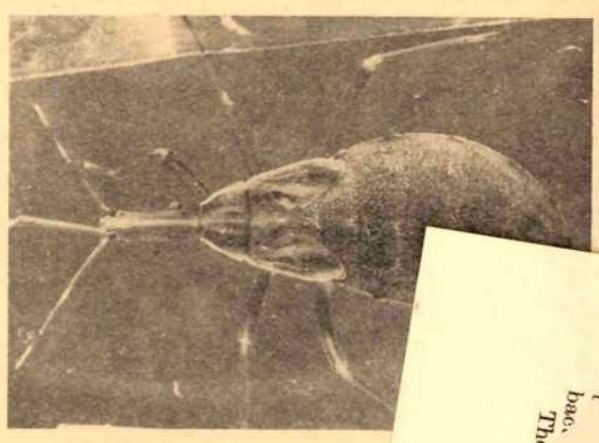

Fig. 1

appreciable and does not differ between normal and operated animals, but that there are differences in the elastic properties which depend on a certain 'cuticular tonus' (as measured by the variation in lymph flow through a cut leg).

Careful observation of an asymmetrical animal (Fig. 1) shows also that the asymmetry results from a different distension of the sclerite cuticle; it may be measured by relating the distance between cuticular setæ or the width of the sternite of the left and right sides.

In normal animals the abdominal cuticle offers a strong resistance to distension when Ringer solution is injected in the hæmolymphatic cavity. The cuticle and the shape of the abdomen of artificially distended animals are similar to those of operated animals. When artificial distension is performed on operated animals, the cuticle breaks between sclerites, even when the volume of injected solution never reaches 50 per cent of the volume normally incorporated through ingestion of blood.

From the foregoing results it may be inferred that in the fifth-stage larvæ of *Rhodnius prolixus* during ingestion there occurs a central nervous controlled modification of the 'cuticular tonus' in the sclerites of the abdominal wall and perhaps in the cuticle of the whole body.

This nervous controlled cuticular modification would consist in a change (decrease) during feeding in the cohesion among chitin micelles accomplished at the level of the structural proteins of the cuticle. Under polarized light modifications are observed in the orientation of chitin micelles which are not related to the process of sclerotization of the cuticular proteins.

On total abdominal disenervation at the level of the mesothoracic fused ganglionic mass or of the connectives between the prothoracic ganglion and the mesothoracic fused ganglionic mass, this cuticular 'antitonus' is eliminated, and when distension occurs profound modifications are produced in the structure and mechanical properties of such unenervated cuticle.

MICROBIOLOGY

Resistance to Copper of some Oxidizing and Reducing Bacteria

Certain types of bacteria, particularly *Thiobacillus thiooxidans* and *Ferrobacillus ferrooxidans*, are known to assist the oxidation of pyritic ores[1–4]. It has also been shown[5,6] that the rate of natural leaching of uranium from low-grade ores can be significantly increased when the leaching is done in the presence of pyrite that is itself undergoing microbiological oxidation. It is possible that a similar enhanced leaching effect could be obtained for other metals from their low-grade ores. This is of particular interest in the case of copper, since it might be anticipated that cupric ions would have a marked toxic effect on the bacteria, and enhanced leaching would be prevented.

We have therefore examined the resistance to cupric ions of a number of pure strains of sulphur-oxidizing bacteria and of iron-oxidizing bacteria. At the same time, we have also studied the effect of copper on the growth of sulphate-reducing bacteria. At different times various hypotheses of sulphide-ore formation have been put forward by geologists, involving bacteria as the agents responsible for precipitating metals from natural waters. Usually these arguments have been refuted in the belief at copper-bearing solutions would be toxic to any such eria[7].

ollowing pure strains have been examined:

(*a*)	Sulphur-oxidizing bacteria:	
	Thiobacillus thiooxidans, strain Iceland	N.C.I.B. No. 8342
	Thiobacillus concretivorus, strain Parker	N.C.I.B. No. 8345
(*b*)	Iron-oxidizing bacteria:	
	Ferrobacillus ferrooxidans, strain Beck	N.C.I.B. No. 8451
(*c*)	Sulphate-reducing bacteria:	
	Desulfovibrio desulfuricans, strain Hildenborough	N.C.I.B. No. 8303
	Desulfovibrio desulfuricans (*aestuarii*), strain El Agheila C	N.C.I.B. No. 8308
	Desulfovibrio orientis, strain Singapore	N.C.I.B. No. 8382
	Clostridium nigrificans, strain Delft 74*T*	N.C.I.B. No. 8395

Stock cultures were obtained from lyophilized cells using the following media: (*a*) for sulphur-oxidizing bacteria, Waksman's *S*12 mineral salts and elementary sulphur medium[8] incubated aerobically at 30° C; (*b*) for iron-oxidizing bacteria, Beck's mineral salt medium[9] incubated aerobically at room temperature; (*c*) for sulphate-reducing bacteria, Baars' lactate-mineral salts medium[10] supplemented with 0·1 per cent yeast extract and 0·01 per cent thioglycollic acid incubated anaerobically at 30° C under hydrogen with 1 per cent carbon dioxide. (55° C in the case of *C. nigrificans*.)

Subcultures were made into fresh batches of the appropriate media supplemented with a small known concentration of copper ions added as copper sulphate. When growth of the subculture occurred, a second subculture was made into medium containing double the concentration of copper. This procedure was continued until a concentration of copper was reached sufficient to inhibit growth. Six successive subcultures were then made at the next lower copper concentration before a second attempt was made to obtain growth at the high concentration. If growth now occurred the process was continued. If inhibition was still obtained, the lower copper concentration was taken as the limiting concentration.

Final figures obtained for limiting copper concentration (Cu^{2+}) were as follows:

Thiobacillus thiooxidans (Iceland)	20,000 p.p.m.
Thiobacillus concretivorus (Parker)	10,000 p.p.m.
Ferrobacillus ferrooxidans (Beck)	10,000 p.p.m.
Desulfovibrio desulfuricans (Hildenborough)	50 p.p.m.
Desulfovibrio desulfuricans (*aestuarii*) (El Agheila C)	20 p.p.m.
Desulfovibrio orientis (Singapore)	30 p.p.m.
Clostridium nigrificans (Delft 74*T*)	30 p.p.m.

The results for the *Thiobacilli* and the *Ferrobacillus* show a remarkable resistance to copper and there seems to be no reason why they should not be used to advantage to assist in the leaching of copper ores.

The sulphate-reducing bacteria were very much more sensitive. It has been reported earlier that 100 p.p.m. copper sulphate (approx. 40 p.p.m. Cu^{2+}) is ineffective in inhibiting *D. desulfuricans* (Hildenborough) and *C. nigrificans* (Delft 74*T*) (ref. 11).

In those experiments, however, the medium used included 0·1 per cent cysteine hydrochloride (that is, was approximately 0·0064 M w.r.t. –SH compared to 0·0011 M w.r.t. –SH in the present experiments). It is to be expected that a larger fraction of the added copper might be rendered ineffective by complexing in the cysteine medium. It seems unlikely that the sulphate-reducing bacteria play a significant part in the deposition of copper sulphide ores.

A Selective Medium for the Isolation of Soft Rot Coliforms from Soil

BACTERIAL species which cause soft rot of plant tissue secrete pectic enzymes which destroy the middle lamella of the cell wall and, *in vitro*, liquefy pectate gel. This property has been utilized by Wieringa[1] and Stewart[2] in the preparation of selective media for isolating soft rotting *Erwinia* spp., and by Paton[3] for the isolation of pectin-decomposing *Pseudomonas* spp. The preparation of these media involves a double-layer technique in which a calcium agar medium is overlaid with a sodium polypectate gel in which the formation of shallow pits serves as a diagnostic characteristic.

During investigations of *E. atroseptica* (the causal organism of potato black leg), the selective-diagnostic medium of Stewart[2], which was developed in these laboratories, has been used for the routine isolation of the organism from diseased plants and tubers and has proved to be extremely efficient for this purpose. On this medium which incorporates McConkey agar plus calcium chloride in the basal layer, *E. atroseptica* develops as red colonies in 'cup-shaped' depressions formed in the pectate gel of the upper layer. The bile salts present in McConkey agar inhibit the growth of certain contaminating bacteria.

In examining the survival of *E. atroseptica* in soil where black leg of potato had occurred it was found, by direct soil isolation methods, that as the diseased plant débris rotted there was a marked increase in numbers of saprophytic bacteria, some of which were pectin-decomposing strains of *Pseudomonas* as described by Paton[3]. On Wieringa's medium these latter types formed depressions indistinguishable from those formed by *E. atroseptica*. On Stewart's medium the fewer colonies of *E. atroseptica* were overgrown and quickly masked by the much more numerous colonies of saprophytic bacteria which included *Pseudomonas* spp. Replacement of lactose by salicin in the basal layer as suggested by Stewart[2] was ineffective.

In an attempt to find a more selective substrate the following formula for the basal layer of the medium utilizing sodium citrate as the sole carbon source was devised: Simmon's citrate agar (Oxoid '*C.M.*155'), 23·0 g; calcium chloride, 3·0 g; bile salts (Oxoid '*L.*55'), 5·0 g; crystal violet, 0·001 g; distilled water, 1 l. These ingredients were autoclaved at 15 lb. pressure for 15 min, cooled, adjusted to *p*H 6·8 and 15 ml. amounts poured into sterile Petri dishes. The surface of the medium was dried before the addition of 4 ml. amounts of the upper layer of pectate solution prepared as described by Paton[4] and adjusted to *p*H 7·2. After drying for 12 h at 37° C the pectate gel set firmly and was ready for inoculation.

After incubation for 48 h at 27° C, *E. atroseptica* develops as pale-blue colonies in 'cup-shaped' depressions, 1·0–1·5 mm in diameter, which contrast clearly with the deep-blue colour of the surrounding medium caused by the production of alkali. Other citrate-utilizing coliform types produce pale-blue colonies but cause no liquefaction of the pectate gel. *Pseudomonas* spp. develop slowly and appear as yellowish-green colonies; the pectin-decomposing types form 'pin-point' depressions, not more than 0·5 mm diameter, which are easily distinguished from the deeper and larger 'cup-shaped' depressions formed by *Erwinia*. The latter may be easily counted by holding the plate over a strong light. Although bile salts and crystal violet are necessary when isolating *E. atroseptica* from soils, they may be omitted in its isolation from soft rotted plant or tuber tissues.

Comparisons of this medium with Stewart's shows that it is more selective for *E. atroseptica*. Whether or not this is due to a preference for citrate rather than lactose as a carbon source or to the suppression of the other competitive bacteria is not yet known. The medium has also proved effective for the isolation of *E. carotovora* and *E. aroideae* from soil.

MISCELLANEOUS

Periodic (Liesegang) Precipitation of Chemicals

LIESEGANG'S periodic precipitation of inorganic chemicals[1] has yet to be explained adequately, possibly because experiments in gathering data to describe it have failed to recognize and control numerous complicating effects influencing it. Some of these are illustrated in the work reported here.

Reagent grade chemicals, single- or triple-distilled water (glass still), Difco 'Bacto' agar and a purified product of this[2] were used for this work. (Ion agar No. 2 and 'BBL' agar for bacteriological media were also used, and gave similar results. A process for de-ionization is described by Crowle[2].) Periodic precipitation was induced in 1-mm layers of 2 per cent agar on 75 × 50 mm microscope slides. When internal reactant was used, it was dissolved in the agar before pouring the latter on to a slide. External reactant was allowed to diffuse from 5 mm disks of Eaton-Dikeman No. 652 filter paper. (By comparison with depot wells punched in agar, this filter paper had no detectable effect of its own on our results, other than that due to absorption of fluid. It was more convenient to use than such wells.) Reactions were allowed to develop in humidified Petri dishes at 2° C; this temperature was permitted to vary ± 2° or ± 0·1° C, depending on the purpose of the experiment. Results reported below are representative of numerous experiments, which among themselves were highly reproducible.

Fig. 1 is a photograph of the numerous Liesegang bands developed overnight at the more constant temperature between 1 per cent silver nitrate and anion contaminants in 'Bacto' agar. This test repeated in de-ionized 'Bacto' agar[2] showed no precipitate, unless appropriate anions purposely were re-added to it. The tendency of the unpurified agar to form Liesegang bands diminished upon prolonged boiling during the process of dissolving it.

Several Liesegang bands will form in de-ionized agar in triple-distilled water between 0·1 per cent silver nitrate external reactant and concentrations of sodium chloride internal reactant 100-fold less than those required to initiate turbidity, detectable by Klett colorimeter, due to silver chloride in liquid, as opposed to gelled, aqueous solution. So sensitive is the agar gel for this effect that brief and light contact with bare fingers, such as occurs when a slide is handled by the edges for a few seconds needed to move it from one place to another, contaminates it with enough chloride ions to form such bands with silver nitrate in the de-ionized system. A similar effect was obtained by making up the de-ionized agar in single- rather than triple-distilled water.

Liesegang bands develop only at certain reactant ratios. This is illustrated in Fig. 1, which shows that until external reactant has diffused a certain distance characteristic for a particular precipitating system the solid disk of precipitate does not begin to break up into concentric rings. But as Fig. 2 shows, such a disk can be broken into similar rings by temperature fluctuations such as occur in the cycling of an ordinary refrigerator (for example, ± 0·5° C in 10 min). Fortunately, by the time the critical reactant ratio favouring true Liesegang precipitation has been reached (for example, immediately outside the solid disk of precipita-

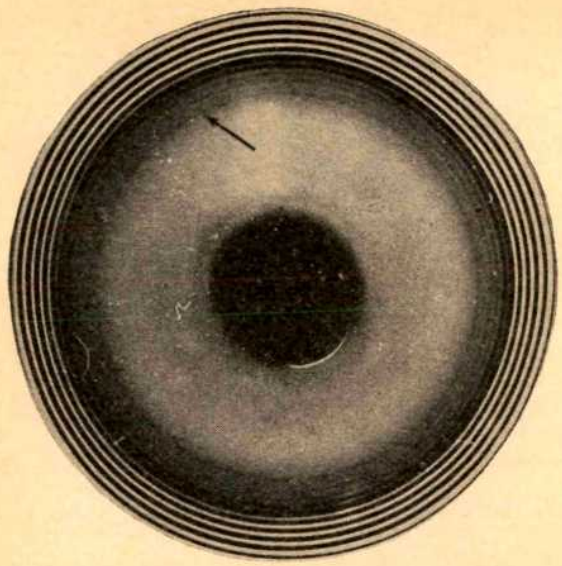

Fig. 1. Heavy precipitation formed by 1 per cent silver nitrate external reactant diffusing from the central dark area and reacting with contaminant anions on unpurified Difco 'Bacto' agar. When silver ions have become sufficiently diluted by diffusion to reach a critical ratio with contaminating anions, silver salts begin to precipitate in the form of numerous Liesegang rings instead of a solid disk (arrow). A control slide set up using de-ionized 'Bacto' agar developed no precipitate of any kind

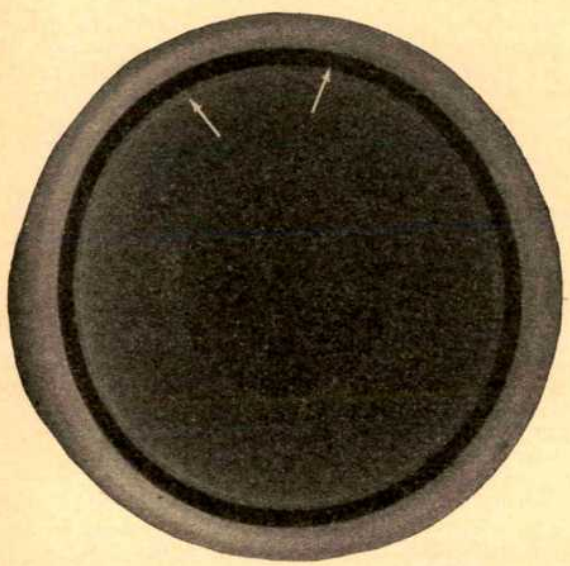

Fig. 2. Effect of temperature variations on the formation of an otherwise uniform disk of precipitate by 2 per cent silver nitrate diffusing through unpurified 'Bacto' agar. The stria pointed out by an arrow was caused by a modest but normal rise in temperature of the refrigerator in which this plate was being held. The gap indicated by a second arrow developed shortly after the plate was held for 1 min at 37° C and then returned to the refrigerator. Control slides set up in the same manner but maintained at a temperature not varying more than ± 0·25° C developed only a uniform disk of precipitate without any striations or gaps

tion in Fig. 1), the sensitivity of these plate tests to temperature fluctuation-induced artefacts has dwindled to the point where fluctuation must be large to produce an artefact (for example, 5° C in 10 min).

The effects observed above are not unique to the silver chloride system. They occur also with other salts as well as with antigen and antibody[3].

These results and other information[3–5] provide some ideas which help explain certain factors affecting and peculiar to Liesegang precipitation. For example, if sodium chloride and silver nitrate are mixed together as very dilute liquid solutions in various proportions, they yield more precipitate at some proportions than at others, even though smaller initial quantities of each may have been used. Furthermore, the lowest concentrations at which sodium chloride and silver nitrate will precipitate in fluid aqueous medium are achieved at unequal molar proportions (for example, 3 : 1), suggesting that the formation of precipitate is a complex phenomenon involving various uncomprehended ion interactions, which occur at some reactant proportions but are suppressed at others.

The piecemeal diffusion and interaction of ions within gel-stabilized aqueous media permits an almost infinite variation in reactant proportions, so that many of the effects of this variation which are missed by tube dilution techniques nevertheless are apparent in gels. For example, precipitation should be expected to occur at much lower reactant concentrations in gel than can be demonstrated practically in liquid, because optimal conditions for precipitation will be achieved far more readily in some plane of a gel-diffusion plate than in any series of concentration variations in liquid media. This effect may also be promoted by the restrictive property of gels upon diffusion of growing molecular aggregates[4].

Another characteristic of gelled medium probably of primary importance in Liesegang precipitation is that because all precipitation in tests using such medium must await arrival by diffusion of reactants at a mutual reaction area, zones of internal reactant depletion can occur immediately ahead of an advancing front of precipitation[3–5]. In time this depletion causes the influx of internal reactant into the reaction plane to drop until it becomes insufficient to precipitate external reactant still persistently diffusing into this area. Consequently, the latter begins to diffuse through this zone of precipitation and the narrow internal reactant-depleted zone immediately to the other side of it without being precipitated, until after passing through the depleted zone it once again begins to encounter sufficient internal reactant to precipitate. This explanation seems to account for the periodicity of Liesegang lines, for their propensity to form progressively and predictably farther apart[6], and for their ability to form only within narrow reactant ratios.

Temperature artefacts differ in several respects from Liesegang banding[3,4]. They may form in the following manner. In a test being held at a given temperature, both reactants are diffusing into a common meeting area where they mix and react in a spectrum of ratios to form a variety of complexes. This dynamic but regular situation is deranged by any temperature shift causing reactant ratio changes. If these are sudden enough for the existing situation, then a temperature artefact will appear. Lowering the temperature causes a gap to appear in the expanding disk of precipitate, while raising the temperature will have the opposite effect and create a stria; both effects are pointed out in Fig. 2. This sensitivity to temperature artefact formation decreases in proportion as the overbalance of external reactant drops, because there is also a proportional drop in the rate at which external reactant feeds into the reaction zone and, consequently, in the events of precipitation.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

DEMONSTRATOR IN THE DEPARTMENT OF GEOLOGY—The Registrar, University College of Wales, Aberystwyth (August 14).

TUTORIAL STUDENT (graduate, or about to graduate) IN GEOGRAPHY—The Registrar, King's College (University of London), Strand, London, W.C.2 (August 16).

ASSISTANT EXPERIMENTAL OFFICER (with a degree in science, horticulture or agriculture, or equivalent), to assist in biochemistry studies on the role of potassium in plant nutrition—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (August 17).

BIOCHEMIST, Basic grade (with a degree in biochemistry or Grad. R.I.C.) IN THE DEPARTMENT OF CHEMICAL PATHOLOGY, for routine and developmental work and special investigations—The House Governor, King's College Hospital, Denmark Hill, London, S.E.5 (August 17).

RESEARCH ASSISTANT (biochemist or physiologist), to assist in metabolic research—The Director, Medical Unit, King's College Hospital Medical School, Denmark Hill, London, S.E.5 (August 17).

ASSISTANT EXPERIMENTAL or EXPERIMENTAL OFFICER (with at least G.C.E. in five subjects, including two scientific subjects at "A" level, or equivalent, or, at age 22, a pass degree, H.N.C., or equivalent, and preferably a knowledge of biochemistry and experience in chromatographic techniques)—The Secretary, Institute of Animal Physiology, A.R.C., Babraham, Cambridge (August 19).

CHIEF ENTOMOLOGIST (with a first- or second-class honours degree, considerable experience in research in applied entomology, and preferably experience in the tropics) at the Gezira Agricultural Research Station, Wad Medani, Republic of the Sudan, to control and conduct research on entomological and associated problems of practical importance—The Sudan Embassy, Appointments Section, 3 Cleveland Row, London, S.W.1, quoting Ref. 4/407 (August 20).

HYDROLOGIST, Principal Scientific Officer (with a first- or second-class honours degree in civil engineering, physics or mathematics, and considerable experience in hydrological or hydrometeorological research) at the Hydraulics Research Station, D.S.I.R., Wallingford, Berks, to take charge of a new and growing Hydrological Research Unit undertaking extensive research on the effects of land management on water balance and other hydrological topics—Civil Service Commission, 23 Savile Row, London, W.1, quoting Ref. S/5640/63 (August 23).

SCIENTIFIC OFFICER (with a university degree in science with chemistry as a major subject) IN THE DIAGNOSTIC SECTION, Agriculture Department, Taieri, New Zealand, for the analysis of animal tissues for trace elements and poisons, and to provide a service in general diagnostic toxicology—The High Commissioner for New Zealand, New Zealand House, Haymarket, London, S.W.1, quoting Ref. B.13/2/19/2137 (August 23).

ASSISTANT LECTURER or LECTURER IN PSYCHOLOGY—The Secretary, University of Exeter, The Queen's Drive, Exeter (August 26).

LECTURER (graduate in medicine, science or veterinary science, preferably with a Master's degree and experience in research) IN PHYSIOLOGY at the University of Queensland, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Brisbane and London, August 30).

LECTURER (with good academic qualifications in geography, successful teaching experience, and preferably qualifications in some other aspect of education) IN EDUCATION at the University of Queensland, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Brisbane and London, August 30).

RESEARCH FELLOW (with a Ph.D. or equivalent experience in high energy physics or a related field) IN HIGH ENERGY PHYSICS in the Research School of Physical Sciences, Institute of Advanced Studies, Australian National University—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 30).

ASSISTANT (experienced in standard biochemical procedures, and preferably some knowledge of chemical pathology) IN THE BIOCHEMISTRY DEPARTMENT—The Secretary, Houghton Poultry Research Station, Houghton, Huntingdon (August 31).

ASSISTANT LECTURER IN PHILOSOPHY with special reference to political philosophy—The Registrar, The University, Manchester 13 (August 31).

ASSISTANT LECTURERS (2) (with a medical or scientific qualification) IN BACTERIOLOGY—The Registrar, The University, Manchester 13 (August 31).

CHAIR OF CIVIL ENGINEERING at the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, August 31).

LECTURER (with a good honours degree in metallurgy or chemistry or equivalent qualifications, and experience or special interest in one of the following fields: extraction metallurgy, alloy thermodynamics, electrochemistry, high temperature chemistry or structural inorganic chemistry) IN CHEMICAL METALLURGY IN THE DEPARTMENT OF METALLURGY of the Faculty of Science—The Registrar, The University, Manchester 13 (August 31).

PLANT PHYSIOLOGIST OR BIOCHEMIST (with a good honours degree and preferably some research experience), to study growth regulators in the potato plant, especially those affecting tuber dormancy—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (August 31).

SENIOR LECTURER and a LECTURER IN BOTANY; a LECTURER IN GEOGRAPHY; and a LECTURER IN GEOLOGY at Victoria University of Wellington, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, August 31).

ZOOLOGIST (Scientific Officer grade) IN THE DEPARTMENT OF INSECTICIDES AND FUNGICIDES, to study the mode of action of insecticides using histochemical and radioactive-tracer techniques—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (August 31).

ASSISTANT LECTURER IN VETERINARY ANATOMY IN THE DEPARTMENT OF PRE-CLINICAL SCIENCES, University of Melbourne, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 1).

RESEARCH ASSISTANTS (2) (honours graduates in chemistry or biochemistry, with research experience, preferably to Ph.D. level) IN CHEMISTRY, for work on peptide and protein chemistry under the supervision of Prof. H. N. Rydon—The Secretary, University of Exeter, Northcote House, The Queen's Drive, Exeter, Devon (September 1).

SENIOR BIOCHEMIST (graduate in chemistry or biochemistry and at least five years postgraduate experience in a hospital laboratory) IN THE DIVISION OF BIOCHEMISTRY, The Royal Women's Hospital, Melbourne, to assist the Head of the Division in the maintenance and development of the clinical chemistry service of the Hospital, to carry out special investigations and to undertake research in some aspect of clinical science—Head of the Division of Biochemistry, D. Watson, Esq., The Royal Women's Hospital, Melbourne, c/o Australia House, Strand, London, W.C.2 (September 1).

RESEARCH FELLOW (graduate in physics, electrical engineering or metallurgy, with experience in the physics of alloys) IN PROPERTIES OF NON-FERROUS ALLOYS IN THE DEPARTMENT OF PRODUCTION TECHNOLOGY AND CONTROL ENGINEERING, to undertake research into, and development of, alloys having optimum electrical characteristics for the manufacture of stable resistors—The Secretary, Northampton College of Advanced Technology, London, E.C.1 (September 7).

TEMPORARY CONTRACT ASSISTANT (with experience of transistorized circuitry) IN THE DEPARTMENT OF PHYSICS, to construct and test electronic equipment for satellite instrumentation—The Secretary and Registrar, The University, Southampton (September 7).

LECTURER IN INORGANIC AND PHYSICAL CHEMISTRY; and a LECTURER IN ORGANIC CHEMISTRY at Makerere University College, East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (September 10).

LIBRARIAN (with a university degree, experience in an academic library, and a professional qualification)—Secretary to the Trustees, Magee University College, Londonderry, Northern Ireland (September 11).

LECTURER (honours graduate in architecture, engineering or science, with an interest in building services, and preferably with qualifications in both architecture and science, with research experience) IN ARCHITECTURAL SCIENCE at the University of Sydney, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 13).

RESEARCH FELLOW (with a degree in science, medicine, or veterinary science, postgraduate experience in research, and a working knowledge of the parasitic arthropods) IN PARASITOLOGY, to be concerned with the establishment of a nucleus of postgraduate education relating to the parasitic insects and arachnids, and the initiation of a programme of research on the feeding mechanisms of parasitic arthropods, in relation to the development of allergic and immunological response—The Registrar, University of Queensland, Brisbane, Australia (September 13).

CHAIR OF ADULT EDUCATION—The Registrar, The University, Manchester 13 (September 20).

LECTURER (medical or non-medical) IN CHEMICAL PATHOLOGY—The Dean, Postgraduate Medical School of London, Ducane Road, London, W.12 (September 20).

CHAIR OF MECHANICAL ENGINEERING—The Registrar, The University, Sheffield (September 30).

CHAIR OF MATHEMATICAL STATISTICS—The Registrar, University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (October 15).

SENIOR LECTURER and a LECTURER IN PHYSICS at Victoria University of Wellington, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, October 15).

ABSTRACTOR (with a working knowledge of a Slavonic language, and preferably a second foreign language, a scientific background, preferably biological)—The Director, Commonwealth Mycological Institute, Ferry Lane, Kew, Surrey.

ANIMAL TECHNICIAN (experienced in animal work), to take charge of a well-equipped animal unit concerned with research on the nutritive value of cereals—The Director, Cereals Research Station, Old London Road, St. Albans, Herts.

ASSISTANT LECTURER IN THE DEPARTMENT OF CHEMICAL TECHNOLOGY, to lecture mainly in the field of fuel science and technology—The Secretary, The Royal College of Science and Technology, George Street, Glasgow, C.1.

ASSISTANT LECTURER IN THE DEPARTMENT OF PATHOLOGY at Camden TOWN, with a special reference to morbid anatomy and histopathology—The Secretary, Royal Veterinary College (University of London), Royal College Street, London, N.W.1.

BIOMETRICIAN (with an interest in human biology and preferably experience in biometrical work and programming) in a department investigating growth and development of children and animals—The Secretary, Institute of Child Health (University of London), Great Ormond Street, London, W.C.1.

BOTANIST, ZOOLOGIST or GENETICIST (graduate, with an interest in cytogenetics) IN THE BIOPHYSICS SECTION, for work concerned with investigation of the effects of ionizing radiations on living cells, particularly the effects on the nucleus and cell death—The Administrator, Radiobiological Research Unit, Medical Research Council, Harwell, Didcot, Berks, quoting Ref. GJN/5.

CHEMIST or BIOCHEMIST (graduate, preferably with some research experience) at the Chester Beatty Research Institute, Fulham Road, London, S.W.3, to join a group studying basic mechanisms of damage of mammalian cells by ionizing radiation—The Secretary, Institute of Cancer Research, Royal Cancer Hospital, 34 Sumner Place, London, S.W.7, quoting Ref. 300/G/19.

CHEMIST or BIOCHEMIST (with an honours degree in chemistry or biochemistry, or Grad. R.I.C.) IN THE BIOCHEMISTRY DEPARTMENT, to assist in studies in the clinical chemistry of respiratory disease—Mr. T. P. Whitehead, Queen Elizabeth Hospital, Edgbaston, Birmingham 15.

EDITORIAL ASSISTANT (with scientific qualifications, and preferably a knowledge of French and/or German) FOR METALLURGICAL ABSTRACTS—The Editor, Institute of Metals, 17 Belgrave Square, London, S.W.1.

FIELD ASSISTANT (female, with a university degree in botany, preferably with subsidiary geography)—The Warden, Flatford Mill Field Centre, East Bergholt, near Colchester.

JUNIOR RESEARCH ASSOCIATE (graduate in biological sciences, with interests in histology, electron microscopy and tissue culture) IN THE DEPARTMENT OF PATHOLOGY, for experimental work on pulmonary disorders—The Professor of Pathology, The Medical School, The University, Newcastle upon Tyne.

JUNIOR TECHNICIAN (male, preferably with some experience in basic biochemical methods and a mechanical aptitude), to assist with varied research programmes in the new well-equipped biochemistry section of the Pædiatric Research Unit—The Secretary, Pædiatric Research Unit, Guy's Hospital Medical School, London Bridge, London, S.E.1.

MATHEMATICIAN-PROGRAMMER (with an honours degree in mathematics from a recognized university, and preferably with a higher degree and possessing experience in programming and numerical analysis) IN THE NATIONAL RESEARCH COUNCIL (Canada) COMPUTATION CENTRE, for duties involving the analysis and programming of problems originating in the various scientific and engineering divisions of the Council—The Employment Officer, National Research Council, 100 Sussex Drive, Ottawa 2, Canada, quoting File ER-282.

MEDICAL RESEARCH OFFICER (male/female, with a registrable medical degree and two years postgraduate research experience, preferably in im-

munology, protozoology or tissue culture techniques) AT THE WEST AFRICAN INSTITUTE FOR TRYPANOSOMIASIS RESEARCH, Kaduna, Northern Nigeria, for research on human trypanosomiasis—The Crown Agents, 4 Millbank, London, S.W.1, quoting Ref. M.3/54323/NF.

PHYSICS TECHNICIAN, Senior grade (male or female, with at least three years experience as a technician, passed the Ordinary National Certificate in applied physics, or its equivalent, and previous experience in handling radioactive substances) IN THE PHYSICS DEPARTMENT, for duties which include work in the Radioactive Isotope Unit—The Secretary, General Hospital, Southend-on-Sea, Essex.

POST-DOCTORAL ASSISTANT, to work with Prof. J. S. Anderson, F.R.S., on the study of chemical reactions on metal surfaces by means of the Field Ion Microscope—The Secretary, Inorganic Chemistry Laboratory, The University, South Parks Road, Oxford.

RESEARCH ASSISTANT (organic chemist or biochemist), to work on problems in chemical carcinogenesis—Dr. D. B. Clayson, Department of Experimental Pathology and Cancer Research, School of Medicine, Leeds 2.

RESEARCH ASSISTANT (with a degree in a scientific subject and some knowledge of statistics) IN THE DEPARTMENT OF MEDICAL STATISTICS, for work which will include the analysis of clinical and laboratory data in connexion with research projects carried out over a wide field in the Hospital and Medical College—The Clerk to the Governors, St. Bartholomew's Hospital, London, E.C.1, quoting Ref. AC/195.

RESEARCH SCHOLAR or ASSISTANT (graduate in biochemistry or chemistry) IN THE DEPARTMENT OF EXPERIMENTAL NEUROPHARMACOLOGY, to work on aspects of the biosynthesis of phospholipids in the nervous system with Dr. G. B. Ansell—The Head of the Department of Experimental Neuropharmacology, The Medical School, The University, Birmingham 15.

RESEARCH STUDENT (graduate holding a good honours degree in pharmacology or other biological subjects) IN PHARMACOLOGY, to work on problems related to the physiological function of histamine—Dr. P. B. Marshall, Department of Pharmacology and Therapeutics, Queen's College (University of St. Andrews), Dundee.

SENIOR LECTURER/LECTURER IN MECHANICAL ENGINEERING; and a LECTURER IN ENGINEERING at the University of New South Wales, Broken Hill Division—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2; and The Appointments Section, The University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia.

SENIOR TECHNICIAN, to be in charge of two newly equipped Chemistry Teaching Laboratories—The Administrator, Department of Zoology, The University, Oxford.

TECHNICAL ASSISTANT (with a degree in biological sciences, Higher National Certificate or equivalent qualification, and previous training in microbiology) IN THE DEPARTMENTS OF BOTANY AND ORGANIC CHEMISTRY, to join a group investigating microbiological aspects of fungal biosynthesis—The Registrar, The University, Liverpool 3, quoting Ref. CV/374/N.

TECHNICIAN (male) IN THE DEPARTMENT OF PATHOLOGY, for routine research and work with an electron microscope—Prof. R. C. Curran, Department of Pathology (West Wing), St. Thomas's Hospital Medical School, London, S.E.1.

VETERINARY RESEARCH OFFICER (male/female, member of the Royal College of Veterinary Surgeons (or its equivalent), and at least two years experience in research) AT THE WEST AFRICAN INSTITUTE FOR TRYPANOSOMIASIS RESEARCH, Northern Nigeria, for research work, etc., in the Veterinary Section—The Crown Agents, 4 Millbank, London, S.W.1, quoting Ref. M.3/54322/NF.

TECHNOLOGY IN HIGHER EDUCATION

IN his Handley Page Memorial Lecture at Cranfield on May 21, the Duke of Edinburgh combined an apt tribute to Sir Frederick Handley Page with a discussion of education for technology in which the needs of both the technician and craftsman and of the technologist were equally recognized. The Duke quoted repeatedly from Handley Page's own writings on technical education to illustrate some of the defects of our present system, and particularly the irrelevant division which is customarily made between general and vocational education. This, he suggested, was largely responsible for weaknesses in our existing system and for its failure to provide men and women of the qualities required in sufficient numbers.

Handley Page himself, as the Duke showed, was fully convinced that it was impossible to divide education into vocational and non-vocational. Competence in a particular craft or profession must be accompanied by a cultural, intellectual and spiritual life if men and women were to develop full personalities. After some shrewd comments on some particular weaknesses in our present system and a trenchant repudiation of the social differentiation between certain jobs and professions, the Duke strongly endorsed Handley Page's plea in 1955 that our technological training should be directed towards producing the ability to remain contemporary in thought and to develop the habit of thinking in terms of technical matters of to-day and to-morrow and not in terms of what was learnt five, ten or even twenty years earlier.

"Unless we can develop in the technologist that ability to remain contemporary in thought and stimulate in him an intellectual curiosity he will have little chance of holding his own in an era in which the progress of technology makes heavier demands on his intellectual capacity and adaptability than at any time in our long history". With this quotation from Handley Page's address on *The Art of Training*, the Duke closed his own address, remarking that Handley Page possessed this ability to remain contemporary in thought to an unusual degree. This emphatic repudiation of the false dichotomy between two cultures of the humanities and the sciences, and between vocational and non-vocational education is reflected in an inaugural lecture by Prof. H. Irving which has been published by the Leeds University Press under the title *The Three Cultures**. Like the Duke of Edinburgh, Prof. Irving pays a tribute to the Colleges of Advanced Technology, and the title of his lecture, in fact, derives from his belief that in these colleges, in which general studies are introduced to familiarize the student with problems of value in contemporary society, we may have the makings of a distinctive third culture—of a group of people who, unlike their contemporaries in the universities, will have been closely in contact during their professional training with the industries into which the majority will ultimately be assimilated.

Prof. Irving does not accept uncritically Sir Charles Snow's thesis of the two cultures, but he welcomes its insight and, like Sir Charles, is doubtful whether we are choosing the right people to be our leaders. Further, he believes that acceptance of the concept of experiment, and the full acceptance of the implications of an experiment, has produced a most significant change in intellectual outlook in the world. Moreover, he suggests that if trends in the recruitment of students were to follow entirely different patterns, for example, from grammar school to university, and from modern secondary school to college of technology, differences between the scientific and the technological cultures could well be exacerbated. Intercommunication on purely technical subjects might present no serious difficulties, but this might not apply to contacts on more humanistic planes.

For this reason, Prof. Irving suggests that the diversification of interests and ideals which the colleges of technology could offer should be welcomed and encouraged, and he points out that the colleges of advanced technology in particular may often be able to offer conditions in laboratories and equipment far superior to what many university departments can offer. Whatever views may be held as to the soundness of Prof. Irving's diagnosis of a third culture, it is undeniable that the colleges of technology offer opportunities which are fully comparable with those of many university institutions. It would be a national disaster if the social distinctions which the Duke of Edinburgh condemned so firmly were allowed to hinder the colleges from making their full contribution to the expansion of higher education, and beyond this it is manifest they have a contribution to make in their own right. It is not simply a question of whether they can fill the gap between the available university places and the huge excess of applicants: they should be receiving many of those applications in the first instance.

Prof. Irving's stout championship of the claims of technology would be welcomed merely for its contribution to the public understanding of what these colleges have already done and are able to do, and, like some recent addresses of the Duke of Edinburgh, it should help to dispel any idea of intellectual inferiority to a university, at least so far as the colleges of advanced technology are concerned. It is indeed of vital importance that the idea that a post in a university carries a social prestige greater than that of a similar post at a college of technology should be destroyed as soon as possible, and Prof. Irving frankly welcomes a social climate in which there ceases to be any distinction between the man who has received his higher education in the university and in the college of technology. Nor is he concerned at the outcome of competition between the scientific and technological cultures he postulates for students as well as staff. Indeed, he deliberately postulates the question whether the survival of a purely scientific culture such as the universities provide is desirable.

A negative answer to that question is implicit in some of the criticism of the products of the present system such as Mr. R. F. Tuckett voiced in a challenging broadcast, "Down with Ph.D.s", printed in *The Listener* of March 28. Mr. Tuckett not only indicted the science graduate as almost illiterate and disclaimed any confidence in a British Ph.D. course as an educative influence; he questioned whether the two- or three-year course of research for a higher degree as organized by the Department of Scientific and Industrial Research or some similar body, for example, favoured truly original thinking, though he admitted that the quality of research training in Britain and

* *The Three Cultures*. By Prof. H. Irving. Pp. i+26. (Leeds: The University Press, 1963.) 2*s*. 6*d*.

elsewhere is extremely variable. He pleaded for more attention to the broader aspects of research training and education, for an attempt to re-think and streamline the content of a first degree and for recognition that the specialized honours course might be ill-adapted to the needs of many of the increasing numbers of students who would be coming forward in the next ten years.

Mr. Tuckett recognized that the opportunity to re-think the whole purpose of a university provided by the present expansion was, in fact, being grasped and that the idea of a new model of the old concept of a broadly educated man was already being discussed, though he had nothing to add about the contribution of even the colleges of advanced technology. Prof. Irving suggests that the success of these colleges, in providing a technological education appropriate to the needs of contemporary society and in effectively combining professional training with a measure of general studies, is largely due to the fact that they are in the enviable position of being able to work from foundations of their own creation and are not handicapped by any pre-existing organization or curricula. To some extent the new universities have the same freedom of manœuvre, but Prof. Irving is much concerned about the extracurricular education of the student who goes straight into lodgings and remains in lodgings for the whole of his academic career, especially if those lodgings are at some distance from the centre of the university.

This is a problem which could arise in the new universities as well as in the older Redbrick universities if measures are not taken to ensure that every student has the opportunities of assimilating what we believe to be the ethos of a university. Prof. Irving does not suggest that halls of residence are the ideal and the only solution to problems of student accommodation and their extra-curricular education. He does suggest that universities should be more concerned with the training of character and that residential experience has a great part to play here because character can be conspicuously developed by the exercise of leadership in every branch of communal activities, nor does he believe that such development of character is incompatible with academic specialization.

What is noteworthy is not so much that the views on the importance of character training expressed last year by Lord Fleck in his presidential address to the Society of Chemical Industry should find some strong support on academic quarters as that narrow specialization should be attacked in such a forthright manner. Here is further evidence of fresh thinking about teaching methods and of a readiness to reassess curricula and examination procedures such as Prof. T. L. Cottrell, for example, has already given us, which shows that the United States is not alone in working out new methods of teaching science. Prof. Irving is explicitly prepared to see that while specialist chemists are trained to the increasingly high standards demanded to-day, sufficient leisure time is left for the equally important aspects of their extra-curricular education.

It might have been hoped that the Federation of British Industries, in its recent report on management education and the training needs of industry†, would have shown something of the interest if not concern displayed by Lord Fleck towards the broader aspects of a university education. However, although the working party in this report distinguishes between three levels of management for which training is desirable it has little or nothing to say about the basic education which a manager of any type should receive. That the working party advocates a clear distinction between management and supervision and the restriction of the term management to courses which are not concerned largely with supervisory aspects makes it the more unfortunate that so little is said about the educational foundations. A new approach is indeed suggested, but while the working party suggests that the success of many graduates in industry or commerce is due rather to their innate ability than to the suitability of their education, it is content to observe that it would be encouraging to think that those taking a first degree who will not be staying in the academic world could study a modern version of the humanities in the future, along the lines being developed in the new universities.

Nor does the pamphlet *The Case for Advance*‡ put out by the 1963 Campaign for Education quite measure up to the opportunity. Sir Geoffrey Crowther, it is true, challenges the hierarchical structure of our education, as does Mr. Allan Bullock, who refers specifically to the intellectual snobbery which still prevents sufficient attention being paid to the development of applied studies, not only in technology and management but also the whole range of the application of economics and social studies to our problems. Mr. Bullock himself recognizes that the expansion of higher education should include the colleges of technology, but although he comments on the existence of class barriers in education, neither he nor the other contributors to the pamphlet appears to sense the opportunity which such a campaign for education affords of removing the misunderstanding and prejudices or even sheer ignorance which leave places unfilled in the colleges of technology and the technical colleges while universities may be turning half their applicants for places away.

Clearly the nation cannot afford such waste even at the present level of expenditure let alone the much higher level for which Mr. Bullock, Sir Geoffrey and their colleagues, Lady Albemarle, the Archbishop of Canterbury and Sir Ronald Gould argue so cogently. It is reasonable enough, as Mr. Bullock admits, to await the Robbins Report before adopting many new measures affecting the pattern of the development of higher education, but there are many ways in which the effectiveness of the present system could be improved meanwhile, and to secure the full use of the colleges of technology and the technical colleges is clearly one. To bring the colleges of advanced technology at the least to the clearing-house for university admissions is an obvious step, and although it might be at least a year before it becomes effective, the psychological effect in breaking down prejudice could be immediate and considerable.

Apart from such practical steps, the more existing practices are re-examined and subject to critical constructive thinking the better the ground will be prepared for action on the recommendations of the Robbins Committee. The value of Prof. Irving's address lies largely in its contribution to that, and this is also the merit of a contribution from Prof. B. R. Williams in the current issue of the *Manchester School of Economic and Social Studies*, in which the problems of university capacity and expansion are subjected to economic analysis. As Sir Geoffrey Crowther points out, an immense increase in higher education is inevitable, and this will involve a very large increase in national expenditure.

† *Management Education and Training Needs of Industry: a Report by an F.B.I. Working Party.* Pp. v+27. (London: Federation of British Industries, 1963.) 6*s*.

‡ *The Case for Advance.* By the Archbishop of Canterbury, Lady Albemarle, Alan Bullock, Sir Geoffrey Crowther, and Sir Ronald Gould. Pp. 16. (London: 1963 Campaign for Education, c/o Hamilton House, Mabledon Place, W.C.1, 1963.) 1*s*. 6*d*.

That will be secured the more readily if assurance is forthcoming that the institutions on and through which that expenditure is incurred are most efficiently and wisely administered. If proposals such as Prof. Williams advances, on the ground of making the most efficient use of universities and their staffs, for giving two courses in one year and doubling the academic staff, are to be rejected, it must be for convincing and valid reasons and not merely on grounds of tradition. Here again is room for much critical thinking, though it is only fair to note that both the University Grants Committee and the Advisory Council for Scientific Policy are already fully aware that much more effective use could be made of academic staff both in teaching and in research if they were provided with more ancillary assistance.

Here again the problem is largely one of finance in which the Government's start–stop policy is liable to prove penny-wise pound-foolish. It is reasonable to expect of university institutions that they should, as Prof. Williams urges, make the best possible use of their equipment and facilities, that they should be efficiently managed and that they should see that their most precious and expensive asset—their highly trained staff—should be provided with whatever assistance it needs to give of its best and that it should not be employed on duties for which much less highly trained labour is competent. But this is not the only test of an institution of university rank. If it is to exercise its vital creative function, whether in teaching or research, if it is really to father discovery, to use Dr. Magnus Pyke's apt phrase, it must first ensure that it provides the fundamental conditions in which creative work is possible.

LAW, HISTORY AND LAND USE

The Common Lands of England and Wales

By Dr. W. G. Hoskins and Prof. L. Dudley Stamp. (The New Naturalist: a Survey of British Natural History.) Pp. xvii + 366 + 28 plates. (London: William Collins, Sons and Co., Ltd., 1963.) 42*s*. net.

COMMON land is probably the most misunderstood part of our national heritage, and therefore a volume giving a clear account of the issue is welcome. The joint authors were members of the Royal Commission on Common Land, and each contributed an appendix to the report. They now present their findings in a readable and telling form.

The term 'common land' has no precise meaning in England and Wales (it does not exist as such in Scotland) and the nearest estimate of the area is about 1½ m. acres—a formidable 4 per cent of the land surface. The importance of common land lies in the number of interested parties of whom, apart from those concerned with agriculture, recreation and building development, there is a succession of historians, geographers, archæologists, ecologists, conservationists and Nature lovers. The legal tangles concerning doubtful ownership, the uncertain rights of the commoners and questions concerning public access frequently defy the understanding of even the initiated, and have been responsible for limiting, and even prohibiting, the purposeful use of certain commons, and encouraging the dereliction of others in both upland and lowland areas.

Dr. Hoskins traces the history of common land, and although the origin is obscure the common rights antedate the very conception of private property. Since the imposition of the manorial organization all such land has been, and still is, private property, owned by the lord of the manor, or his descendant or his legal representative. Common land is unique in that a large number of people have legal rights over the area which they exercise in common. The main use to which it is put is grazing and the gathering of wood for fuel, but there are other customs, some long in disuse, which made common land essential for peasant economy up to the end of the eighteenth century. The public by custom, with or without rights, wander more or less freely over the common land areas.

The history is interesting and often exciting. The vast reservoir of land that existed at the time of the Domesday Book has been drawn on heavily by an increasing population from the eleventh century onwards, leading eventually to stinting on common land, and inevitably to bitter disputes which reached a climax during the period of Parliamentary Inclosure. A movement to protect common land was bound to follow, but it left in its wake a system of laws and rules far from beneficial to present-day needs.

Prof. Dudley Stamp deals with the general state and usage of commons, features of special interest and geographical distribution; the geographical distribution depends largely on soil type, terrain and geological factors. The picture is presented on a regional basis, starting with the lowland heart of England where commons are few, moving progressively to the upland areas where commons are more widespread—the north of England and Wales (30 per cent of Breconshire is common land).

Research workers and those professionally concerned will find a wealth of information in this part of the book, also in the appendix that follows extending to more than 100 pages and providing for the first time a county-by-county list of the known commons, village greens, common gravel pits and fuel allotments of England (Wales presented an impossible confusion!). Other readers will doubtless concentrate on the areas with which they are most familiar—their native heath or favourite fell. Readers who delve deeper than this will find that no two commons are alike and they will be rewarded by fascinating reading of history, anachronism, human fallibility as well as fact. One is often surprised by the wide range of activities and opportunities that exist on common land.

The authors maintain a balanced view and a sympathetic appreciation of the demands of all concerned.

ROY HUGHES

IMMUNOLOGICAL PHENOMENA AND CLINICAL ALLERGY

Allergology

Proceedings of the IVth International Congress of Allergology, New York City, October 15–20, 1961. Edited by Ethan Allan Brown. Pp. xii + 455. (London and New York: Pergamon Press, 1962.) 105*s*.

IN this volume some of the promise of the rapidly increasing understanding of immunological phenomena for clinical allergy is foreshadowed, although the gap between scientific and clinical aspects is still only too obvious. The rate of progress is shown by Dr. J. M. Andrews's comments on the meteoric increase, from £30,000 to £2 million devoted to this subject by the United States in the past six years, and in the number of projects from 9 to 277. One wonders how the figures for the United Kingdom compare with this.

Of the 43 papers by leading workers, at least half are well worth reading. Part 1, the most impressive of seven parts, commences with a review by M. Heidelberger on the "Unity and Heterogeneity of Antibodies", showing how the introduction of precise quantitative chemical micro-methods, established, for example, the identity of agglutinins and precipitins, and the predictability of cross- and homologous-specific reactions, based on the chemical structure of antigens and particularly of poly-

saccharides. S. Cohen and R. R. Porter describe the chemistry and biological function of 19*S* and 7*S* γ-globulin and of the three pieces obtainable from 7*S* γ-globulin by enzymatic digestion: piece 3 with its capacity to sensitize skin and promote placental transfer, and pieces 1 and 2 with their antibody combining sites and allotypic specificity. These findings add to the interest of B. N. Halpern's work on "Le processus de Sensibilization", showing the remarkable competition for cellular attachment between normal γ-globulin and antibody γ-globulin. D. H. Campbell discusses the importance of antigen–antibody ratios for the tissue reactions produced by their complexes. J. Humphrey discusses biochemical mediators of antigen–antibody reactions, with reference to two performed mediators, histamine and serotonin, two produced mediators, *SRS*-A and bradykinin, and complement-fixing esterase activation in anaphylaxis.

Immunological and clinical aspects of drug hypersensitivity are discussed with an introduction by M. W. Chase on chemical considerations. In reviewing the immune response of hypersensitivity, S. Raffel concludes that the early appearing Jones–Mote type of sensitivity to protein antigens is probably of the delayed tuberculin type. L. E. Thomas argues that the teleological significance of delayed-type hypersensitivity is protective, by destroying potentially neoplastic cells. S. B. Salvin and H. N. Eisen discuss delayed-type sensitivity to protein and simple chemicals respectively.

In the section on auto-allergy, homograft rejection is discussed by E. Billingham, hypogammaglobulinæmia and immunological responses by C. A. Janeway, and autosensitization to thyroid and to vascular antigens by E. Witebsky and D. Pressman respectively, with a paper on the inhibition of immune reactions by J. Sterzl.

Useful reviews of techniques are given, on the measurement of antibody by D. W. Talmage, and on hæmagglutinating factors in allergic sera by A. H. Sehon. Agar-gel, immunoelectrophoretic and fluorescent antibody techniques are well covered by J. Oudin, P. Burtin and M. H. Kaplan respectively. The uses and interpretations of the passive cutaneous test for anaphylaxis are discussed by Z. Ovary, and O. G. Bier concludes with a critical discussion of the rôle of complement-fixation in immediate hypersensitivity reactions.

The discussions on the clinical use of steroids, psychotherapy, general methods and the use of mineral oil emulsions for 'desensitization' show the need for more precise investigations in these fields. J. Pepys

DISCUSSIONS OF STATISTICAL INFERENCE

The Foundations of Statistical Inference

A Discussion. Opened by Prof. L. J. Savage. (Methuen's Monographs on Applied Probability and Statistics.) Pp. 112. (London: Methuen and Co., Ltd., New York: John Wiley and Sons, Inc., 1962.) 15*s*. net.

THIS monograph is divided into three parts. In the first, Prof. L. J. Savage expounds his views on statistical inference, arguing that all statistical practice should be based on Bayes's theorem, that there is no dichotomy of statistical problems into inference or decision, and that all probabilities are "subjective". In the second, five eminent British statisticians (Profs. Bartlett, Barnard, Cox, Pearson and Dr. C. A. B. Smith) present their views on this topic and then, in the third part, the discussion at the seminar at which these lectures were given is recorded.

The dust jacket proclaims "most of the monograph is non-technical and should interest anyone concerned with statistical inference". Both these statements are true! There are very informative discussions of such purely "objectivist" problems as testing a simple hypothesis without specifying an alternative. On this topic, for example, Prof. Cox points out that in a great many "testing situations" any test-statistic will itself generate a family of alternative hypotheses against which it is "optimum"; one is left wondering whether it would not always be better to make some attempt to specify alternatives rather than have it done, so to speak, for one. The major part of the monograph is, however, taken up with the discussion of points of disagreement between the subjectivists and the objectivists, and here the non-technical nature of the monograph has, I think, been taken too far.

There is no statement of the basic axioms used and of the major results derived by Prof. Savage in his book *The Foundations of Statistics*. This makes the outline of the area of disagreement unnecessarily vague, which means that certain parts of the discussion will not appear fruitful to a reader unacquainted with a formal statement of Savage's position. Indeed an explicit statement of the axioms and the main result in *The Foundation of Statistics* would, I think, have helped in the discussion itself. For example, a direct attack on the axioms or the derivation of the main result would then have been called for, which might have cleared the way to a better understanding of where the points of disagreement lie.

The discussion is, however, always interesting and the book is well worth buying on a number of counts. For example, for the discussion on the difference between the precision expected from an experiment before it is performed and the precision actually yielded by it when it is performed, and for Prof. Barnard's discussion on likelihood functions and their interpretation. The reader will find the monograph more rewarding, however, if the first few chapters of Prof. Savage's book and the paper of Prof. A. Birnbaum are read first[1]. The book deals with a "decision" or "potential decision" situation and the subjective probability distributions derived are really shorthand descriptions of "betting" behaviour. An understanding of this should help one to decide, for example, whether in fact Prof. Savage's discussion on inference derives backing from his book, and whether Prof. Barnard is in fact at cross-purposes with Prof. Savage when he states (p. 41) "Whoever manages to guess the prior distribution most accurately will obtain the best decision rule". Finally, Prof. Birnbaum's paper based on purely "objectivist" ideas, proves, on the basis of some apparently compelling axioms, that "objectivist inference" should be based on the likelihood function alone, and it is interesting to follow the discussion with this latter result in mind. M. C. Pike

SYMPOSIUM ON SPACE SCIENCE

Space Research III

Proceedings of the Third International Space Science Symposium, Washington, D.C., May 2–8, 1962. (Organized by the Committee on Space Research—Cospar, and the U.S. National Academy of Sciences.) Edited by Prof. Wolfgang Priester. Pp. xvi+1275. (Amsterdam: North-Holland Publishing Company, 1963.) 220*s*.

THIS volume contains most of the papers presented at the third International Space Science Symposium at Washington in May 1962. It does not include the papers on life sciences or the contributions to the two related international conferences at Washington which immediately preceded the Symposium, namely, those on "Rocket and Satellite Meteorology" and on the "Use of Artificial Satellites for Geodesy". The papers on these topics are being published in three separate volumes.

Even with these omissions, the book has a wide range, covering the Earth's atmosphere from a height of 80 km up to its outermost limits, the Sun and the interplanetary plasma, the Moon and planets, galactic astronomy and the technology of space research. There are more than a hundred papers, almost all of them in English, and each is preceded by a summary in English and Russian. The Committee for Space Research (COSPAR), which organized the conference, has always been genuinely international, and so are the papers: though a large proportion comes from the United States or the U.S.S.R., there are also many excellent contributions from other countries.

The first group of papers, totalling 170 pages, is devoted to the Earth's upper atmosphere from heights of 80 to about 2,000 km, and includes elegant analyses of variations in atmospheric density by L. G. Jacchia, H. K. Paetzold and others, and a long review of upper-atmosphere chemistry by V. I. Krassovsky. The second group of papers (150 pages), dealing with the charged particles in the same region of the atmosphere, is dominated by the many reports on measurements of electron-density profiles. The third group of papers (170 pages) is on the magnetosphere, that is, the atmosphere from a height of approximately 2,000 km out to the farthest limits of influence of the Earth's magnetic field, at about 10–15 Earth radii on the sunlit side. This group includes accounts of various measurements of the Earth's magnetic field and the zones of trapped radiation.

An excellent review by C. de Jager, on "Emission of Gas from the Sun", sets the scene for the next two groups of papers (250 pages), which are concerned mainly with the outflow of charged particles from the Sun, the 'solar wind', and its interaction with the Earth's atmosphere. This complex, fascinating and rapidly developing subject has in the past few years completely altered our view of the Earth's environment: what was an absolute blank not long ago now stands revealed as the scene of a rich and fluctuating hydromagnetic struggle. Notable among the papers on this subject are those giving results from the *Explorer* 10 satellite, which probed the fluctuating boundary of the magnetosphere.

The next group of papers (110 pages) covers solar radiation, ultra-violet and X-ray, and records an impressive number of detailed measurements of the solar spectrum between 5 and 3000 Å by rockets and satellites. There follow three papers on the astronomical unit, including a useful review by A. A. Mikhailov, who recommends a value of 149,550,000 km. Then come four papers on meteorites and tektites, including an excellent survey of interplanetary dust measurements, and ten papers on some larger solid bodies of the solar system, namely, the Moon, Mars and Venus.

"Space Astronomy" is the subject of the next group of papers (70 pages), which includes reports on the first southern-hemisphere observations of stellar ultra-violet radiation, made by a *Skylark* rocket in 1961, and the γ-ray measurements by *Explorer* 11.

The final section of the book (110 pages) is concerned with the technology of space research and consists chiefly of papers describing instruments used, plasma probes, mass spectrometers, photo-detectors, and others.

The editor, Prof. W. Priester, and the North-Holland Publishing Co. are to be congratulated on producing, within a year of the Symposium, such a handsome, well-edited and well-printed volume, which provides an authoritative survey of most aspects of space science. One of the book's most remarkable features—which reflects particular credit on the translators of the Russian papers—is the excellent literary style of the contributions. When one considers that the papers are in English, which is not the native tongue of many of the authors, that the editor comes from Germany and the publishers from Holland, the stylistic felicity of the book is quite admirable.

D. G. KING-HELE

SNOW CRYSTALS

Snow Crystals

By W. A. Bentley and W. J. Humphreys. (Dover Edition *T*287). Pp. 226. (New York: Dover Publications Inc.; London: Constable & Co., Ltd., 1962.) 24*s*.; 2.95 dollars.

THIS is a paperback re-issue of the book originally published by McGraw-Hill in 1931. It represents the collected work of W. A. Bentley, who spent nearly fifty years photographing snow crystals at Jericho, Vermont. The appearance of this new issue is superb; it is a masterpiece of paperback book production. The contents are reproduced exactly as they appeared in the earlier edition.

From the scientific point of view it is a pity that there is no record of the magnification or amount of retouching on the prints, particularly since some of them show unusual and interesting forms. Dobrowolski, in his treatise *Historja Naturalna Lodu* (1923), made extensive use of Bentley's pictures, but Nakaya in *Snow Crystals* (1954) was critical of his technique of cutting out the snow crystal negative and printing to produce a black background. This gives a very impressive picture but tends to diminish the scientific value.

The pictures could contribute much to the study of snow crystal form if it were known that they possessed the original outlines and features. This is illustrated by two photographs in the collection, on p. 205 and p. 207; these show an apparent overgrowth anomaly. A plate crystal has formed round a columnar crystal but the hexad axis of the plate is perpendicular to the hexad axis of the column.

It appears that Bentley was concerned with the scientific aspects of his work and he published several papers in *Monthly Weather Review* during 1901–27. The introduction to the collection was added by Humphreys for the publication after Bentley's death and he presents the pictures as true representations of the snow crystals with the exception of a few plates which have had arms and details trimmed off. The more elaborate and unusual crystals are accurately portrayed.

I. J. SMALLEY

VEGETATION AND SOILS OF THE WORLD

Vegetation and Soils

A World Picture. By Dr. S. R. Eyre. Pp. xvi + 324 + 32 plates. (London: Edward Arnold (Publishers), Ltd., 1963.) 36*s*. net.

AS the Freedom from Hunger Campaign gains momentum and the public at large begins to give thought to the problems associated with food shortage, any book on soil will catch the eye. In other words, there is already a wide readership for any publication which will outline fairly and factually the scope of the world's potential resources in this medium of plant growth. Accepting this premise, one may expect from authors on this topic texts which are explicit and discernible, which inform and educate. Dr. Eyre's work measures up to some of these requirements, but by no means all.

The subject is a complex one and integrates basic knowledge from many not-so-kindred sciences. Indeed, it is a project that might well have been undertaken by a botanist, an agriculturist or a soil scientist. But the author, a geographer, tackles it from his own particular point of view.

As a generalization on the world distribution of vegetation and soils it is quite valid. Both on established vegetation (climatic climax) and transient vegetation (ecotones) an adequate picture is given. The relating of the Krakatoa

explosion to the field of vegetation and soil history certainly shows this catastrophe in a fascinating soil-forming perspective.

In places the author is distinctly speculative—an admirable trait in a subject that is at times beleaguered by hesitancy and procrastination (*vide* the lack of agreement among soil scientists on systems of soil classification). His explanation of the uneven terrain in the tundra is simple but entirely acceptable, although his declamations on the role of fire in vegetation ecology require more statistical evidence than is provided.

In terms of balance, the text leans very heavily on the side of vegetation. An outstanding account is given of the principal species to be found in the various climatic zones with cogent reasons for their being there. This will make excellent reading for foresters and decorative horticulturists in their pursuit of soil studies. Incidentally, the bracketing of tree names with Latin binomials is not as pedantic as would at first seem. The vegetation maps and tables of climatic climax correlations help to illuminate the script and do credit to the publishers.

When considered as a reference book on soils, its limitations are soon apparent. Pedologically, the author does not appreciate, or fails to stress, that vegetation is only one facet of a single soil-forming factor. Dokuchaev's concept of soil being the product of five soil-forming factors (namely, parent material, organic matter—including vegetation, climate, relief and time) each of equal importance if differing in content and quantity, is universally agreed by soil scientists.

The mechanisms of physical and chemical actions are clearly enough explained for the type of reader referred to in the cover although chemical terms could be used more exactly, and a number of interesting and intriguing statements are made without due qualification, for example, on the formation of raised bogs and on the absence of ice sheet in Asia. Finally, there could have been at least a hint at the agricultural possibilities of the various soils.

Notwithstanding the criticisms, this is a book which had to be written, and it will certainly find a place in recommended if not essential reading for students of many faculties and others interested in botanical geography and its relation to soils. W. S. Wilson

ANIMAL BEHAVIOUR

Roots of Behavior

Genetics, Instinct and Socialization in Animal Behavior. Edited by Prof. Eugene L. Bliss. Pp. xi + 339. (New York: Harper and Brothers. A. Hoeber Medical Book, 1962.) 16 dollars.

TITLES of books on behaviour have almost exhausted the possible permutations of a small population of words. We have had the organization, principles, elements, foundations, structural basis of behaviour, the behaviour of organisms. One recent work bore the unadorned title, *Behaviour*. The work under review has found a new word—"Roots". It is a symposium of twenty-three papers by thirty-one authors (S. Altmann, Bruell, Calhoun, Carpenter, Clark, Collias, D. E. Davis, Denenberg, Dethier, Dilger, Fuller, Goy, Harlow, Eckhard Hess, J. Hirsch, Jakway, Lehrman, S. Levine, McClearn, D. A. Rodgers, Rosenblatt, Ross, Sawin, Schneirla, Scott, Shaw, Tobach, Turkewitz, Waller, W. C. Young, Zarrow). Their contributions are grouped under four headings: "Genetics of Behavior", "Instinctual Behavior", "Early Experience", and "Social Behavior". From the groupings it can be inferred that the various roots penetrate into different soils, and indeed some of the roots seem to be the crop as well. The crop is quite definitely spelled -ior and not -iour; it is a pity that no non-American participants were included, since the views of leading authorities such as Tinbergen, Hinde, Thorpe, Lorenz, and others are represented only indirectly.

Be this as it may, the volume will be a useful addition to many departmental libraries, although it is unlikely that many individuals will think it worth 16 dollars. It is useful because of its breadth—very few of us can keep up with detailed knowledge in all four areas of interest: it contains a number of articles of authority and substance. I suspect the book will be of greater interest to experimental psychologists than ethologists, who will tend already to be familiar with much of it.

It is obviously impossible to give a detailed review of 23 papers. I found the genetics papers by Bruell and by Rodgers and McClearn quite helpful both as general reviews and as accounts of current experimentation. The section on instinctual behaviour is the longest and meatiest. Young's paper on sexual behaviour is a brief but clear and provocative review by one of the pioneers in that area of research; Lehrman follows on from it quite naturally and with a sensible analysis. Harlow's account of his important developmental work with monkeys will be familiar, by now, to many readers, but as always it makes for entertaining reading.

Fuller and Waller's paper on early experience is useful for its analysis of the methodological aspects of the problem and for its discussion of experimental design. Again, many readers will be familiar already with Levine's experiments on infantile stimulation, but some new facts are presented which seem to require a modification of his earlier conclusions. Levine appears to combine, in this paper, a reluctance to speculate with polemics, depending on the facts under review, and one of his main conclusions, that "stimulated animals are more reactive to distinctly noxious situations, but the nonstimulated animal appears to react to a greater variety of environmental changes" (p. 250) seems plausible but is based on very little evidence. Hess and Collias both deal usefully with imprinting and following responses, Collias taking a broader and somewhat more cautious approach than Hess, whose paper is principally concerned with his admirably quantitative research in an area that is apt to be rather anecdotal. His distinction between imprinting and ordinary discrimination learning, however, does not appear to me to be carefully reasoned.

Finally, the section on social behaviour is flimsy, perhaps necessarily so. Only Carpenter's paper combines substance with clarity. His account of the long-term observations of howler monkey populations over thirty years is surely unique, but the analogy between animal groups and homeostatic mechanisms is very rough, and there is a sense of anti-climax by the end of the paper.

The editor admits that "the volume, like any collection of papers by different authors, lacks the evenness of style to be found in a textbook by one author". But there is little evidence of the editor's red pencil having been much exercised. The book often gives the appearance of having been hurried and first-draftish, and sometimes authors are quite unnecessarily ponderous and verbose, for example, ". . . the food hopper [in the diagram] may be identified by its cone-shaped dorsal aspect"—nothing else in the diagram is cone-shaped except the food hopper. "Unfortunately, no measures of disruption of this behavior were made. I say unfortunately because as discussed below, alteration of the duration of this behavior—that is, shortening it—should be the first behavior disrupted." ". . . studies in our laboratory indicate that the behavioral bond between the female and her offspring begins at partuition." In Hess's paper we find, "We make use of the Hess Pecking Preference Apparatus (Hess, 1956)". And so on. But those who can tolerate a bit of fertilizer with the roots will find most of these plants healthy and worth cultivating. L. Weiskrantz

STRUCTURE OF HÆMOGLOBIN

A THREE-DIMENSIONAL FOURIER SYNTHESIS OF REDUCED HUMAN HAEMOGLOBIN AT 5·5 Å RESOLUTION

By HILARY MUIRHEAD and DR. M. F. PERUTZ, C.B.E., F.R.S.

Medical Research Council Laboratory of Molecular Biology, Cambridge

MAMMALIAN hæmoglobin is a protein of molecular weight 64,500. It consists of four polypeptide chains, which are identical in pairs, and of four hæm groups. In horse oxyhæmoglobin each of the chains has a configuration closely resembling that of sperm whale myoglobin[1,2]. The four chains form a tetrahedral array with the hæm groups facing outwards, each hæm group lying in a separate pocket or fold of its own globin chain. The wide separation of the four hæm groups is a puzzling feature of the structure, since it rules out any direct kinetic interaction between them, of the kind postulated to explain the sigmoid shape of the oxygen dissociation curve.

Since Haurowitz's discovery that a change in crystal form follows the reaction of horse hæmoglobin with oxygen[3], a mounting body of evidence has accumulated suggesting that this reaction is accompanied by some major change in the structure of hæmoglobin[4]. In myoglobin, which consists of only a single chain, no such evidence has been found, which would seem to indicate that the structural change in hæmoglobin is somehow dependent on the interaction between the four chains.

After the structure analysis of the oxyhæmoglobin of the horse[1], the obvious next step would have been an attack on its oxygen-free or 'reduced' form. Unfortunately, this crystallizes with a unit cell and space-group unsuitable for detailed X-ray analysis[5], so that we had to turn to a different species. Reduced hæmoglobin of man crystallizes in three different forms[6,7], one of which was chosen as suitable for X-ray analysis. We have now obtained a three-dimensional electron density map at 5·5 Å resolution which is sufficient to reveal the general course of the polypeptide chains and the positions of the hæm groups. As in horse oxyhæmoglobin, the molecule is divided into four sub-units which correspond to the pairs of α- and β-chains of the chemical sequence[8–11]. At the present resolution no significant differences can be detected between the structures of corresponding globin chains in horse oxy- and human-reduced hæmoglobin, nor in the relative arrangement of the two α-chains. However, the two β-chains in human reduced have moved apart, increasing the distance between their two hæm groups by 7 Å compared with that in horse oxyhæmoglobin. On the atomic scale this represents a striking change of structure.

It would have been more satisfying if this discovery could have been accompanied by a demonstration that the oxyhæmoglobins of horse and man have the same structure; but in this we have not yet succeeded, because our crystals of human oxyhæmoglobin have failed to form isomorphous heavy atom compounds. However, a close similarity between the hæmoglobins of the two species is likely on chemical grounds; indirect X-ray evidence suggesting that the structural change observed by us is due to the oxygenation reaction, rather than to the difference of species, is presented in the accompanying paper on hæmoglobin H (ref. 12).

Method of X-ray Analysis

X-ray pictures were taken of crystals grown from solutions containing 2·6 M ammonium sulphate and 0·01 M ferrous citrate, buffered to *p*H 6·5; the crystals were mounted in an atmosphere of nitrogen. The crystals belong to the monoclinic space group $P2_1$. The unit cell has the dimensions $a = 63{\cdot}4$ Å, $b = 83{\cdot}6$ Å, $c = 53{\cdot}9$ Å, $\beta = 99° 15'$, and contains two molecules. Thus, unlike the molecules of human and horse oxyhæmoglobin which lie on two-fold symmetry axes, those of the reduced form lie in general positions, which meant that the number of reflexions contained in one-quarter of the limiting sphere of $(5{\cdot}5\ \text{Å})^{-1}$ was 2,000, as compared with 1,200 in horse oxyhæmoglobin. hkl and $\bar{h}kl$ reflexions were recorded photographically on Buerger Precession Cameras, using a Broad rotating anode tube[13] and a Joyce–Loebl microdensitometer. Intensities were put on an absolute scale by comparison with horse oxyhæmoglobin. All calculations were made on *Edsac II* at the Mathematical Laboratory, University of Cambridge.

The phase angles were determined by the method of isomorphous replacements with heavy atoms. Three heavy atom compounds were used: one in which each of the two reactive sulphydryl groups is combined with parachloromercuribenzoate (PCMB); another in which the same groups are combined with dimercuriacetic acid (DMA); and a third in which two of the four 'unreactive' sulphydryl groups[14] are combined with mercuric acetate ($HgAc_2$).

The parameters of the mercury atoms in the first two compounds were found from three-dimensional difference Patterson syntheses using $[|F_{\text{protein + mercury}}| - |F_{\text{protein}}|]^2$ as coefficients[15]. Fig. 1 shows a section through the three-dimensional difference Patterson of the PCMB compound in which the vector peaks due to interactions between the mercury atoms stand out above the background. No such clear-cut results could be obtained from difference Pattersons of the $HgAc_2$ compound, partly due, as we now know, to its incomplete substitution. Its mercury atoms were eventually located in a three-dimensional difference Fourier synthesis using $[|F_{\text{protein + mercury}}| - |F_{\text{protein}}|]$, modified by a weighting factor m, as coefficients, and α_{protein} as the phase

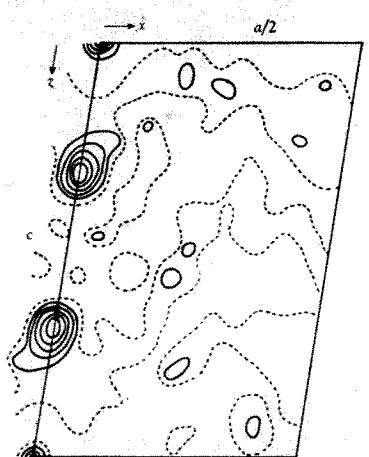

Fig. 1. Section at $y = 2/40$ through the three-dimensional difference Patterson synthesis of PCMB versus native hæmoglobin. The two prominent peaks occur at 18 and 37 Å from the origin, and mark vectors between pairs of mercury atoms in the structure. The peak at $x = z = 0$ is part of the maximum at the origin. The zero contour is marked by a broken line. Negative contours are omitted

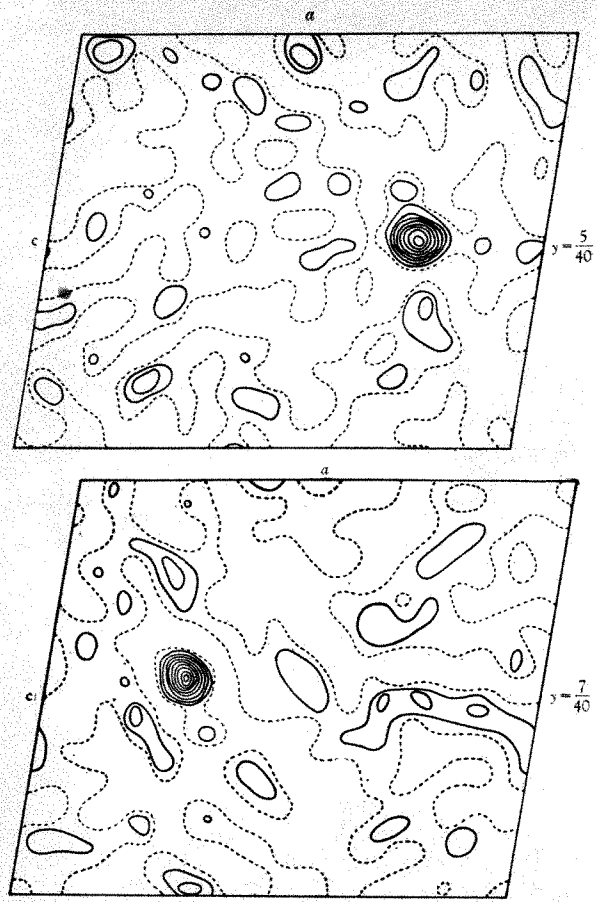

Fig. 2. Sections through the three-dimensional difference Fourier synthesis of the $HgAc_2$ compound versus native hæmoglobin. The high peaks mark the positions of mercury atoms. Contours are at arbitrary intervals; those below the broken line are omitted

angle; the values of α and m were calculated by the isomorphous replacement method using only the PCMB and DMA compounds. Owing to the close proximity of the mercury atoms in these two compounds, the phase angles were not much better than if they had been calculated from a single isomorphous replacement[16]. Nevertheless, the difference Fourier showed two prominent peaks on a low background (Fig. 2), corresponding to the two moles of mercuric acetate per mole of hæmoglobin added to the crystallization mixtures. The peaks were later found to lie close to the known positions of non-reactive sulphydryl groups[14,26].

Phase information derived from the isomorphous substitution and anomalous scattering of the three compounds was now combined, and each structure amplitude was multiplied with a weighting factor proportional to the accuracy of the particular phase angle[17,18]. The average error in phase angle was estimated as 45°, but may in fact be somewhat greater, compared with 37° in horse oxyhæmoglobin. The electron density was calculated at intervals of about 2 Å and plotted in sections normal to *b*.

Results

(*a*) *Structure of the sub-units.* As in the electron-density maps of myoglobin and hæmoglobin calculated earlier, long, straight, cylindrical regions of high density are among the prominent features (Fig. 3); these regions tend to join up to form the same kinds of three-dimensional figures[1]. However, in some regions the density is not continuously high along what would be the course of the polypeptide chains in horse oxyhæmoglobin, and the breaks which occur might have made the chain unrecognizable without previous knowledge. In other regions the course of the chains is clearly defined. Prominent peaks appear in positions corresponding to those of the hæm groups in myoglobin and oxyhæmoglobin; but again they would not easily have been recognized as such, because they do not stand out above the density of the chains as they did in the other two proteins. However, despite these imperfections, which are probably due to the larger error in phase angle, the main features of the structure had emerged clearly from the maps even before any models had been built.

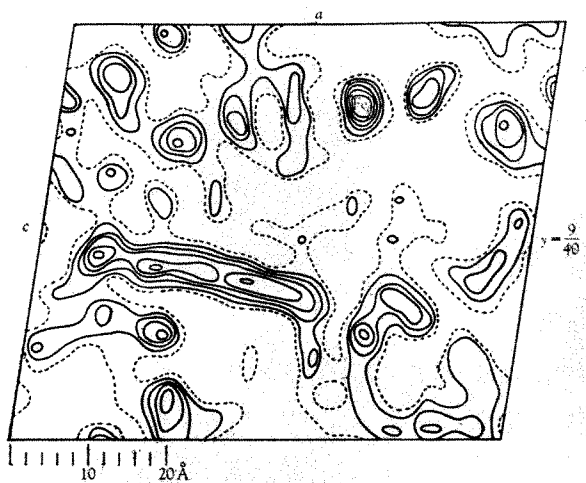

Fig. 3. Section through the three-dimensional Fourier synthesis of reduced human hæmoglobin showing one of the straight cylindrical regions of high density, later identified as helix *G* of one of the α-chains, and a spheroidal peak (Fe_4) representing the hæm group of its symmetrically related partner. Contours are drawn at intervals of approximately 0·075 electrons/Å^3, and the broken line is at 0·42 electrons/Å^3, which is the average density of the hydrated protein. The second plain contour was taken as a reference density for building the models. Contours below 0·42 electrons/Å^3 are omitted

Models of the electron density distribution were constructed by cutting from a sheet of plastic the shape of each peak where the density exceeds 0·57 electrons/Å^3, and then assembling the pieces according to their positions in the different sections. Figs. 4 and 5 show the α- and β-chains next to the corresponding chains of oxyhæmoglobin. (The β-chains were recognized by the mercury atoms attached to their reactive sulphydryl groups.) The figures illustrate both the similarities in structure and some of the imperfections of the new Fourier. A more quantitative comparison was obtained by measuring the directions of the straight segments of chain which are known to correspond to α-helical regions[2], and calculating the angles between them (Table 1). The α-helical segments have been given the labels *A*–*H*, starting at the amino-terminal end[19], but only the directions of the longer segments (*A*, *B*, *E*, *F*, *G* and *H*) can be measured with reasonable accuracy (~ ± 5°). The angles between segments within any one sub-unit of reduced hæmoglobin were found to be the same, within the limits of error, as in the corresponding sub-units of oxyhæmoglobin. If any change has occurred in the folding of any of the chains, it is too small to be detected at the present resolution and accuracy.

Table 1. Angles between Helical Segments of the Polypeptide Chains (See also Fig. 6)

Segments	Horse oxyhæmoglobin	Human reduced hæmoglobin	
	α-Chains		
		α_1	α_2
AB	94°	92°	93°
BE	117°	123°	124°
GE	97°	87°	83°
GH	156°	158°	151°
	β-Chains		
		β_1	β_2
AB	90°	86°	88°
BE	117°	116°	122°
EF	151°	155°	156°
FG	113°	108°	108°
GE	91°	86°	85°
GH	158°	159°	159°

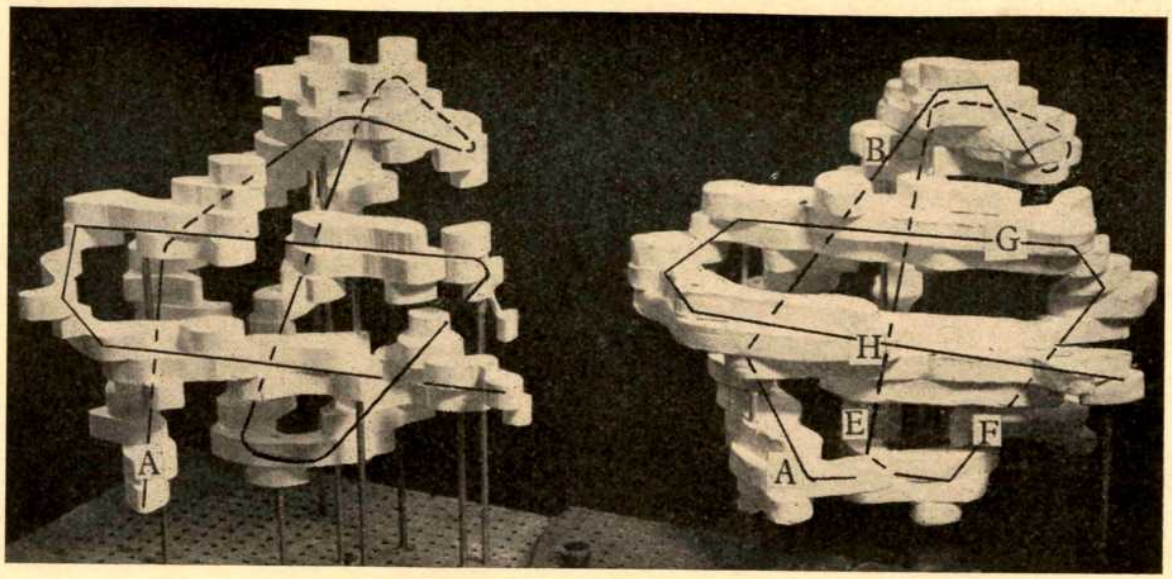

Fig. 4. Models of α-chains in human reduced (left) and horse oxyhæmoglobin (right)

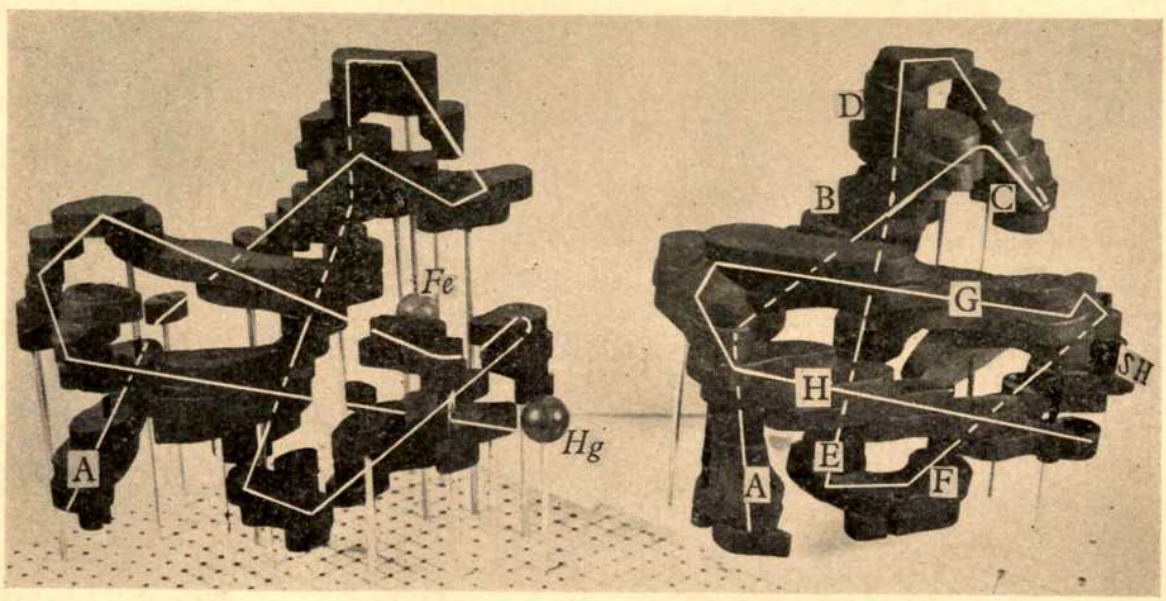

Fig. 5. Models of the β-chain in human reduced (left) and horse oxyhæmoglobin (right). Figs. 4 and 5 show the models of the two hæmoglobins with the a and b axes of the two lattices in parallel, because the orientation of the molecules relative to these axes happens to be approximately the same in the two structures. However, the correspondence is not exact, and the chains of the human and equine forms are seen here from slightly different angles. A comparison with the idealized model pictured on the left of Fig. 6 may help the reader to visualize their three-dimensional structure

So far as can be judged, the positions of the hæm groups relative to the globin chain are also the same as in oxyhæmoglobin. A quantitative estimate is possible in the β-chain, where the iron atoms are linked to the mercury atoms of PCMB through the intermediary of only two residues, the hæm-linked histidine and the cysteine immediately following it. The distance from the hæm to the mercury peaks is 14·4 Å in reduced, as compared with 13·6 Å in oxyhæmoglobin; the difference of 0·8 Å is within the limits of error of the present Fourier. In horse hæmoglobin the orientation of the hæm groups had been determined by electron spin resonance of the ferric or *met* form[20], which is paramagnetic, but forms isomorphous crystals with the diamagnetic oxyhæmoglobin used for the X-ray work. Reduced hæmoglobin is also paramagnetic, but its crystals failed to give sharp electron spin resonance lines in preliminary tests, so that the orientation of the hæm groups has not yet been determined. In the models their positions have therefore been indicated by balls rather than disks.

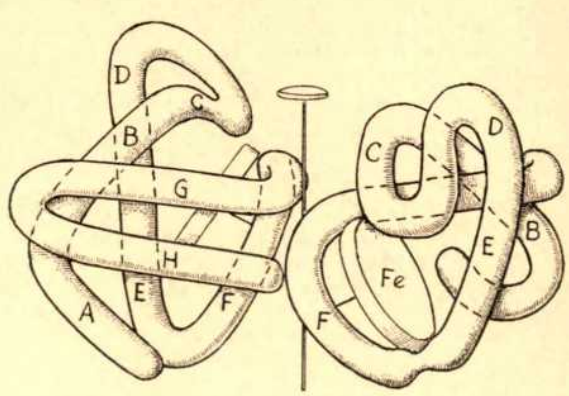

Fig. 6. Idealized drawing of the two β-chains in horse oxyhæmoglobin. The sign at the centre marks the two-fold symmetry axis. The α-chains form a similar pair (see Fig. 6 of ref. 1)

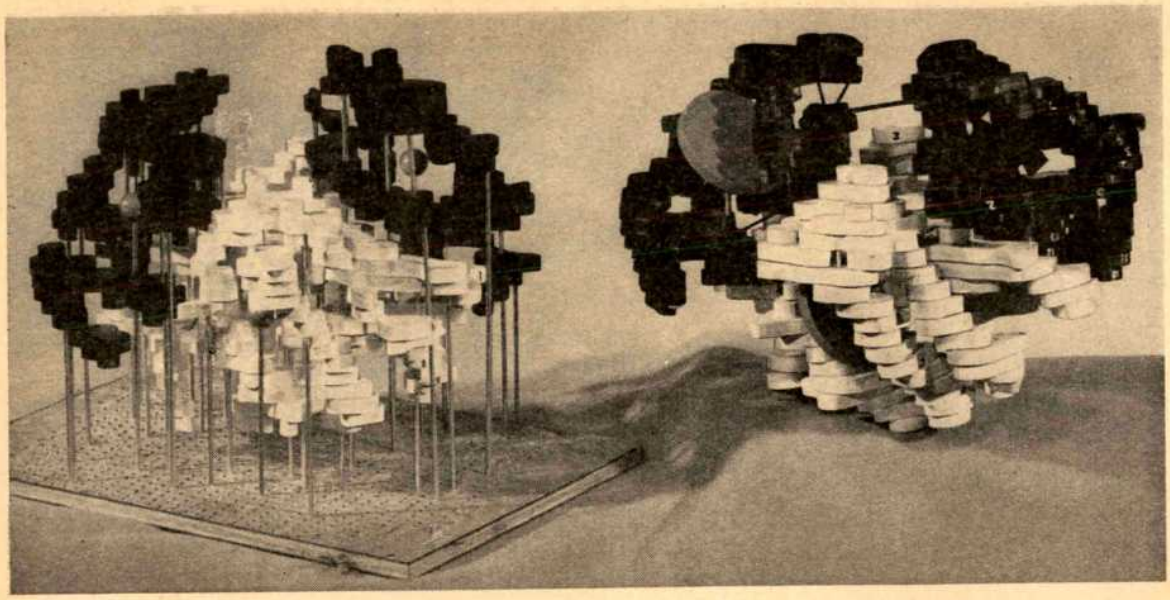

Fig. 7. Complete models of human reduced (left) and horse oxyhæmoglobin (right). The inclination of the hæm groups in the reduced forms is not known; their positions are indicated by balls instead of the grey disks used in the oxyhæmoglobin model

(*b*) *Arrangement of the sub-units.* The model of the complete molecule, like that of oxyhæmoglobin, is assembled by first arranging the sub-units in symmetrically related pairs (Fig. 6); one pair, the black, say, is then inverted and placed over the top of the white so as to form a tetrahedral array (Fig. 7). To examine the arrangement of the sub-units more accurately, sections of the Fouriers containing the hæm groups and the long C-terminal helices *G* and *H* were projected on a plane perpendicular to the crystallographic *b* axes. Figs. 8 and 9, showing sections of the α- and β-chains of the two proteins side by side, illustrate once more the similarity in structure of the individual sub-units. In Fig. 10 the outlines of the dense projected regions of the reduced and oxygenated forms are superimposed. The α-chains show no significant differences, the apparent shift of the hæm groups being due to the different tilt of the two molecules relative to the *b* axis. The two β-chains, on the other hand, cannot be superimposed at the same time; if one chain of the reduced is superimposed on one of the oxygenated form, their symmetrically related partners are displaced relative to each other by 7 Å. The displacement opens a gap between the two β-chains in the reduced form (Fig. 11).

The distance between the two iron atoms attached to the β-chains is 40·3 Å in the reduced compared with 33·4 Å in the oxygenated form, and the distances between the two mercury atoms attached to the β-chains differ by the same amount (Table 2). On the other hand, the distances between the iron atoms attached to the α-chains of the two forms are identical within the limits of error, and the same is true, surprisingly, of the distances between the iron atoms which lie in adjacent pockets of the α- and β-chains ($Fe_1 - Fe_3$; these belong to the two hæm groups in closest proximity, shown in Fig. 8*a* of ref. 1).

Table 2. Distances between Hæms and Mercury Atoms

	Horse oxyhæmoglobin	Human reduced hæmoglobin
Fe_1–Fe_2	33·4	40·3
Fe_3–Fe_4	36·0	35·0
Fe_1–Fe_3	25·2	25·0
Fe_1–Fe_4	30·4	37·4
Fe_1–Hg_1	13·6	14·4
Hg_1–Hg_2	30·0	37·7

Fe_1 and Fe_2 refer to the hæms in the β-chains, Fe_3 and Fe_4 to those in the α-chains, Hg_1 and Hg_2 are the mercury atoms of PCMB attached to cysteine 93 of the β-chains. The location of the groups is shown in Fig. 4 of ref. 1.

So far as can be ascertained, no measurable change in the relative orientation of the four sub-units accompanies the shift of the β-chains.

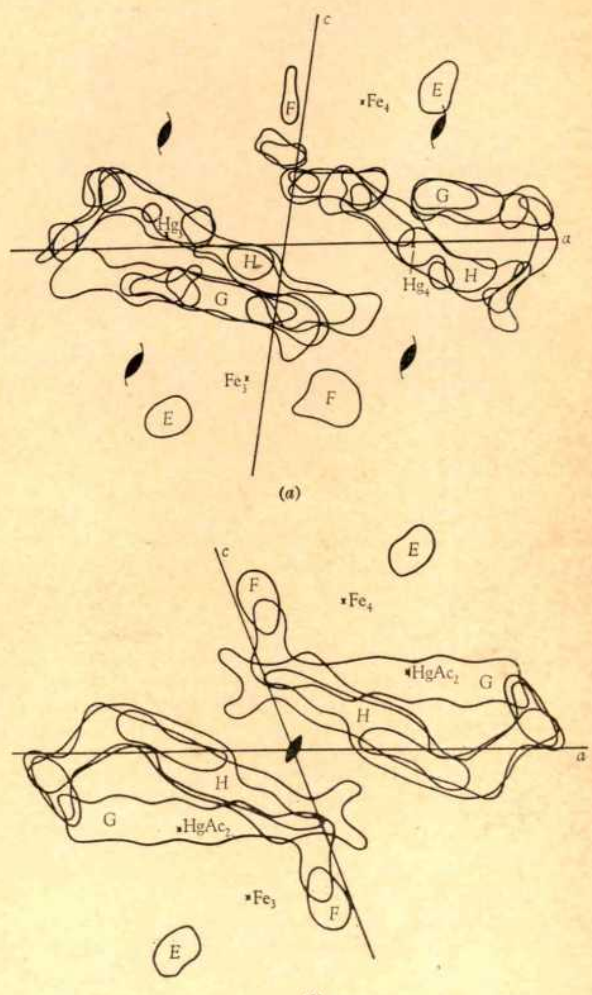

Fig. 8. α-Chains. The helical regions *G* and *H*, the hæm groups and sections through the helical regions *E* and *F*, projected along the *b*-axis in (*a*) human reduced and (*b*) horse oxyhæmoglobin. All contours are drawn at the reference-levels used for the construction of the models (0·57 electrons/Å^3 in human and 0·54 in horse hæmoglobin). Contours at several levels of *y* are superimposed to produce the projected images. Fe marks the hæm positions. In (*a*) the screw dyads are indicated; in (*b*) the dyad is shown at the centre

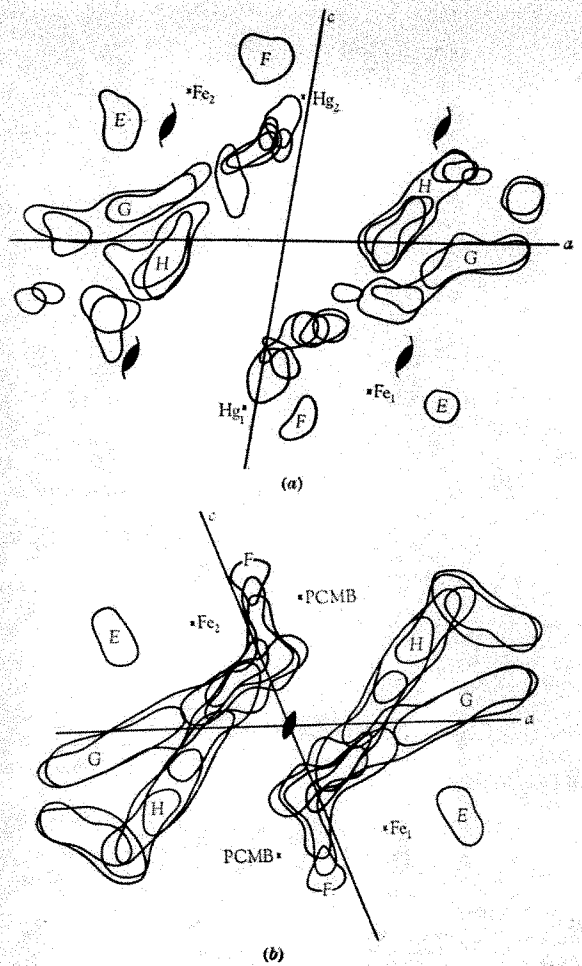

Fig. 9. Same as Fig. 8 for the β-chains. The electron density in the β-chains of the human reduced form is lower, and the number of gaps interrupting the chains is larger than in the α-chains, due probably to oxidation of the hæmoglobin during exposure to X-rays, which would displace the β- but not the α-chains (see Fig. 11)

(c) *Molecular symmetry, shape and packing.* In oxyhæmoglobin, two-fold symmetry of the molecule follows from the crystal symmetry; but this is not true of the reduced form in which the molecules lie in general positions. However, failure of the molecular symmetry to be expressed by space-group symmetry is a situation frequently encountered in crystal structure analysis and does not make molecular symmetry less probable. The difficulty lies in checking molecular symmetry at the present limited resolution and in the face of errors which are liable to affect symmetry-related parts of the molecule unequally. A comparison of distances between symmetry-related iron and mercury atoms, shown in the two columns of figures in Table 3, reveals no significant differences. From the co-ordinates of these atoms, the orientation and position of the probable molecular two-fold axis can be deduced: if this axis is denoted as d, the angles it encloses with the crystal axes are $ad = 79°$, $bd = 11°$, $cd = 96°$ and $c^*d = 94°$. It passes through the point $x = 0{\cdot}23$, $y = 0$, $z = 0{\cdot}77$, where $x = z = 0$ is the locus of the crystallographic screw dyad and $y = 0$ is at the level of one of the mercury atoms in the PCMB compound (Hg_2).

Table 3. Interatomic Distances Related by the Molecular Dyad Axis

Fe_1–Fe_3	25·2	Fe_2–Fe_4	24·7
Fe_1–Fe_4	36·9	Fe_2–Fe_3	37·8
Fe_1–Hg_1	14·4	Fe_2–Hg_2	14·4
Fe_3–Hg_2	20·3	Fe_4–Hg_1	19·6
Hg_1–Hg_2	25·6	Hg_2–Hg_1	24·8
Hg_1–Hg_1	27·8	Hg_2–Hg_2	27·8

Hg_2 and Hg_1 are the mercury atoms of $HgAc_2$ attached to the non-reactive SH groups, probably cysteine 104 of the α-chains (see Fig. 1*a* of ref. 26).

Large differences in the electron-density distribution of symmetry-related parts of the globin chains are noticeable in certain regions, for example, in the non-helical region *CD*, but these are probably due to error, because differences of this kind diminished markedly when going from the first, tentative, Fourier which had been calculated on the basis of only two heavy atom compounds, to the present one.

Like oxyhæmoglobin, the molecule is a spheroid with a height of 50 Å parallel to the two-fold symmetry axis and a width of 55 Å perpendicular to it. Its length is 69 Å, compared with 64 Å in the oxygenated form, and it is cut across by a groove separating the two β-chains (Fig. 7). The packing of the molecules in the crystal is body-centred as predicted by Bragg and Perutz[5]. Their orientation had also been forecast correctly from the early X-ray data[5,7].

Discussion

The first question which comes to mind is whether the structural differences between horse oxy- and human reduced hæmoglobin are really due to the oxygenation reaction, or whether they merely represent a species difference. The amino-acid sequences of the human and equine α-chains differ in only 17 places, and six of the replacements are trivial ones, such as alanine taking the place of glycine[6–11,21]. The sequence of the β-chain of equine hæmoglobin is known only in part; preliminary results indicate that it also is very similar to that of the corresponding chain of the human form[22], which makes large differences in molecular structure unlikely. The massive body of chemical and kinetic evidence in favour of a major structural change accompanying the oxygenation reaction has already been referred to[4]. An interesting piece of indirect evidence is reported in the accompanying

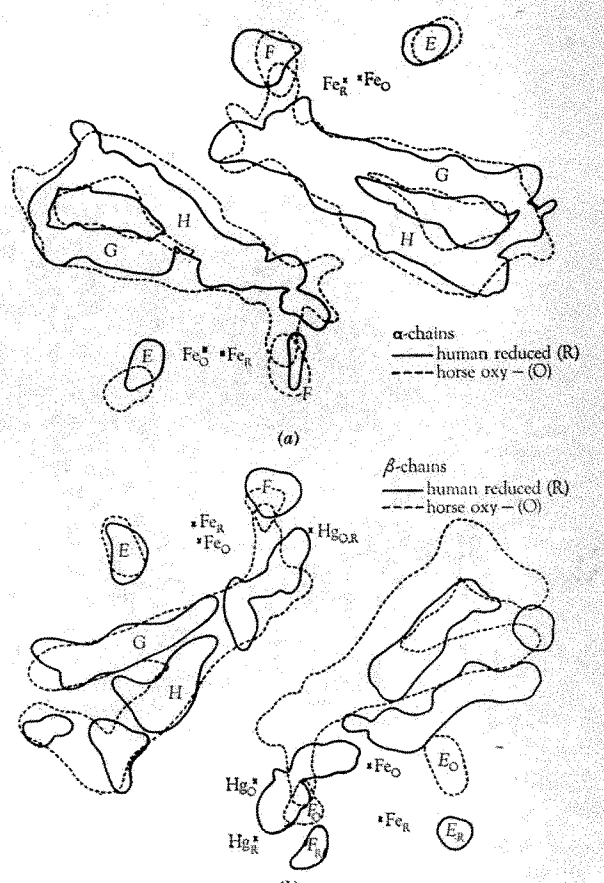

Fig. 10. *a*, Superposition of the outlines of Figs. 8*a* and *b*; *b*, superposition of the outlines of Figs. 9*a* and *b*

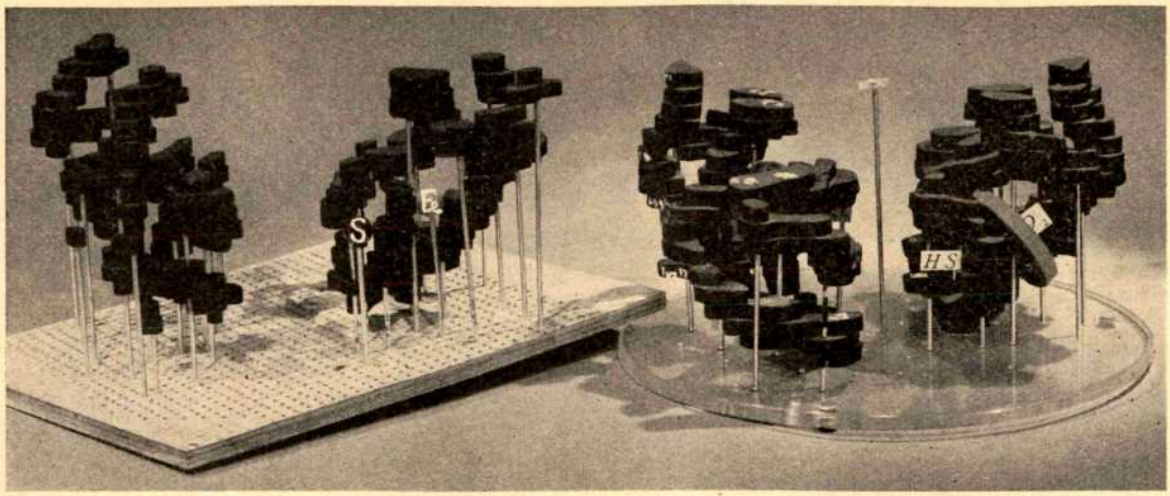

Fig. 11. View of the two pairs of β-chains, showing the widening of the gap between them in the human reduced form (left), as compared with horse oxyhæmoglobin (right). The hæm groups in human reduced hæmoglobin are indicated by balls, those in horse oxyhæmoglobin by grey disks. *S* marks one of the mercury atoms of PCMB

paper on hæmoglobin H (see p. 639), which shows no hæm–hæm interaction and appears to have the same crystal structure in the oxygenated and reduced states[12]. This suggests that the occurrence of a structural change in normal hæmoglobin is linked to hæm–hæm interaction; but it still does not prove, of course, that this change corresponds to the difference between horse oxy- and human reduced hæmoglobin, a point which can be settled only by solving the structure of the oxygenated and reduced forms in the same species.

On the whole, it seems likely that the structural differences are genuinely due to the oxygenation reaction; but it is not at all clear what they mean. The rearrangement which takes place cannot be caused by interaction between the two β-chains by themselves, since in the reduced form these are no longer in contact. The results on hæmoglobin H also preclude that possibility. If the rearrangement is brought about by interaction between the α- and β-chains, as seems likely, it may be triggered off by structural changes within both these chains, and there is as yet nothing to indicate what these are. Nor is it clear how the rearrangement of the β-chains can affect the oxygen affinity of the hæm groups, which lie near the surface, seemingly unaware of what goes on inside the molecule. The Bohr effect may be easier to explain, since the rearrangement of the β-chains would affect the environment and hence the dissociation constants of many polar groups. The increased uptake of bromthymol blue by the reduced as compared with the oxygenated form[23] would be consistent with the greater free surface of the former. A clearer picture of the stereochemical factors involved in the structural rearrangement and of its meaning in terms of reaction kinetics might emerge if the crystal structure could be solved at higher resolution; this would make it possible to find the atomic positions of the iron atoms and of the amino-acid side-chains which surround then, as well as the exact orientation of the hæm groups.

Hæmoglobin may be regarded as an enzyme with oxygen as one of its substrates. The structural change which accompanies the reaction of hæmoglobin with oxygen suggests that there may be other enzymes which undergo a major change of structure on combination with their substrate. In recent years a class of enzymes has been discovered which have been called allosteric[24]. These are concerned with the biosynthesis of essential metabolites, such as amino-acids, and usually the terminal metabolite synthesized in any given pathway inhibits the rate of its own synthesis by means of a specific action on one enzyme, generally the first in the pathway. The kinetics of inhibition suggest that these enzymes possess at least two different active sites, one for combining with the substrate and another for combining with the inhibitor, and that the interaction between two sites resembles that between the oxygen-combining sites in hæmoglobin. There are indications of structural changes in these and other enzyme systems[25].

We thank Mr. D. A. G. Broad and Mr. L. G. Hayward for designing and constructing the nitrogen box in which we mounted the crystals, and Mr. Michael Scott, Miss Sadie Nicholson and Miss Joanna Wheatley for their assistance with computing and model building. One of us (H. M.) thanks the Rockefeller Foundation for supporting her during her first year of research and the Medical Research Council for a scholarship during subsequent years. We also thank the Director and Staff of the Mathematical Laboratory, University of Cambridge, for their help and co-operation in the many long calculations involved in this work.

A PRELIMINARY X-RAY ANALYSIS OF HAEMOGLOBIN H

By Dr. M. F. PERUTZ, C.B.E., F.R.S., and L. MAZZARELLA

HÆMOGLOBIN H is an abnormal human hæmoglobin which consists of four β-chains[1,2]. Its oxygen equilibrium curve is similar in both shape and position to that of myoglobin, showing that the four hæm groups react with oxygen independently of each other and that their oxygen affinity is higher than normal. Like myoglobin, it exhibits only a negligibly small Bohr effect[3].

Crystals of oxyhæmoglobin H, suspended in 2·3 M phosphate buffer of *p*H 6·7, were given to us by Dr. Helen M. Ranney of the Albert Einstein College of Medicine in New York. They were strongly birefringent monoclinic prisms. Birefringence was negative, with the optic axial plane approximately normal to the prism axis. The crystals were only just large enough to be mounted in glass capillaries for X-ray analysis. Their unit cell dimensions and space group are shown in Table 1. The space group is the same, and the unit cell dimensions are closely similar to those of normal human reduced hæmoglobin, and quite different from those of any of the forms of human oxyhæmoglobin[4]. The habit of the hæmoglobin H crystals is different from those of normal human reduced hæmoglobin, the former being prisms elongated along [001], while the latter are elongated along [100].

Table 1. UNIT CELL DIMENSIONS OF NORMAL HUMAN REDUCED HÆMOGLOBIN AND OXYHÆMOGLOBIN H (β_4)
Space group $P2_1$; $n = 2$

	Reduced human hæmoglobin	Oxyhæmoglobin H
a	63·39	63·29
b	83·63	82·40
c	53·91	54·07
β	99·25°	91°

However, crystallization of oxyhæmoglobin H in a lattice similar to the normal reduced form suggests that the oxygenated and reduced forms of hæmoglobin H both have the same, or very similar, crystal structures, and that no major change in molecular structure accompanies its reaction with oxygen. We have not yet prepared crystals of reduced hæmoglobin H, but have tested the point by performing the following experiment.

Crystals of oxyhæmoglobin H were immersed in a solution containing 2·8 M phosphate buffer of *p*H 6·7 and 0·01 M ferrous citrate until their absorption spectrum had changed to that of reduced hæmoglobin. No other change was observed in the appearance of the crystals. They were then mounted in glass capillaries in an atmosphere of nitrogen, and X-ray diffraction pictures were taken. These showed sharp reflexions extending to a spacing of 3 Å. The unit cell dimensions were the same as those of oxyhæmoglobin H. The distribution of intensities in 9° precession photographs of the *h0l* and *0kl* zones was very similar, though small alterations in the intensities of certain reflexions were noticeable.

If crystals of normal oxyhæmoglobin (human or horse) are reduced, or crystals of normal reduced hæmoglobin are oxygenated, the crystals develop numerous cracks and become opaque. Reflexions of more than 8 Å spacing are much weakened and those of less than 8 Å spacing fade out altogether. In these crystals the reaction with oxygen evidently introduces stresses which break up the regularity of the lattice. There is no sign of any such stresses in crystals of hæmoglobin H, where structural changes, if present, must be very slight.

The absence of structural changes accompanying the reaction with oxygen in hæmoglobin H was predicted from the absence of hæm–hæm interaction, and with the idea in mind that in normal hæmoglobin this interaction is linked to structural changes[3,5]. It is interesting to find this prediction confirmed by X-ray analysis.

However, there are two puzzling points arising from our observations. It is not clear why a hæmoglobin consisting of four β-chains should have the same structure as the normal reduced, since one might expect both pairs of β-chains to be equivalent and each pair to take up the relative position shown in Fig. 11 (left) of the preceding article, with a corresponding increase in width in the region of the molecule normally taken up by the α-chains. The second point concerns the kinetic properties. If the oxygen affinity of hæmoglobin H is as high as that of myoglobin, then its configuration should be that of normal oxyhæmoglobin, which is the fast-reacting, rather than that of reduced, which is the slowly reacting modification. These difficulties will need further study.

We thank Dr. Ranney for giving us the crystals and one of us (L. M.) thanks the Fondazione Alberto Beneduce of Naples for a fellowship.

THE NATIONAL PHYSICAL LABORATORY

MORE than 150 items from the research programme of the National Physical Laboratory were on display during Open Week, May 13–17, which was attended by several thousand visitors, including many from overseas. Lectures were given by Dr. W. P. Jones (superintendent of the Aerodynamics Division) on "The Work of Aerodynamics Division", and by Mr. A. Silverleaf (superintendent of Ship Division) on "Experiments with Ship Models".

In Standards Division, much interest was shown in an exhibit describing the method used to relate clocks over transatlantic distances by means of an active communication satellite. The inherent symmetry of the arrangement enables the classical method of comparing clocks to be applied, in which signals are transmitted from remotely situated clocks, at the speed of light, and the time differences between the received and local clock signals are observed. If these differences are equal then the clocks are regarded as synchronized; if not, the discrepancy indicates the magnitude and sense of the relative clock adjustment.

An experiment of this form was carried out in August 1962 by the National Physical Laboratory in co-operation with the U.S. Naval Observatory, making use of the *Telstar I* satellite to relate quartz clocks at the satellite ground station at Andover, Maine and Goonhilly Downs, Cornwall. It was determined that the clocks differed in their setting by 72·6 μsec. Due partly to the wide band-width of the radio circuit and its relatively high signal-to-noise ratio, the overall accuracy of the comparison was 1 μsec, an improvement of some three orders over existing methods of synchronization. The path via the satellite is continuously changing and means have to be provided for recording the reception time of the

signals, which may vary at rates of several μsec/sec. This is now done automatically by a servo-controlled 'tracking' system which indicates continuously the arrival time of the signal relative to the local clock, to an accuracy of 0·1 μsec.

The narrow band-width and coherence of the light emitted by a gaseous optical maser make it particularly suitable for use in the measurement of length by interferometry over much greater distances than is possible using the light given out by normal sources. Unfortunately, in spite of the remarkably narrow band-width of its radiation, the wave-length of the laser emission is not by itself sufficiently stable to form a good standard. Variations in the distance between the mirrors of the maser can change the wave-length by about one part in a million. In the laser on display in Standards Division, such variations of wave-length are considerably reduced by a feed-back system which maintains the wave-length near the peak of the spontaneous emission spectral profile. The stability is thus brought to the same level as the usual secondary wave-length standards.

The application of the gaseous optical maser to the measurement of linear movements is simplified by an effect discovered at the Services Electronics Research Laboratory at Baldock. If the light from the laser is reflected back along its path so as to re-enter the laser, then interference occurs with the effect of either strengthening or weakening laser action, depending on the phase relationship. The result is that a mirror moving towards, or away from, the laser can be made to turn the laser on and off at intervals of half a wave-length.

At the National Physical Laboratory, a machine utilizing a helium–neon optical maser is being developed and applied to the measurement of errors in a metrological grating of the type used for automatic machine tool control. The grating is mounted on a moving carriage which also carries part of the optical system in the laser beam. As the carriage moves, the laser gives out pulses of light and signals are obtained from the grating reading head. An automatic electronic system counts the number of laser pulses between each hundredth pulse from the grating and determines on a time scale the position of the grating pulse between two laser pulses. With the optical system used, the laser pulse separation corresponds to about 5 microinches and this is sub-divided electronically into 50 parts. The final accuracy achieved will be limited by mechanical considerations and temperature uncertainties, but is expected to be better than 5 microinches in the measurement of a 36-in. grating.

Research on optical masers in the the Light Division is being concentrated on pulsed systems using ruby or neodymium glass. A programme of optical and spectroscopic assessment of these materials is now well under way, and both high-power and low-power applications are being investigated. Especial attention has been given to the problem of resonator design and the control of optical feed-back. Studies of the light patterns emitted have confirmed that the performance of these devices is very sensitive to minor variations in refractive index or errors in the optical alignment of the resonating crystal. Given sufficient optical homogeneity, recognizable mode patterns are produced, and with neodymium glass there is a good possibility of obtaining a high-power output the directionality of which is limited only by diffraction effects. With ruby operated at room temperature, all the output can be concentrated into a single wave-length, but neodymium sources are less satisfactory in this respect.

A continuous gas laser provided by Services Electronics Research Laboratory is now being used for testing, by multiple beam interferometry, some of the passive resonators which have been constructed, in order to stabilize against frequency drift. Giant single pulses with a peak power of 1 MW have been produced by operating a ruby in conjunction with an external reflector rotating at 6,000 r.p.m. The duration of such a pulse is less than 1 μsec, the beam-width less than 0·2°, and the spectral line-width less than 0·01 Å, so that it is an ideal source for many experiments in high-speed interferometry and non-linear optics. Interferograms have, for example, been obtained showing the instantaneous variations of thickness of a freely falling sheet of water. A more conventional laser flash with an energy of 3 joules and duration of 1 msec has also been used for drilling holes 0·3 mm deep in diamond. The durability of various types of optical element is being investigated with the view of avoiding breakdown under high light intensity.

Also on display in the Light Division was the newly developed method of time ratio photometry. With this technique, the attenuation of the light beam by the sample being measured is matched with the attenuation produced by a continuously variable repetitive shutter, using a detector that gives the same response to a periodically varying flux $\Phi(t)$ as to a steady radiation of the value $\int_0^T \frac{\Phi(t)dt}{T}$, where T is the repetition period (Talbot's law). The novelty and higher accuracy of the National Physical Laboratory's technique derive from the use of a very accurate method of timing the 'open' and 'shut' times O and S of the variable shutter at the desired setting. The transmission or reflexion factor required is then given by $O/(O + S)$. The shutter only needs short-term stability so that the adjusted value is held for a few seconds at a time. Various types of shutter are being examined, and experiments have shown that vacuum photocells and photomultipliers obey Talbot's law to within 1 part in 10^5 for shutter frequencies greater than 30 c/s.

The Optics Section exhibited an improved version of their recording goniometer utilizing radial diffraction gratings and the moiré fringe technique. In the present goniometer, a grating of finer pitch (60 sec of arc) is carried on an adjustable kinematic mounting which enables it to be centred without difficulty to better than 5×10^{-5} in. The spindle carrying gratings and specimen is mounted in a semi-kinematic arrangement of two radial bearings of nylon impregnated with molybdenum disulphide and a 'wobble-pin' thrust bearing—a system which provides negative radial clearance but no detectable slip-stick effects.

Visitors whose field of work involves the measurement of a.c. currents and voltages were interested in a new development in instrumentation by the Applied Physics Division. The electro-thermal converters commonly used as transfer instruments from a.c. to d.c. have a single temperature-detecting element, although in the U.S.S.R. a system having twenty elements in series has been used. At the National Physical Laboratory a multi-junction converter has been developed in which the alternate (hot) junctions are located at intervals of 0·006 in. along a heater about 1 in. in length, giving a total of approximately 160 thermo-elements. The cold junctions are either embedded in a copper block or the whole system is arranged so that they hang freely in a stout copper housing which is evacuated. The principle of the multi-junction is similar to that of the single-junction system; but in the new design a precision of 0·001 per cent is represented by 1 μV when the output from the thermo-electric system is about 100 mV and the heater is only a few tens of degrees centigrade above the surroundings. There are obvious advantages over the single-element converter, which has a maximum available output of the order of 5 mV, and where it is necessary to measure less than 0·5 μV with certainty to obtain a precision of 0·01 per cent.

If the multi-junction thermal converter was perhaps the smallest piece of apparatus on display, the largest new equipment was certainly the mobile audiometric labora-

Fig. 1. Application of an optical maser as a source of light in high-speed interferometry. The interferogram depicts variations in the thickness of a freely falling sheet of water. At the centre of the picture the water impinges on a thin wire obstacle and divides so that none passes into the lower quadrant. The duration of the laser flash was 0·2 μsec and the peak power about 1 MW. The fringes were formed in transmission by a scatter fringe interferometer

tory which will be used by a team from the Acoustics Section of the Applied Physics Division in a series of experiments on occupational hearing loss, which will be conducted jointly with the Medical Research Council in a programme sponsored by the Ministry of Pensions and National Insurance. Although some progress has been made on the problem of impairment of hearing due to exposures to noise of high intensity, there is insufficient evidence to say whether or not industrial deafness should be prescribed as an industral disease in Great Britain. Factors contributing to the complexity of the problem include the variety of noise exposures encountered, variation in susceptibility to noise between individuals, the effects of non-occupational factors such as age and disease on hearing, and the difficulty in agreeing on a criterion of deafness. The widely used criterion of "preservation of the ability to hear speech" is not sufficiently strict and is difficult to interpret. Increasing use is being made of temporary shift in the threshold of hearing as an index of acoustic trauma, and as a means of predicting permanent hearing loss for continued exposure, but this method has not yet been established scientifically.

The report of the Wilson Committee on Noise has made the general public aware of the difficulties of defining human tolerance to noise, as well as the practical problems of preventing or excluding excessive noise from our environment. A related problem, the measurement of the sound absorption coefficients of materials, has been examined for several years in the reverberation chamber of Acoustics Section. A research programme organized by the International Standards Organization with the co-operation of twenty-seven other laboratories has developed methods of minimizing discrepancies between the results of measurements of different testing laboratories by sound diffusion techniques (Fig. 2). This work, and further research on effects of diffraction at the edges of the specimens undergoing tests which was on display, has been embodied in the recently published British Standard method of measurement of sound absorption coefficients in a reverberation room. Now that the initial research has been completed and other laboratories are suitably equipped, routine testing of proprietary materials at the National Physical Laboratory has been discontinued, and future work will be limited to materials of particular scientific interest.

The Autonomics Division demonstrated the translation of four simple Russian sentences on the *ACE* computer, looking up vocabulary and idioms from an abbreviated 2,000-entry dictionary, including information about 150 idioms. The complete research procedure for the translation of a sample phrase was explained diagrammatically on a display board showing the various stages from input card punching, card reading into *ACE*, dictionary look-up, idiom search, and syntactic analysis to output card punching by *ACE* and the print-out of a final legible form.

In the large water tunnel of the Ship Division, fundamental investigations with a cavitating disk were demonstrated. The disk of 5 in. diam. is supported from downstream on the shaft normally used to drive model propellers in the 44 in. diam. working section of the tunnel. Air can be fed to a point just downstream of the disk and, at a sufficiently low tunnel pressure, a remarkably large air-filled bubble is formed behind the disk. This cavity is probably larger than any previously investigated. Preliminary measurements of the pressure inside the cavity suggest that buoyancy forces have an important effect on it at relatively low tunnel speeds, in the region of 20 ft./sec, and thus the cavitation number appears to be exceptionally large. Further work is needed to confirm this observation and to investigate the effect of factors such as the air content of the water. The ultimate aim of the work is to understand better the large cavities which may be encountered with hydrofoils and new types of fully cavitating propellers.

Among the projects immediately related to ship design demonstrated by the Ship Division, were experiments in irregular head waves representative of actual sea conditions, to evaluate the sea-keeping performance of a model. One of the objects of this work is to determine the pitching and heaving behaviour of the model and to measure the propulsion characteristics. From the point of view of design, comparative experiments with different models can be made in the same wave conditions so that critical factors such as vertical acceleration at a particular point,

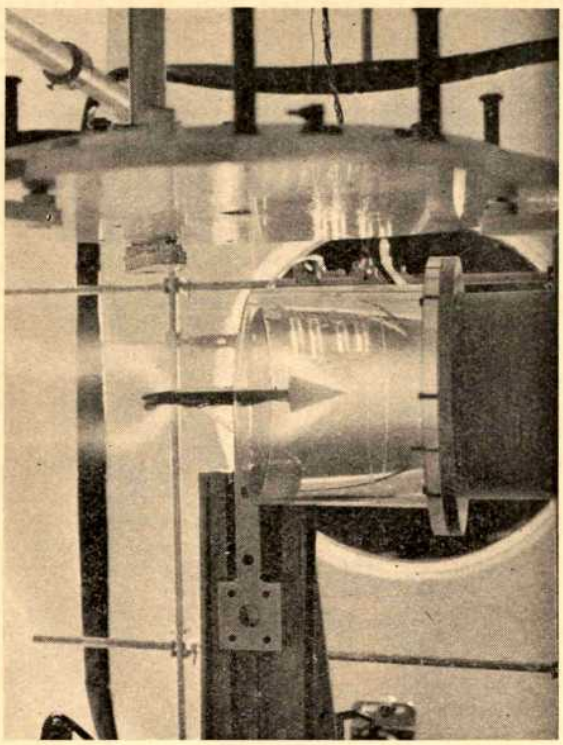

Fig. 3. Flow visualization by means of argon afterglow in the National Physical Laboratory low-density wind-tunnel. The flow is about a cone at twice the speed of sound, and the free stream pressure is 25μ mercury

occurrence of slamming, propeller emergence and shipping of water can be observed or measured. Correlation is being established between full-scale ship motion results and model behaviour in equivalent wave conditions.

The Metal Physics Section of the Metallurgy Division exhibited work which has led to an explanation of the greater increase in hardness during ageing of iron–carbon alloys compared with iron–nitrogen alloys. An important factor in the hardening of metals by precipitates is the degree to which the slip plane in the metal matrix is continued in the precipitate particle. Precipitates which are isomorphous with the matrix are easily sheared by slip dislocations, whereas precipitates with an atomic structure different from the matrix act as obstacles, thus leading to increases in strength and rate of work-hardening. Thin foil electron microscopy has provided a means of estimating the degree of mismatch between the precipitates and surrounding matrix by allowing detection of the magnitude and direction of the strains in the neighbourhood of the precipitates while *in situ* in the metal. The visibility of small precipitates in the electron microscope (in common with other crystal defects), appears to be mainly due to the altered conditions of Bragg diffraction which result from the atomic displacements near the defect. If the diffraction conditions are deliberately changed by altering the angle between the specimen and the incident beam, the image contrast will change and it is possible to analyse the nature of the local atomic displacements around any selected defect. Metallurgy Division have used these techniques to study the strain fields associated with the disk-shaped ε-iron carbide and iron nitride precipitates formed during the ageing of iron–carbon and iron–nitrogen alloys, and their observations show that the slip planes through the nitride precipitates match those through the surrounding iron but that those through the carbide precipitates do not. Nitride precipitates would therefore be expected to be sheared easily by slip dislocations, whereas carbide particles should act as barriers. Thin foil observations of aged and strained iron–nitrogen and iron–carbon alloys containing about the same volume of precipitate have confirmed these ideas.

New facilities for research at high Mach numbers were on display in the Aerodynamics Division. A 15 in. by 10 in. direct discharge wind-tunnel which has just been installed will provide a wide range of flow conditions for Mach numbers of 2–7—an important speed-range for vehicles designed for continuous flight in the atmosphere at very high speeds, and for others during certain phases of their re-entry from space. High stagnation pressures are used to compensate for the reduced scale of the models so that the flow over a 50-ft. long aircraft, for example, can be simulated for 2,000 m.p.h. and the appropriate altitudes between 80,000 and 140,000 ft. A hypersonic wind-tunnel using helium as the working fluid has recently been constructed, for research on flow problems at speeds between 5 and 25 times the speed of sound. The use of helium as the test gas at room temperature, in place of air, allows expansion to very high speeds without liquefaction taking place. Similar conditions would require pre-heating of air as the test gas to about 3,000° K—a formidable engineering problem. This tunnel will reproduce the Mach numbers of sub-orbital flight, but not the high-heating characteristic of hypersonic flight, which is studied separately in high-temperature facilities such as the 'Hotshot', which allows a flow duration of about 30 msec at Mach numbers of 10–20 through its 8 in. diam. working-section. This is the only wind tunnel of its kind in the United Kingdom. An additional electromagnetic shock tube which produces a shock-wave travelling at Mach numbers between 30 and 40 is providing useful experimental information in the field of magneto-gasdynamic.

At 40–50 miles above the Earth's surface, the air may no longer be regarded as a continuous fluid since the mean free path of the molecules is of the same order as some dimensions of the flying object. However, free molecular flow does not occur until the mean free path is of the order of five times the dimensions of the flying object—about 75 miles altitude in the case of a 3-ft. sphere. To study aerodynamics in the lower transitional-flow region, a low-density tunnel is used, having a $7\frac{1}{2}$ in. diameter working-section and operating at a Mach number of 2 and at pressures of 10–100μ of mercury. One of the problems encountered at pressures as low as this is that conventional optical methods, such as shadowgraph, schlieren and interferometry, cannot be used to visualize the flow about the model. Instead, the gas flow is partly ionized by an intense radio-frequency discharge and the recombination process occurring during the flow down the nozzle and over the model is accompanied by a glow discharge, the intensity of the glow being proportional to the local density. Shock waves show up, therefore, as discontinuous increases in brightness. Argon is the most suitable gas to use for this process: an alternative method enriches air with a small quantity of nitric oxide to stimulate bright after-glow. The low-density tunnel is being used to investigate the fundamental nature of flow about simple wings and bodies in the transition region.

The staff of the Mathematics Division were available during the open day to discuss their research with visitors, but no exhibits were arranged because of the inherent difficulty of displaying theoretical work. The Basic Physics Division did not exhibit their work as they were preparing to move into their new building, which has just been completed.

For the staff of the Laboratory the open days provide a welcome opportunity to show the latest developments in their work to other research workers and to technical staff from industry. A warm invitation is extended to all who are interested in attending the open days in 1964 which will be held during May 27–28. Requests for invitations should be addressed to the Director, National Physical Laboratory, Teddington, Middlesex.

NEWS and VIEWS

Botany at New South Wales: Prof. H. N. Barber, F.R.S.

Prof. H. Newton Barber has been appointed to the Foundation chair of botany at the University of New South Wales. Prof. Barber has been professor of botany at the University of Tasmania since 1948. In March of this year, he was elected a Fellow of the Royal Society, "distinguished for his work in experimental cytology, population genetics and the genetics of flowering". He is also a Fellow of the Australian Academy of Science and a Member of the Advisory Council of the Commonwealth Scientific and Industrial Research Organization, being chairman of the Tasmanian State Committee. A graduate of the University of Cambridge, he gained first-class honours in both of the Natural Sciences Tripos in 1935 and 1936, and was awarded a Ph.D. degree by the University of London after spending four years as a research cytologist at the John Innes Horticultural Institute. During the Second World War he was a scientific officer at the Telecommunications Research Establishment, Ministry of Aircraft Production, and in 1946 accepted appointment as lecturer in botany at the University of Sydney. Prof. Barber spent the years 1953 and 1954 at the California Institute of Technology on a Rockefeller special fellowship, and was visiting professor at the Australian National University and at University College, Townsville, during 1961. Prof. Barber will become head of the Department of Botany, which is one of the four Departments which form the School of Biological Sciences.

Plant Physiology and Biochemistry at Newcastle: Prof. S. L. Ranson

The appointment of Dr. S. L. Ranson to a chair in plant physiology and biochemistry, personal to him from July 1, 1963, at Newcastle upon Tyne (University of Durham), will be welcomed by his many friends and colleagues. Dr. Ranson was trained in the Department of Botany in King's College, and commenced research under Prof. (now emeritus professor) Meirion Thomas, on Crassulacean acid metabolism. He was appointed lecturer in 1946, senior lecturer in 1958, and reader in 1960. During the academic session 1949–50 he held an Earl Grey memorial fellowship at Washington University, St. Louis, where he worked with Prof. M. D. Kamen. He has extended the work on Crassulacean acid metabolism initiated by Prof. Thomas by the application of isotopic methods and he has investigated the enzyme systems involved. All his work has been characterized by meticulous attention to detail and a very critical appraisal of the results. Dr. Ranson and his group are now extending their studies on the relation of acid metabolism to the more general problems of carbon dioxide fixation and intermediary metabolism. He has collaborated with Prof. Thomas in recent editions of the latter's well-known textbook and he has also provided an important contribution on techniques for the separation and estimation of plant acids in *Modern Methods of Plant Analysis*. This appointment recognizes not only Dr. Ranson's considerable personal achievement but also the importance and notable part played by plant physiology and biochemistry in the Department of Botany at Newcastle.

Physics at Manchester : Prof. S. F. Edwards

Dr. S. F. Edwards, reader in theoretical physics in the University of Manchester, has been appointed to a newly established additional chair of physics, in the field of theoretical physics, as from October 1. Dr. Edwards received his school education at Swansea Grammar School. In 1945 he entered Gonville and Caius College, Cambridge, to read for the Mathematical Tripos. During 1949–51 he was a research student at Cambridge and in 1951 was awarded the J. H. Cheate Memorial fellowship at the University of Harvard, where he worked under Prof. J. Schwinger. He then spent a year at the Institute of Advanced Study, Princeton, returning to Britain in 1953. In that year he was awarded the degree of Ph.D. (Cambridge) and was appointed Imperial Chemical Industries Research Fellow in the University of Birmingham. Two years later, he was appointed senior lecturer in theoretical physics, and in October 1961 promoted to a readership in theoretical physics in the University of Manchester.

Royal Society Research Professorships

The following have been appointed to Royal Society research professorships: Dr. R. A. Hinde, of the Sub-Department of Animal Behaviour, Department of Zoology, Cambridge, who is well known for his work in the field of the experimental study of animal behaviour, has been appointed as Royal Society Research Professor at the University of Cambridge as from October 1; Prof. F. Sondheimer, head of the Chemistry Department at the Weizmann Institute, Rehovoth, Israel, who is distinguished for his work in the field of organic chemistry, Royal Society Research Professor at the University of Cambridge in the University Chemical Laboratory—he is expected to take up his appointment during 1964.

British Aid to Developing Countries

The first of a series of pamphlets giving a factual survey of British aid to developing countries, issued by the Overseas Development Institute, deals with educational assistance (*British Aid*—3: *Educational Assistance—a Factual Survey of the Government and Private Contribution to Overseas Development through Education and Training*. Pp. 125. London: Overseas Development Institute, 1963. 7*s*. 6*d*.). Following a short historical survey, it sets forth first the part played by the British Government, describing both the organization of the effort and the scale and character of the official programme. Next the private contribution is described, including that of the missionary societies and churches, the various volunteer schemes, and the part played by the foundations and trusts and the universities. Finally, information on overseas students in Britain is summarized, including their distribution in various types of institutes, the Government contribution, the various technical assistance schemes, etc., and the role of the British Council. The pamphlet provides a most useful and comprehensive picture of an effort that already amounts to a very considerable total and one to which full justice is seldom done, though the account is neither designed nor intended to induce complacency. It points out specifically that Britain's present programmes, valuable as they are, represent only a small part of what needs to be done. The study, and those to follow, have been requested by the Foreign Office. The pamphlet questions whether the present system, in which eight different Government departments control funds for educational assistance, allows priorities to be determined effectively. It suggests that British teachers going abroad may not be staying long enough in their posts and that the possibility of a career service for British teachers overseas should be reconsidered. It considers that there are some gaps in the programme of financial assistance and that greater efforts should be made in teacher and in technical training, the provision of cheap books and

research into the educational problems of developing countries.

Overseas Technical Co-operation

In written answers in the House of Commons on July 16, the Secretary for Technical Co-operation, Mr. R. Carr, stated that of the £16 million provided for Commonwealth education during the five years ending in 1965, about £2 million was being made available for the Commonwealth Scholarship scheme, and about £1·7 million for teacher-training bursaries. Actual expenditure up to March 31 was £867,000 on scholarships and £814,000 for bursaries. On the advice of the Committee for University Secondment, he was supplementing existing arrangements by offering a limited number of special awards of £1,500 a year to outstanding men and women in British universities who were willing to serve for at least two years in selected posts in developing countries of the Commonwealth. These would be additional to the total emoluments ordinarily paid to British university staff in the countries concerned, and the first award would be made in 1964. Overseas universities were being consulted about the posts that they would like to be filled in this way, and he was confident that the British universities and academic institutions which he was consulting would co-operate fully in the selection and secondment of people of high distinction. Present commitments under Section 1 (3) of the Commonwealth Teachers Act, 1960, were expected to result in an expenditure of at least £5 million, and it was desirable at this stage to maintain the uncommitted balance of £6 million made available for the quinquennium to meet new requirements which might arise in the next two years. In a written answer in the House of Commons on July 23, the Secretary for Technical Co-operation, stating that he was himself satisfied that Government funds allocated to Voluntary Service Overseas were being effectively used, announced that a target of 500 graduate volunteers had been fixed for 1964 and that the Government had again agreed to meet half the British costs. In addition, Voluntary Service Overseas would send about 300 school-leavers, and the Government would contribute half the cost of this programme instead of a third as this year. The number of volunteers going overseas would thus have risen from about 20 in 1958 to 800, and the number of graduates from 36 to 500 over three years.

Scientists and Civil Research in Britain

In written answers in the House of Commons on July 16, the Parliamentary Secretary for Science stated that 236 British scientists were interviewed by the Joint Board in North America this year, of whom 171 were in the United States, and so far 68 candidates, of whom 51 are working in the United States, had been offered appointments in the United Kingdom. Estimated Government expenditure on civil research in 1963–64 was £171·447 million. This included £2·841 million for the Ministry of Agriculture, Fisheries and Food and £1·957 million for the Department of Agriculture and Fisheries for Scotland, £7·387 for the Agricultural Research Council, £701,000 for the Nature Conservancy and £420,000 for Forestry Commission; £24·8 million for the Department of Scientific and Industrial Research (including capital and current expenditure on buildings by the Ministry of Public Building and Works), £621,000 for the Ministry of Power and £445,000 for the Ministry of Transport; £7·606 million for medical and health research, including £6·908 million for the Medical Research Council; £2·309 million for overseas research; £48 million for the Atomic Energy Authority and £7·87 million for the National Institute for Research in Nuclear Science; £26·2 million for universities and £227,000 for learned societies; £37·778 million for Ministry of Aviation, £631,000 to Air Ministry for meteorology, £606,000 to the Admiralty for observatories, oceanography, etc., and £362,000 to Home Office and Scottish Home Department.

Forestry in Britain

In a statement in the House of Commons on July 24, the Minister of Agriculture, Fisheries and Food, Mr. C. Soames, announced that over the decade 1964–73 the Forestry Commission would aim at planting a further 450,000 acres. It would continue to concentrate on acquiring land in the upland areas, particularly in England and Wales, where the population is declining and expansion of forestry can bring considerable social and employment benefits. The Commission would be able to acquire land in other areas where there are good economic reasons, or where planting can maintain or improve the beauty of the landscape. The planting programme for each year, and its distribution between the three countries, would be determined from time to time by the Forestry Minister. In preparing its future programmes, the Commission would bear in mind the need, where possible, to provide public access and recreation, and would direct more attention to increasing the beauty of the landscape. No change was proposed in the structure of the present grants to private woodland owners. The Government welcomed the increasing acreage of timber planted by private owners, and the tradition of skill and knowledge and the research which had been carried out in private forests had been of great benefit to the nation. This steady expansion in both public and private forestry meant that a growing volume of home-produced timber will be coming on to the market which would benefit Britain's balance of payments already of about £14 million a year. Clearly, it would become more necessary to direct greater attention to the whole problem of the marketing and use of home-grown timber. In answer to questions, Mr. Soames said that with planting by private owners, some 80,000 acres a year would be planted for the next five years and the Commission would, in particular, consult the National Parks Commission in respect of amenity and the beauty of the landscape, employing a landscape architect to assist. Mr. Soames also agreed that the closest co-operation between farming and forestry interests was essential.

Department of Scientific and Industrial Research and NATO Studentships

In a written answer in the House of Commons on July 19, the Parliamentary Secretary for Science, Mr. D. Freeth, gave the number of students holding Department of Scientific and Industrial Research studentships (including NATO studentships) at November 1, 1962, as 3,473, of whom 3,412 held their studentships at universities and colleges in Great Britain and 2 in Northern Ireland. They represented 38·5 per cent of full-time postgraduates in their fields in these institutions. Of 991 such students who entered employment on the termination of their awards in the year ended September 30, 1962, 357 joined the staffs of home universities (201 in teaching and 153 in research posts) and 18 the staffs of colleges of advanced technology. In addition to these 991 students, 141 were continuing their postgraduate training and 48 had taken research fellowships from the Department or NATO. A further 165 students joined the staffs of overseas universities, 97 for teaching posts and 68 for research.

A Blood Typing Service for Cattle

Following discussions with organizations interested in cattle breeding, the Agricultural Research Council is to set up a blood typing service for cattle at its Animal Breeding Research Organization in Edinburgh. The objectives of such a service, which will be available to cattle breeders on a fee basis, are, from the point of view of the farmer, to obtain a description of the blood characteristics of a cattle beast which can be used to determine its relationship to another animal for which similar

information is available, for example, whether it is the progeny of a particular bull. From the point of view of the Council the objective is to obtain data which will be of value in the study of the genetics of cattle. The preliminary organization, equipping of laboratories, and particularly the training of staff, will take some time, and it will not be possible for samples to be received for test for at least a year. The establishment of the service is being facilitated by the action of certain bodies which have guaranteed their support, and priority will be given in the first instance to samples sent in under the auspices of these bodies. When the service is in a position to accept samples, a further announcement giving details of the service will be made.

Political and Economic Planning

THE annual report of Political and Economic Planning for the year ended March 31, 1963, reports briefly on the six projects in the current research programme started in the two previous years and due for completion by 1964 (Pp. 20. London: Political and Economic Planning, 1963). That dealing with community mental health services has concentrated on comparative field studies in four areas where such services are well developed, and in each area a statistical survey, an interview survey of psychiatric patients living at home and of members of their families has been in progress, as well as a survey of mental health work. In that concerned with prisoners and their families, the field-work on the national sample has been completed and a more intensive study commenced of the families of up to 100 prisoners living in the London area. The enquiry into education and training programmes for developing areas is fully under way, and that on Trade Unions in a changing society is due for completion in autumn 1963. The two-year project on attitudes in British industry was started in April 1962, and the main publication during the year of the programme on Britain and European integration was *Atlantic Tariffs and Trade*.

Directory of European Dental Research Workers

THE Commission on Dental Research of the Fédération Dentaire Internationale is in the course of compiling a Directory of European Dental Research Workers. The Commission will be corresponding direct with all dental schools in the United Kingdom requesting information on research personnel. In addition, however, it is desired to include particulars of research workers who are not necessarily dentally qualified and not necessarily working in dental institutions, but who are engaged on studies directly pertaining to dental science. Information concerning institutions where such workers are based should be sent to the Commission on Dental Research, Fédération Dentaire Internationale, 35 Devonshire Place, London, W.1.

Literature in Nuclear Sciences

Publications in the Nuclear Sciences, 1963, is a complete catalogue of 100 pages of the publications of the International Atomic Energy Agency, and is the fifth edition in the series of catalogues, superseding all previous issues and supplements. The titles are listed in inverse order of publication, that is, with the most recent first, under nine general subject headings: biology, medicine and agriculture; health, safety and waste disposal; physics, plasma physics and electronics; chemistry, geology and raw materials; reactor physics and reactors; industrial applications; economics; law; and miscellaneous and documentation. The publications mostly fall into the following groups or series: "The Proceedings Series", being the proceedings of conferences, symposia and seminars under the ægis of the Agency, which are published in their original language together with abstracts in English, French, Russian and Spanish; "The Safety Series", reports on health and safety topics, available in separate English, French, Russian and Spanish versions; "Technical Directories", in English only; "The Technical Report Series", reports on research, mostly in English; "The Bibliographical Series", surveys of world's literature on subjects in the field of nuclear science; and "The Review Series", a completed series of 27 reviews in various languages. Subsequent reviews are now published in the new journal, *Atomic Energy Review*, which appears at irregular intervals. *Nuclear Fusion*, a quarterly journal on plasma physics and thermonuclear fusion, is the other four-language journal, distributed on a subscription basis from Vienna and published by the Agency.

Announcements

ENTRIES for the 1964 Maccabæan Prize and Medal are now invited for an essay of 5,000–7,000 words on some aspect of the history of medicine or pharmacy. Intending candidates, who must be less than thirty years of age on March 15, 1964, can obtain further particulars from the honorary secretary of the Faculty, Dr. F. N. L. Poynter, Wellcome Historical Medical Library, the Wellcome Building, Euston Road, London, N.W.1.

OCEANOGRAPHERS and meteorologists will be interested to know that the well-known 1905 paper by V. W. Ekman, "On the Influence of the Earth's Rotation on Ocean-currents", has been reprinted. Copies are obtainable from the Royal Swedish Academy of Sciences, Stockholm 50, price 3.50 dollars.

THE fourteenth international Astronautical Congress, arranged this year by the French Astronautical Society, will be held in Paris during September 25–October 1. Further information can be obtained from the Société Française d'Astronautique, 6 rue Galilée, Paris 16e.

A ONE-DAY meeting will be held by the British Biophysical Society at the School of Pharmacy, University of London, on September 30. Further information can be obtained from Prof. R. E. Burge, Physics Department, Queen Elizabeth College, Campden Hill Road, London, W.8.

A SYMPOSIUM on "Light Fading and Colour Assessment" will be held by the Society of Dyers and Colourists at St. Anne's on the Sea, Lancashire, during September 11–13. Further information can be obtained from the Society of Dyers and Colourists, P.O. Box No. 244, Dean House, 19 Piccadilly, Bradford 1, Yorks.

A SYMPOSIUM on "Transport and Traffic Noise", organized by the Society of Acoustic Technology and the Institute of Sound and Vibration Research, will be held at the University of Southampton during September 27–28. Further information can be obtained from Dr. G. M. L. Gladwell, Institute of Sound and Vibration Research, the University, Southampton.

THE Fifth International Seaweed Symposium and associated meeting of the International Phycological Society will be held in Halifax, Nova Scotia, during August 25–28, 1965, at Dalhousie University. This meeting has been postponed from 1964 to 1965 due to conflict with other international conferences. Further information can be obtained from the chairman of the local committee, Dr. E. Gordon Young, National Research Council Laboratory, Halifax, Canada.

AN international symposium on the "Thermal Stability of Polymers", sponsored by the Battelle Memorial Institute, Columbus, Ohio, will be held during December 5–6. It will include papers on both pyrolytic and thermal oxidative stabilities of polymeric structures. In addition, papers will be presented on methods for studying thermal stabilities and on stabilizing various types of polymers. Further information can be obtained from Dr. Palmer B. Stickney, Battelle Memorial Institute, 505 King Avenue, Columbus 1, Ohio.

CONDUCTION PROCESSES IN DIELECTRIC LIQUIDS

A CONFERENCE on "Electronic Processes in Dielectric Liquids" was held under the auspices of the Electronics Group of the Institute of Physics and the Physical Society, at Durham, in April 1963. The purpose of the meeting was to discuss electrical conduction and allied phenomena in pure dielectric liquids. The conference lasted three days, and included 43 papers, many of them from abroad.

In the past, a great deal of work has been reported in the literature on conduction and breakdown in liquid dielectrics; a feature of much of this work is that for interpretation it has leaned heavily on the classical studies of Townsend on conduction and breakdown in gases (and, to a lesser extent, on conduction processes in solids) rather than on the study of liquids, *per se*. Perhaps because of this conceptual bias, there has been a tendency to think of conduction in liquid in terms of electronic processes, and at high fields, to talk of ionizing collision, and electron avalanches. Indeed, the title of this conference may be taken as evidence of a preconceived notion that free electrons ought to exist in insulating liquids, whereas the experimental evidence presented at the meeting proved, if anything, rather the contrary.

One important function of the conference was to bring together those concerned with the theory of liquids and with transport properties of liquefied gases, and those who have largely specialized in conduction and breakdown processes in dielectric liquids. The value of the conference from this point of view was enhanced by the invited lecture, given by Stuart A. Rice (University of Chicago), who presented a stimulating survey of the present state of the theory of liquids.

As already implied, one of the most important problems in the examination of conduction processes in liquids is the identification of the charge carrier in the conduction process; a number of papers presented at the conference were concerned with this problem. The methods used depend on the measurement of the mobility of the charge carrier, and all these techniques rely on the production of carriers in the liquid by means of external radiation, by α-particles or X-rays, by the photo-generation of carriers, or by electron injection. (It remains to be seen whether these induced carriers are of the same type as those present under conditions of natural conduction.)

For a number of years now, the workers at the University of Gdansk have been measuring charge carrier mobilities in liquids, using X-rays to create both positive and negative species. These experiments have covered a wide range of liquids, but particular attention has been directed to the hydrocarbons. A large number of measurements of this type were reported by Adamczewski on behalf of the Gdansk group, and in the first paper of this series, mobility measurements in saturated hydrocarbons were described. Positive and negative carrier mobilities have been measured in a number of liquids, including *cyclo*hexane, and the observations extended over a range of temperatures. The mobilities are of the order of magnitude predicted by Stokes's law for molecular ions; moreover, the temperature variation of mobility of the negative carrier shows it to be inversely proportional to viscosity, in agreement with Walden's rule. Jachym, working in the same research group, has made carrier mobility measurements in high viscosity hydrocarbon and silicone liquids, again using the X-ray injection technique. Stokes's law was obeyed by the negative carrier; but the positive carrier mobility varied rather more strongly with temperature, suggesting that the positive species are somewhat unstable.

Two other types of measurement were reported from Gdansk on the X-ray induced charge carriers: Gazda and Adamczewski have measured ion recombination coefficients, and their dependence on liquid viscosity and temperature; for the normal alkanes the recombination coefficients are found to be related to the number of carbon atoms in the molecule, and the results have been interpreted on the basis of Frenkel's hole theory of liquids. Gazda has also measured ion diffusion coefficients in *n*-hexane, using an ionization chamber the geometry of which was chosen to give one-dimensional diffusion in the direction perpendicular to the electrodes; these measurements confirm the validity of the Einstein relationship, for charge carriers in hexane.

A number of workers have used photo-injection techniques to create negative charge carriers in liquids. It has previously been shown that the optical threshold for this process is about the same as for the photo-emission of electrons from metals into vacuum—though more recent observations suggest a major difference between these processes. Inuishi and Chong have used the photo-injection technique up to quite high fields, and they described their measurements of charge carrier mobility in pure hexane and in hexane doped with alcohol. There is a marked decrease of negative carrier mobility with doping, and on this basis it has been suggested that the charge carrier is a polaron; that is, an electron trapped in the polarization field of its surroundings. Ions produced by the injection of photo-electrons from a cathode into the liquid were also investigated by Terlecki. The measurements were made in hexane, octane and decane, up to quite high fields; no change of carrier mobility with field was observed, in agreement with Inuishi and Chong. There is evidence that the carrier mobility increases more rapidly with temperature than predicted by Stoke's law—suggesting that in this case the negative species are somewhat unstable. Watson and Clancy described an electron injection technique for investigating conduction processes in low vapour pressure liquids, including a range of siloxane fluids. Measurements indicate that virtually all the injected electrons are trapped near the point of injection in the liquid, to form stable carriers of low mobility. Currents are space charge limited, and from these measurements values of charge carrier mobility can be inferred.

From these various methods of studying charge carrier mobilities in liquids, a more or less consistent picture emerges; the majority of measurements indicate a negative charge carrier which is presumably a negative molecular ion, though it is possible that in highly polar liquids the polaron model is applicable. In the case of the positive ions, the picture is perhaps not quite so clear; the fact that the mobility of the positive carrier varies more rapidly with temperature than the negative species suggests that the positive ion is not necessarily a stable entity. However, both carriers appear to vary somewhat in behaviour, depending on the experimental conditions.

In view of the increasing body of experimental evidence on the trapping of charges in liquids, there is a need for further theoretical investigations of the nature of the trapping sites; many of the materials chosen for investigation show no tendency to attach electrons and form stable negative ions in the vapour phase, yet they show every indication of trapping electrons in the liquid phase. An adequate understanding of this process is needed. McCubbin reported on some theoretical work on the nature of carrier traps in paraffins in which he suggested that the

density and energy distribution of traps are controlled by the degree of (or lack of) long-range order in the material.

Four papers were presented on electronic and ionic processes in liquefied rare gases. Charge carriers of either sign can be produced by using α-particles to ionize the liquid. With this technique, previous workers have measured very high mobilities (10 cm^2/V sec and greater) for the negative charge carrier in liquid argon, and it has generally been accepted that these carriers are free electrons. New measurements from Chicago, which were presented by Rice, give quite low negative charge carrier mobilities in liquid argon (of the order of 10^{-3} cm^2/V sec), suggesting that the negative carrier is an impurity ion, despite the fact that the liquid used is of high purity. Results presented on behalf of Swan, on the other hand, confirm the high carrier mobilities reported by Williams and others, and suggest that in pure liquid argon the charge carrier is a free electron, but that with oxygen present, negative ions are formed. The attachment coefficient reported for oxygen in liquid argon appears to be of similar magnitude to that observed in oxygen gas, for low-energy electrons. The discrepancy between these two reports suggests that both types of negative carriers are normally present in liquid argon, but that individual experiments may not be capable of resolving both.

The work at the University of Rome on charge carriers in normal and super-fluid helium was described by Careri. The positive charge carrier in normal helium is believed to be He_2^+; the negative carrier may be an electron with a high effective mass caused by electrostriction of its surroundings. In super-fluid helium the nature of the charge carriers is still the subject of controversy. Recent measurements, described by Careri, have revealed that the mobility decreases in a stepwise manner at integral multiples of a certain critical field, and in the case of the positive carrier this has been followed up to six steps in mobility.

Photoconductivity measurements of various organic solutions were described by Ruppel. Solutions of aromatic amines in hexane have a low conductivity in the dark, but ultra-violet irradiation produces short-lived positive ions which increase the conductivity of the solution. Radical ions have been detected by conduction measurements when the solution is excited by a flash of light. Morant described studies of ultra-violet photoconduction in hexane, and reported that illumination of the anode or of the bulk liquid can give currents of almost the same magnitude as illumination of the cathode, implying that the mechanism of charge generation differs from what has been supposed in the past; however, the current is still found to depend on the electrode work function, indicating that it is not simply photo dissociation of the hexane which is involved. Measurements by Terlecki and Gzowski on the photo injection of charge carriers into hexane and decane were described. The currents were proportional to light intensity, and although the measurements were extended up to fields of 200 kV/cm, the current showed no tendency to saturate. In gases the saturation current is a well-established phenomenon; the fact that this is not observed in liquids may be due to space charge effects.

Four papers were presented on the use of liquid-filled ionization chambers. Two of these were by the Polish group, and two were by Blanc *et al.*, all of whom have used ionization chambers filled with dielectric liquids for the detection of nuclear radiation. The best results for fast neutrons, in terms of sensitivity, were obtained using *n*-hexane. Because of the low carrier mobility, however, the response is slow and for the detection of individual particles the best results were obtained with liquid argon.

Nowak has used an ionization chamber to investigate conduction processes in liquid benzene, and to determine the mobility of the charge carriers at different temperatures; preliminary measurements were also made of the recombination coefficients of the carriers. Benzene seems to possess a relatively high natural conductivity, and it has been suggested that this is associated with the π electrons of the molecule. One might therefore expect to find some interesting features in its electrical behaviour. Forster has made d.c. conductivity measurements on the series of compounds, benzene, *cyclo*hexadiene, *cyclo*hexene and *cyclo*hexane, and has noted a systematic decrease of conductivity along the series; a probe technique was used to determine the potential distribution in the conduction cell, and by this means it was possible to avoid errors which usually enter into d.c. conduction measurements as a result of electrode polarization phenomena. On the basis of their measurements, both Nowak and Forster suggested that the conduction mechanism in benzene involves an electron transfer process between molecules.

Conduction in purified polar liquids has been investigated by Felici and by Briere; in the past, highly polar liquids have been rather neglected in both research and engineering, and to a large extent this lack of interest may be ascribed to the sensitivity of these liquids to electrolytic impurities. The use of ion exchange materials and efficient dehydration techniques now makes it possible to purify these liquids to a considerable extent, and measurements were described on ethyl alcohol, for example, for which resistivities greater than 10^9 ohm cm have now been obtained; this probably represents the limit set by dissociation of the liquid itself. Coelho and Belloc described a novel type of technique to study impurity ions in liquids. They used two sets of coaxial electrodes, mounted in a flow system; the liquid (hexane) was subjected to a d.c. field between the upper electrodes and then passed on to the lower electrodes where an electrometer was used to analyse the residual charge in the liquid. Measurements of the net charge have shown that even at very low fields (100 V/cm) some impurity ions are removed. The passage of current through polar liquids is accompanied by an increase in apparent viscosity; Hart has shown that this visco-electric effect is not due to polarization boundary layers at the electrodes, but is probably due to momentum transfer from charge carriers; calculations indicate that the charge carriers are large, and may in fact be sub-microscopic dust particles.

The final day of the conference was devoted to high-field conduction, breakdown and applied phenomena in insulating liquids, and opened with a review paper by Macfadyen. Zaky, Tropper and House reported on their d.c. conduction measurements in hydrocarbon liquids, with fields up to 10^6 V/cm, and using various cathode surfaces. In order to obtain consistent measurements, it was necessary to condition the system by allowing current to flow for a considerable time—before conditioning, severe current fluctuations occurred. This erratic nature of d.c. conduction currents was also stressed by Morant and Kahan; they found that in highly purified hexane, at fields greater than 200 kV/cm, two distinct sets of currents vs. voltage characteristics could be obtained, and transitions between these values appeared to occur spontaneously. At the moment, no satisfactory explanation for this exists; but an adequate understanding of the part played by space charges may give the required answer.

There are a number of techniques for examining pre-breakdown phenomena in dielectric liquids: Murooka, Nagao and Toriyama have made high-speed camera studies using a bubble chamber as the test cell. By this means, pre-breakdown ionization and vaporization processes in the highly stressed liquids can be studied; interesting effects involving growth and movement of bubbles were shown. Toriyama, Sato and Mitsui presented a paper on the mechanism of breakdown of dielectrics, using Lichtenberg figures to investigate the distribution of ionization in the gap. It was concluded that discharges in the gas phase were often present, but that these may not be essential to breakdown.

One of the most interesting pre-breakdown phenomena in liquids is that of light emission at high fields. Gosling has examined the electro-luminescence of carefully purified fractions of mineral oils at high fields, and finds that both light output and conduction current vary in a manner similar to that found in solid phosphors. The position and brightness of the light emitted depends on the gas content of the oil, its chemical constitution, and the degree of electrode oxidation. Darveniza was among the first to observe light emission from liquids at high fields; recent work of his was reported, in which he investigated the phenomena in both liquids and in solid dielectrics doped with fluorescent solutes (these include anthracene and *p*-terphenyl).

The electric strength of liquids, measured with short rectangular pulses, can be changed appreciably by the application of a static stress to the system before the pulses are applied. Ward described measurements of this type in hexane; it was suggested that a static stress sets up charge layers on the electrodes and that these layers modify the emission from the cathode and hence change the pulse strength of the liquid. Gallagher has made breakdown measurements in liquid argon using direct and impulse voltages, applied to uniform and non-uniform gaps. The effect of gaseous impurities was investigated and small quantities of dissolved oxygen were found to increase the strength. It was noted that the breakdown strength depends also on the condition of both cathode and anode.

A thermal mechanism of liquid breakdown was described by Watson and Sharbaugh, based on their conduction current measurements under microsecond pulse conditions. It was suggested that local currents are large enough to be space charge limited, and the energy input needed to cause breakdown is that required to vaporize the liquid. Krasucki has shown that in viscous liquids the first stage of breakdown involves the formation of a region of low density, which has a lower breakdown strength than the surrounding medium. He suggested that this also occurs in non-viscous liquids, and a model was set up for the formation of the bubble involving the hydrodynamic forces of liquid motion adjacent to the cathode. It is likely that under many conditions the breakdown process involves a thermal process, and the formation of a vapour region; it is therefore important to know the breakdown strength of liquid and vapour at high temperatures and pressures. Sharbaugh and Watson described measurements of the electric strength of hexane through the vapour to liquid. No discontinuity in strength was found in going through from vapour to liquid, in the critical region.

A number of conclusions regarding conduction processes in liquids can be drawn from the work presented at the conference. From measurements of charge carrier mobility, it is clear that, in insulating liquids in general, the conduction process is an ionic rather than an electronic process, and that except in the liquefied rare gases free electrons do not normally exist in insulating liquids. An electron would be expected to have a mobility of 1 cm^2/V sec or greater; for lower mobilities one can no longer talk of free electrons—though hybrid species may exist, such as thermally excited electrons, moving from trap to trap (the so-called 'hopping' electron). The low order of magnitude of carrier mobilities measured in organic liquids implies either an ionic carrier, or a hopping electron; moreover, the variation of the mobility with viscosity seems to follow a Stoke's law type of relationship (though the agreement is not perfect) so that an ionic species seems to be the most likely form of charge carrier. At very high fields the situation is less clear, and the fact that light emission has been observed from insulating liquids containing fluorescent additives, at fields approaching 10^6 V/cm, has been taken as evidence for the presence of energetic electrons in the liquid; other mechanisms of excitation are possible, however, so that even this evidence is not unequivocally in favour of a free electron.

There are a number of speculations as to the nature of the trapping site for electrons in liquids; hydrocarbons such as hexane, for example, do not trap electrons in the vapour phase, yet they seem to contain highly efficient electron traps in the liquid phase. It is possible that the traps are associated with the local degree of disorder of the liquid; the resulting traps must be deep ones, however, for a shallow square well (of the type required by the hopping electron model) does not predict the correct field dependence of mobility. The polaron model may be appropriate, particularly for highly polar materials. The mechanism whereby charge carriers are generated is beginning to look more complicated than had been suspected; until recently one had tended to assume that the charge transfer process, taking place at the interface between electrode and liquid, was similar to that between metal and vacuum, but recent results, implying photo-generation of carriers at both anode and cathode, must make us revise many of these views.

Turning finally to high-field conduction and electrical breakdown in liquids, the question of the relative importance of electronic processes in this region still remains; there is virtually no evidence for collision ionization in recently published work, though it was almost taken for granted a few years ago. Indeed, it is becoming increasingly evident that under the experimental conditions in use at present—even in the use of microsecond pulse techniques—electrical breakdown of liquids is probably not an electronic process in the generally accepted sense, but can often be explained in terms of thermal effects.

It has been impossible, in this report, to mention all 43 papers which were presented at this conference: for a complete list of these papers and authors, the reader is referred to a companion review by M. J. Morant, which is to appear in the *British Journal of Applied Physics*.

P. K. Watson

INSTRUMENT DESIGN: MANUFACTURE AND USE

THE new headquarters of S.I.M.A., the Scientific Instrument Manufacturers' Association of Great Britain Ltd., at 20 Peel Street, London, W.8, were officially opened on January 14. The president, Mr. R. E. Burnett (Marconi Instruments Ltd.), in welcoming the guests referred to 1962 as a particularly busy year for the Association in which a number of significant developments in external relations occurred. The association was invited to co-operate with the National Economic Development Office in its initial examinations of certain sectors of industry, and a survey was made by the Association, based on available published statistics and certain forecasts provided by the industry, of the growth potential of the instrument industry. The exercise disclosed the unsatisfactory nature of the official information, particularly in regard to the classification of products and to industrial employment.

Mr. Burnett emphasized the importance of closer collaboration with instrument manufacturers overseas and reported that during 1962 S.I.M.A. became associated with the Comité Européen de l'Optique et de la Précision de Mécanique. The Comité is an informal organization of parallel trade associations of the Common Market countries and is concerned with the exchange of information,

particularly statistical information, and with the discussion of trade problems of mutual interest. Contact was also made with the Instrument Society of America and the Scientific Apparatus Manufacturers' Association of the United States of America.

In co-operation with the Board of Trade and the Central Office of Information, groups of members of S.I.M.A. took part in six exhibitions in Budapest, Sydney, Helsinki, Vienna, New York and Milan. Individual reports on these exhibitions are given in the January issue of *SIMA Review* (3, No. 1; 1963). A special effort was made during 1962 to expand the sales of instruments in Italy and to stimulate the interest of members of Italian universities, technical colleges and research establishments in British instruments.

Output and exports of instruments were again above the record level of 1961. The latest figures, up to November 1962, showed that exports were running at the rate of about 13 per cent greater than those for the similar period during 1961 and that they were expected to reach about 54 million pounds for the full year, representing a rise of 100 per cent since 1958. Particularly good progress was made by the Optical Instrument Section of the industry. Between 1958 and 1961 production of optical instruments rose by 33 per cent and exports during the past three years totalled some 30 per cent of the production, with the United States and Australia as the main markets.

Following a talk given by K. E. Morgan of the Department of Agriculture, University of Reading, at a meeting of the Electronics Section and Nucleonic Group of S.I.M.A., a number of firms interested in the promotion of the use of measurement and instrumentation in agriculture were formed into a new specialized group, the Agricultural Instrument Group, of S.I.M.A. Contact has been made with the Agricultural Research Council and with other Government bodies. In order to collaborate and maintain contact with the various organizations and projects for the development of new syllabuses for the teaching of physics and related equipment, a steering committee has been appointed by the Educational Instrument Group. Dr. D. S. Beard (Griffin and George Ltd.) is honorary secretary of both the Agricultural Instrument and the Educational Instrument Groups.

The eleventh annual convention of S.I.M.A. was held at Eastbourne during November 7–9, 1962. The theme was "Looking Ahead—The Next Five Years". The opening address was delivered by the president. Mr. R. Brech (Unilever Ltd.) spoke on "The Economic Outlook in the U.K. for the next five years", and divided his talk into an impressionist picture in which the opportunities which exist were outlined and a realistic picture in which the extent to which the opportunities could be seized and used effectively were described. He concluded by stating that the coming five years would be tougher than the previous five years, but that with confidence, marketing skills, good designs and good management Britain would be able to hold its own. Mr. M. Seaman (College of Advanced Technology, Loughborough) discussed education and training in his address on "Future Trends in Engineering and Production", and described some highly sophisticated developments in shipbuilding and their place in the shape of things to come. Following these two sessions the delegates split into three discussion groups to consider the implications of the talks from the points of view of administration and training, technology, and marketing. It was agreed that there was a tendency among many foreigners to regard the British as old-fashioned and stodgy, but it was felt that the 'British image' was not wholly bad, since it had a reputation for quality and integrity. There was a great need for a substantial increase in the availability of information about the reliability of components of all types, and attention was directed to the British Scientific Instrument Research Association survey on "Literature on Reliability". General concern was expressed at the form of education in secondary modern schools, where those who stayed for the further two years did not benefit from the extension. It was considered that the standard of teaching in schools needed improvement and that the teachers should be more alive to the needs of industry.

Three other addresses were given to the convention. Mr. E. G. C. Burt (Royal Aircraft Establishment, Farnborough) gave a review of instrumentation in space research, describing in particular the *Aeriel* satellites, the astronomical telescope satellite, and communications satellites. "Science and Everyday Life" was the title of Dr. G. Margerison's talk in which he surveyed some of the new fields in which instruments had started to be applied. He emphasized that great scope for improvement existed in the fields of agriculture, biology, transport and communications. Finally, Dr. E. Eastwood (English Electric Group) gave an instructive and entertaining evening discourse, illustrated by slides and film, on "Radar Observations on Bird Migration". A report of the convention is given in the January issue of the *Review* and a summary of the addresses and discussions forms an insert to the number.

The education and training of personnel for the instrument industry is of especial interest to S.I.M.A., and recently Mr. C. W. Robson, formerly vice-principal and head of the department of electrical engineering and applied physics at South-East London Technical College, was appointed educational adviser to the Association. He has since visited a number of member companies in connexion with their apprentice training schemes. The course on "Leadership in Instrument Design", which was inaugurated by a joint committee of the British Scientific Instrument Research Association and S.I.M.A. and planned by the Northampton College of Advanced Technology to commence in October 1962, attracted only two students. The course had failed because it was too long and necessitated the absence of senior technical personnel from their firms for a period of some twelve months.

The provision of a text-book on instrument design for student use has been met by the publication of *A Guide to Instrument Design**, sponsored by the British Scientific Instrument Research Association and S.I.M.A. The book, which has just been published, consists of a group of nine chapters, on varied topics and written by different authors, but which together form a pattern. The preferred method, sometimes called the project method, of carrying out the development of an instrument through its various stages from the initial idea to design studies, prototypes, costing and final production is the subject of Chapter 1, by Dr. J. Thomson (British Scientific Instrument Research Association). In Chapter 2, Prof. H. F. Trewman describes the fundamental limitations in instrument design. The theory of errors, kinematic design, transducers, noise, masers, computers and ergonomics are all, strange to say, dealt with in this chapter and it is difficult to see the connexion that Prof. Trewman wishes to make between them. However, an attempt is made towards the end of the chapter to emphasize the general principles by brief considerations of a few individual instruments. Mechanical design, the subject of Chapter 3 by G. Birkbeck (Mullard Research Laboratories), will appeal to engineers, as also Chapters 5 and 6, where electronic instrument design and nucleonic instrument technology are treated. These two chapters are remarkable for the almost complete absence of circuitry and for the amount of valuable information, largely omitted from the usual text-books, which they contain. Dr. W. T. Welford (Imperial College of Science and Technology, London) is well known as an able teacher

* *A Guide to Instrument Design. Produced by the Scientific Instrument Manufacturers' Association of Great Britain (SIMA) and the British Scientific Instrument Research Association (BSIRA).* Edited by the Staff of BSIRA. Pp. xii+444. (London: Taylor and Francis, Ltd., 1963.) 63*s*. net.

and writer on optics, and Chapter 4, which he contributes, is an outstandingly lucid and comprehensive manual on optical design. Within 130 pages, he clearly distinguishes between the three different types of optical instrument and lists their design parameters, and then describes in detail how the parameters may be determined for particular optical systems and how systems with given parameters may be designed from available light sources, optical materials and detectors. The chapter concludes with an extensive list of references to which the interested student may refer for additional study.

Two important but somewhat neglected topics are considered in Chapters 7 and 8. These are the reliability of instruments and intrinsic safety. Finally, since an instrument is a piece of equipment to be used, the concluding remarks in the brief six pages of Chapter 9 on integrated design are valuable because they serve to remind the designer that instruments should be such as the user will like to handle and which will give him the information he requires in the most easily assimilated manner.

The Association continues to receive a large number of enquiries from home and overseas, and the Enquiry Service has been dealing with an average of 400–450 a month. A new leaflet directing attention to the service is being prepared for distribution to members. The card index system used to answer enquiries has been brought up to date. The Publicity Committee has been concerned with the improvement of Press relations for the greater dissemination of information about the instrument industry, and arrangements have been made in conjunction with the Central Office of Information to commission a series of articles on new developments and applications in instrumentation. The articles will be offered in the language of the country to technical journals overseas and also to selected journals in the United Kingdom. Mrs. H. Conway was appointed Press relations officer in July 1962.

S. WEINTROUB

THE NEW YORK ACADEMY OF SCIENCES

THE 145th annual meeting of the New York Academy of Sciences was held on December 5, 1962, at 2 East 63 Street, New York. During the year ending October 31, 1962, considerable progress was made in the recovery of the Academy's financial status, both for improvement of its operating budget and for strengthening its investments. The increase in income permitted an extension of the budget for conference and publication costs, an increase from thirty-nine to fifty in the staff, and the establishment of a medical care and group life insurance scheme for the staff. The financial statements, together with the reports of the Chairman of the Board of Trustees, the Treasurer and the Recording Secretary, are published in the January issue of the *Transactions* of the Academy (25, 265; 1963).

The Sciences, the new publication of the Academy, which was established in 1961, has been brought up to date on its publishing schedule. Thirty-one issues of the booklet, totalling 496 pages, were published during the year under review. In the *Annals* thirty-eight monographs, comprising 6,206 pages, and containing 501 papers by 796 authors, were published. As from January 1963, the publication date of any conference monograph will be within fourteen weeks subsequent to a conference, provided the authors submit their manuscripts within two weeks of the conference. Beginning with Volume 25, the *Transactions* will also follow this schedule. The demand for conferences to be held by the Academy continues to grow and the number of papers independently presented for publication in the *Annals* is also increasing regularly each year. Consequently, the Scientific Council has decided that with the current year, 1963, members of the Academy may select up to twenty separate monographs listed each year, with the added privilege of purchase of any publications of the Academy at a 20 per cent discount.

During the year, eighty-five meetings were held by the various sections and divisions of the Academy. The section of Biological and Medical Sciences held a joint meeting during January 1962 with the Columbia University seminar on "Genetics and Evolution" and a joint symposium with the division of Microbiology during April. The division of Instrumentation held a series of eight symposia on "Electronics in the Medical Specialities", and the papers in this series will be published shortly as a monograph. Details of the twenty-two conferences held between November 1961 and October 1962 are listed in the annual report.

The membership had a net increase of 622 during the year, with a record total of 16,249 members in October 1962. A maximum of fifty candidates may now be nominated each year to the fellowship of the Academy. The following were elected officers for 1963: C. H. Mushett, president, Rev. J. J. Lynch, president-elect, and K. Maramorosch and C. C. Stock, vice-presidents of the Scientific Council; C. R. Noback, recording secretary, and R. F. Nigrelli, corresponding secretary.

The Academy consists of the sections of biological and medical sciences, chemical sciences, physical sciences, and planetary sciences, and the divisions of anthropology, instrumentation, microbiology, psychology, biochemistry, biophysics, engineering and mathematics. The sections and divisions meet regularly, one evening a month, during the academic year, October–May, inclusive, in the Academy's premises in New York. The conferences are held at irregular intervals.

UNIVERSITY EDUCATION IN INDIA

THE fourth annual Conference of Vice-Chancellors of the Indian universities and institutions 'deemed as universities' was held at New Delhi during October 11–13, 1962. The report of this Conference* includes the inaugural address of Dr. K. L. Shrimali, Minister of Education, Dr. D. S. Kothari's address on some aspects of university education, the address of the Prime Minister, Sri Jawaharlal Nehru, and the recommendations of the three Committees dealing with admissions, medium of instruction and related matters; service conditions of college and university teachers, and three-year degree courses; and contents of education and co-ordination of research. The most important feature of Dr. Shrimali's address is the stress laid on the medium of instruction. While any university or college will be completely free to continue to use English as a medium of instruction if it wishes, and use of English has been recommended as an alternative or associated medium by the National Integration Council, Dr. Shrimali is firmly convinced that unless

* India. University Grants Commission and Ministry of Education Vice-Chancellors' Conference, 1962. Pp. v+81. (New Delhi: University Grants Commission and Ministry of Education, 1963.) Rs. 2.00; 4*s.* 8*d.*; 0.72 dollars.

the universities adopt and develop their own Indian languages, India will not succeed either in the dissemination of knowledge among the Indian people or in the stimulation of research and the creation of new ideas. There was no desire to minimize the importance of the English language and for keeping abreast of science and technology; where knowledge of a foreign language was essential, English was particularly convenient in India. Dr. Shrimali also stressed the importance of the university's function to seek truth and to advance the frontiers of knowledge. This function of research gave substance to teaching and brought the student into contact with the process of discovery, and he welcomed the recent decision of the Indian University Grants Commission to meet the major part of expenditure on the establishment of schools of advanced studies at universities. He also thought it might be necessary to re-group or federate some existing departments in order to strengthen research.

Dr. D. S. Kothari, chairman of the Indian University Grants Commission, who also referred to the medium of instruction, insisted that it was important that the introduction of regional languages should not exclude the use of English in university life and work. More and more instruction would be through the medium of English as the undergraduate proceeded, but it was also important to produce books and literature, particularly scientific and technical, in the regional languages. Dr. Kothari suggested that the central problem in higher education in India was to raise standards and reduce wastage, and for this energetic steps to improve the quality and strength of the teaching staff, to make good books available at reasonable prices, and to provide reading seats in libraries and hostels were essential. As regards expansion, an increase was needed not so much in pure science as in medicine, engineering and especially in agriculture and veterinary science. Other matters which received attention at the Conference and were discussed briefly in this address included the shortage of teachers, staff appointments, assistance to outstanding teachers, standards of education, the establishment of new universities and centres of advanced study and collaboration between universities and other institutions.

Sri Jawaharlal Nehru also welcomed the use of regional languages as the medium of instruction, but emphasized the desirability of at least one other foreign language besides English if the student was to be in touch with modern thought. He insisted especially on the need to maintain quality, which should never be sacrificed to quantity, and finally referred to the importance of the scientist having some understanding of the humanities and of the non-scientist having some understanding of science.

FREEDOM FROM HUNGER CAMPAIGN: COMBATING DEFICIENCIES OF PROTEIN

MORE than a half the world's population lives in the Far East on a quarter of the total food produced. This is made up of only one-fifth of the world's animal and fish protein and less than one-half of land crops. In contrast to this, 29 per cent of the world's population living in Europe, Oceania and North America has available to it 57 per cent of total supplies, 69 per cent of animal and fish protein and 38 per cent of land crops. The situation in other less-developed regions is also unsatisfactory. These are among the broad conclusions reached in the *Third World Food Survey** recently published by the Food and Agriculture Organization, Rome.

So far as the position in Africa, the Near East and Latin America is concerned, the survey points out that these regions share of the total available food is approximately in proportion to their share of the world's population. It stresses, however, that diets there are low in all-important animal protein and the population is growing at a faster rate than food supplies.

The Food and Agriculture Organization's short-term targets for the developing regions provide for an increase of 5–6 g of animal protein to a total of 15 g per person per day, amounting to 22 per cent of total proteins. The long-term target is 21 g, which is equivalent to 28 per cent of the total.

In the preface to the survey, Mr. B. R. Sen, director-general states "If we are to achieve a reasonable improvement in the level of nutrition, then world food supplies will have to be increased by more than 50 per cent. . . . By the year 2000 it is expected that the world population will be at least double the present figure, while the population in the less-developed countries will have increased by 150 per cent. . . .

"These figures give some indication of the magnitude of the task confronting us, and indicate how timely and urgent is the Freedom from Hunger Campaign".

The annual report for 1961–62 of the Central Food Technological Research Institute of Mysore, India†, refers to a vigorous programme being pursued in the production and development of protein-rich foods. The Institute's work in this field, based on high-protein low-fat oil-seed meals which are plentiful in India, has been recognized by the joint Protein Advisory Group of the World Health Organization, the Food and Agriculture Organization and the United Nations International Children's Emergency Fund. This has led to the offer by the U.S. National Institutes of Health of the *PL* 480 funds for the intensification of work on vegetable protein supplements. The report summarizes the research carried out at the Institute in a large number of fields, including biochemistry and nutrition, engineering, processing and storage, infestation control, microbiology, sanitation and packaging.

APICULTURAL RESEARCH

AS research into bees and beekeeping has expanded and become progressively more scientific it has grown increasingly obvious that a new journal in English was needed for research work which was too technical for the popular beekeeping Press. The Bee Research Association has for some years past published *Bee World*, which contained a mixture of scientific and more popular articles, plus news items and the very valuable *Apicultural Abstracts*; but the Association has, however, recognized that a separate journal could usefully be devoted to scientific work alone. As a result it has now commenced the publication of the *Journal of Apicultural Research**.

* *Journal of Apicultural Research*, Vol. 1. (Southall, Middx.: Hon. Treasurer, Bee Research Association, 60 North Road, 1963.) 40*s*. per annum.

The new journal is edited by Dr. Eva Crane, director of the Bee Research Association, with Dr. James Simpson of the Bee Department at Rothamsted Experimental Station acting as associate editor. They are assisted by an international Editorial Advisory Board of nine members well known in different fields of bee research. The stated policy of the journal is to cover all aspects of subjects relating to bees (*Apis* and other bees), and also research on methods and equipment for the management of bees and their products. This is carried out satisfactorily in the first issue.

The general presentation of the journal is acceptable, since it has clear print and tables, and diagrams of a suitable size. All the papers in the first issue are concisely written, which perhaps emphasizes the impression that the proportion of short contributions is rather high. However, this might have been largely remedied if two of them (by W. P. Nye and M. W. Pedersen; and B. Furgala) had been placed in a separate section for preliminary reports, since the first gives rather inconclusive results of two experiments on the relationship between nectar sugar concentration and alfalfa pollination, while the second promises more data and a fuller discussion of the subject—the residual activity of fumagillin in relation to *Nosema* infections—in another paper. It is also a little difficult to see why two short papers by M. V. Smith have not been combined, although the editors may be following a policy of separating descriptions of apparatus from experimental work where possible. In this case, one paper is a report of experiments culminating in the successful transportation of honey-bee brood from Britain to the United States by air, with the object of importing new stock into the United States, and the other describes the portable incubator used for this purpose. Another minor point is that one wishes that some diagrams had been included in the very detailed and clear description of the pre-pupal and pupal ecdyses of the honey-bee by S. Cameron Jay, but no other matters concerning the actual presentation of this journal call for any comment.

As stated earlier, the scope of the first issue is wide, and the remaining papers cover the genetics, behaviour and biology of bees, and the antibactericidal properties of honey. The latter paper is a brief one by D. Adcock on the destructive effect of catalase on the "inhibine" and peroxide values of various honeys. J. Woyke has a paper on the hatchability of "lethal" eggs of honey-bees, in which he reports fairly normal hatching rates in these eggs but rapid removal of the young larvæ by the workers. There is a very useful description of a controlled environment flight room for the study of behaviour inside and outside the hive, together with records for pollen collecting activities in the room at different light intensities (W. P. Nye). J. B. Free shows that geraniol, although it is the principal volatile constituent of honey-bee scent gland secretion, is not nearly so attractive as scent-gland odour itself, and therefore concludes that the attractiveness of the latter depends partly on other constituents.

In a paper describing the events following construction of the queen cell in honey-bee colonies N. E. Gary and R. A. Morse give results demonstrating the extreme variability which exists in the rearing and replacement of queens; it is apparent that swarming or supersedure does not necessarily follow queen rearing. The longest paper is by Cécile Plateaux-Quénu on the biology of *Halictus marginatus*, which she claims to have a type of social organization previously unknown in insects. Workers and queen are morphologically indistinguishable, and both are capable of mating, although for most of the developmental cycle of the colony (5–6 years) they have no contact with the males. Various aspects of social life in this bee are considered, and although more numerical data could have been desired, it is an interesting description.

In conclusion, it can be said that the first issue of the *Journal of Apicultural Research* augurs well for the future, and that, once it has become properly established, it should be a valuable publication.

M. Delia Allen

SPECTROGRAPHIC ANALYSIS AS AN AID TO DIESEL ENGINE MAINTENANCE

THE replacement of the steam engine as the traditional motive power by Diesel locomotives has now become familiar on British Railways, and in fact in many other countries this transition is all but complete. The economic arguments in favour of this change are that the Diesel unit offers to the railways greater efficiency, lower fuel costs and greater availability. Technically these advantages may to some extent be offset by the much greater complexity of the Diesel as compared with the steam locomotive, and problems of maintenance of the complicated machinery involved in the oil-driven engines are constantly arising. The risk of accidental damage to Diesel mechanisms, involving sudden breakdowns with their attendant disruption of operating railway schedules, equally heavy repair costs, is very real. One way of control in prevention of these contingencies has been found by routine spectrographic analysis of Diesel engine crankcase oil. An informative account of this procedure is contained in the well-designed house organ of the British Petroleum Co., *B.P. Magazine* (No. 8; 1963), in an illustrated article by J. K. Lock and P. R. Mason, respectively, of the lubricants and analytical sections of the B.P. Research Centre, Sunbury-on-Thames, where such spectrographic facilities are available as are similarly developed at the Company's Centre at Melbourne, Australia.

As with other internal combustion engines, normal wear in a Diesel engine over a period of time occasions entrance in the crankcase oil charge of minute metal particles. In this case, however, there is little if any sedimentation or sludge as ordinarily understood; the metal particles are so small that they are measured in parts per million; conventional methods of chemical analysis are not applicable to their identification because of their low concentration. In such cases spectrographic technique supplies the answer. "If regular samples of the crankcase oil charge are taken and analysed for these metal contents, a normal pattern of wear can be recognized for any one engine, performing a specified duty. If, however, a fault develops in the engine that causes an increase in wear, this pattern of wear is disturbed and can be recognized at an early date." The authors continue: ". . . the value of the service is that it permits small faults to be recognized and rectified, whereas if these faults were allowed to progress without rectification, serious damage and an expensive repair bill might ensue". Normally, nine elements are determined spectrographically in these crankcase oils: iron, copper, lead, tin, silicon, chromium, boron, aluminium and silver. The significance of the determination of each of these elements in the oil and their interpretation in terms of Diesel engine wear and tear constitute an expert enquiry. This article conveys impressively the substance of the technique involved.

H. B. Milner

EVIDENCE FOR A HUMORAL THYMUS FACTOR RESPONSIBLE FOR THE MATURATION OF IMMUNOLOGICAL FACULTY

By Dr. DAVID OSOBA* and Dr. J. F. A. P. MILLER

Chester Beatty Research Institute, Institute of Cancer Research: Royal Cancer Hospital, Fulham Road, London, S.W.3

MICE thymectomized within 24 h of birth show a marked deficiency in the lymphoid cell population of their blood and tissues, a diminished capacity to produce circulating antibodies in response to some antigens and a severe impairment of homograft immunity[1,2]. All these effects can be prevented by grafting subcutaneously whole intact neonatal thymus within several days of thymectomy[1]. They cannot, however, be prevented by a single intravenous injection of a suspension of dissociated neonatal thymus cells given within a day of thymectomy[3]. It would appear, therefore, that the whole thymus architecture is an essential part of the restorative system under these conditions. The mechanism by which the thymus ensures the development of the immune apparatus is not clear. The thymus could act either by providing the environment in which differentiation and multiplication of cells with immunological potential can take place, or by providing a non-cellular factor which enables lymphoid precursor cells pre-existing in the peripheral lymphoid organs to attain immunological competence.

Up to the present time, there is no direct, unequivocal evidence to show that cells leave the thymus to populate the lymphoid tissues. There is, however, some indirect evidence which suggests such a migration. The first site of lymphocyte production in the embryo is the thymus and only later do lymphocytes appear in other organs[4]. Mitotic activity of lymphoid cells during embryogenesis is high in the thymus but minimal or absent in peripheral lymphoid tissues. It becomes evident in these tissues only after birth, presumably as a result of antigenic stimulation. Auerbach[5], using elegant tissue culture techniques, showed that a suspension of 14-day-old embryonic spleen cells could aggregate to form follicles and small lymphocytes *in vitro* only in the presence of embryonic thymus cells. When the embryonic spleen cells were separated from the thymus cells by a millipore barrier, follicle formation did not occur.

Experiments using chromosome marker techniques in adult irradiated mice given syngeneic marrow gave results which showed "that the re-formation of lymphoid elements occurs sooner in the thymus than in the lymph nodes" thus suggesting that "the thymus continues to seed the other lymphoid tissues"[6]. Experiments performed in this laboratory showed that the majority of cells multiplying in subcutaneous thymus grafts and lymphoid organs of neonatally thymectomized mice were of host type and could not, therefore, be descendants of donor thymus cells[3]. The cells populating the lymphoid tissues of the thymectomized hosts could have been derived either from cells which differentiated in the thymus graft, or from precursors which differentiated in the lymphoid tissues as a result of a humoral factor elaborated by the graft. In support of the humoral theory, the work of Metcalf can be cited[7]. He isolated a factor from the thymus which, when injected into new-born mice, produced a temporary lymphocytosis in the peripheral blood. In this laboratory, non-cellular saline extracts of neonatal thymus tissue were not effective in restoring lymphocyte counts and homograft immunity in neonatally thymectomized mice[3]. The experiments recorded here were designed to test the hypothesis that a humoral factor from the thymus may play a part in the development of the immune mechanism.

At seven days of age neonatally thymectomized (*CBA* × *T6*)F_1 mice were intraperitoneally implanted with 'Millipore' diffusion chambers (pore diameter of 0·3μ) containing either one lobe of new-born or one to three lobes of 14-day embryonic *CBA* thymus tissue. Control groups consisted of neonatally thymectomized mice which either received no further treatment or which were implanted with empty diffusion chambers, and of mice found to be only partially thymectomized at the end of the experiment. Peripheral lymphocyte counts were done on all mice between the sixth and twelfth weeks of age. The capacity to reject homografts was tested by *AK* skin grafts when the mice were six to eight weeks old. Ten days following skin grafting the protective dressings were removed and the graft site was examined daily for signs of rejection. All mice were autopsied and the retrosternal area examined histologically for thymus remnants. The spleen, lymph nodes, Peyer's patches and diffusion chambers were fixed in Bouin's solution. The lymphoid tissues from some of the mice were subjected to chromosomal analysis.

The results of challenge with homografts are presented in Table 1. The majority of mice (18 out of 26) bearing either neonatal or embryonic thymus tissue rejected homografts within 25 days. In this respect there was no significant difference between mice with neonatal thymus (9 out of 14) and those with embryonic thymus (9 out of 12). None of the 13 thymectomized control mice rejected homografts within 25 days. Whereas only 7 of the 26 mice bearing diffusion chambers with thymus tissue retained homografts for more than 40 days, 12 of the 13 thymectomized control mice retained skin grafts for periods exceeding 40 days. No difference was evident in the inability of thymectomized mice bearing empty diffusion chambers to reject skin grafts (6 out of 7) as compared with mice subjected only to neonatal thymectomy (6 out of 6). Mice which were only partially thymectomized had the capacity to reject homografts and therefore behaved as intact non-thymectomized mice.

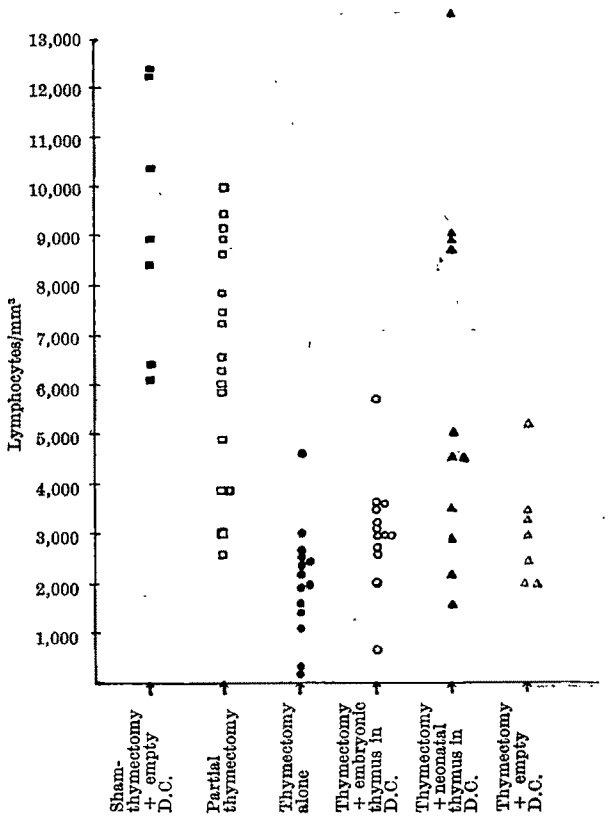
Table 1. SURVIVAL OF HOMOGRAFTS IN (*CBA* × *T6*)F_1 MICE THYMECTOMIZED AT BIRTH AND BEARING *CBA* THYMUSES IN 'MILLIPORE' DIFFUSION CHAMBERS (D.C.)

Treatment	No. of mice	No. of mice with following survival time (days) of *AK* skin graft			
		< 25	25–40	40–60	> 60
None	11	11	0	0	0
Partial thymectomy	15	13	2	0	0
Thymectomy at birth	6	0	0	1	5
Thymectomy at birth; empty D.C.	7	0	1	2	4
Thymectomy at birth; embryonic thymus in D.C.	14	9	0	4	1
Thymectomy at birth; neonatal thymus in D.C.	12	9	1	0	2

The peripheral lymphocyte counts are shown in Fig. 1. The findings may be summarized by stating that all mice which were subjected to neonatal thymectomy, regardless of their subsequent treatment, showed in general significantly depressed lymphocyte counts with the exception that some of the mice bearing diffusion chambers containing neonatal thymus tissue had normal counts. A few partially thymectomized mice had sub-normal counts.

Histological examination of the lymph nodes of mice with thymus tissue in diffusion chambers showed in some cases islands rich in lymphocytes scattered in the cortex[8].

* Fellow of the Canadian Cancer Society. Present address: Department of Hæmatology, Vancouver General Hospital, Vancouver 9, Canada.



In general, however, there was still evidence of lymphocyte depletion in most lymphoid tissues and therefore no marked difference in comparison with the findings in the control thymectomized mice.

The tissue recovered from the diffusion chambers did not contain any recognizable lymphoid tissue and consisted only of epithelial and reticular cells[8] (Fig. 2) occurring either in clumps or scattered singly in a loose bed of fibrous tissue. In some cases structures resembling acini lined by epithelial cells and containing material which stained positively with periodic acid–Schiff reagent were present. At no time was there any direct histological evidence of cells traversing the chamber walls.

All the host lymphoid cells which were subjected to chromosomal analysis were found to contain the *T*6 chromosome.

The results presented here show that mice bearing embryonic or neonatal thymus tissue enclosed in diffusion chambers have the capacity for rejecting skin homografts. It might be possible to explain these results by: (1) cell leakage from the diffusion chamber; (2) incomplete thymectomy; (3) adjuvant effect of the diffusion chamber; or (4) elaboration of a humoral factor from the enclosed tissue. Passage of cells through the 'Millipore' barrier is unlikely to have taken place because: (1) cytological studies failed to show the presence of any donor cells in the host lymphoid tissues; (2) no lymphoid cells were found in the tissue in the chamber. If cells had gained access to the chamber, one might have expected, by analogy with studies on subcutaneous thymus implants, that these cells would have re-populated the thymus epithelial-reticular framework.

Incomplete thymectomy cannot account for the results obtained in the experimental group since only mice, afterwards found by histological examination to be completely thymectomized, were included in the results in this group. Thymectomized mice bearing empty

(Thymectomy performed at birth; diffusion chamber (D.C.) inserted intraperitoneally at 7 days)

Fig. 1. Absolute lymphocyte levels in 6- to 12-week-old mice thymectomized at birth and bearing thymuses enclosed in 'Millipore' diffusion chambers

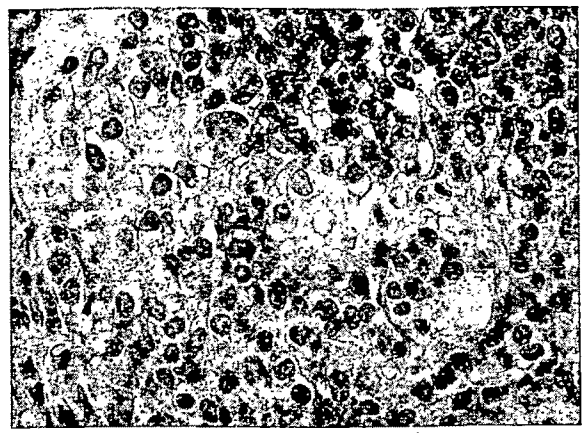


Fig. 2. Fourteen-day-old embryonic thymus enclosed for 6 weeks in diffusion chamber in neonatally thymectomized mouse. Note epithelial-reticular cells and absence of lymphocytes (× *c.* 337)

diffusion chambers were found to behave as mice subjected to neonatal thymectomy alone. This showed that the 'Millipore' material itself had no role in the establishment of homograft immunity.

The lymphocyte population of neonatally thymectomized mice bearing thymus tissue enclosed in diffusion chambers was in most cases not significantly different from that of control thymectomized mice. It seems, therefore, that the capacity of mice to reject homografts is not dependent on the quantity of lymphocytes present in the animal. This is supported by experiments on mice thymectomized in adult life: these mice show permanent depletion of the lymphoid cell population but no impairment of homograft immunity even as late as 100 days after thymectomy[9].

The absence of lymphoid cells in the tissue enclosed in the diffusion chambers[8] suggests that the persisting epithelial-reticular framework of the thymus is the functional factor responsible for equipping the mice with the capacity for rejecting homografts. It would appear therefore that, under the conditions of the present experiments, epithelial-reticular cells elaborate a humoral factor which enables host lymphoid cells to become immunologically competent cells. Whether such a factor plays a part in normal development remains to be determined. Further work is clearly required to characterize this influence and determine its mode of action.

We thank Prof. Alexander Haddow for his interest in this work, and to Miss Barbara Burnett and Miss Winifred House for assistance. The investigations were supported by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council, the British Empire Cancer Campaign, the Anna Fuller Fund and the National Cancer Institute of the National Institutes of Health, U.S. Public Health Service. They also received special support through a grant from the Tobacco Manufacturers Standing Committee.

INHIBITORY SYNAPSES ON SOMAS OF PURKINJE CELLS IN THE CEREBELLUM

By Dr. P. ANDERSEN, Sir JOHN ECCLES, F.R.S., and Dr. P. E. VOORHOEVE
Department of Physiology, Australian National University, Canberra

IN the hippocampal cortex a very powerful postsynaptic inhibition is produced by synapses concentrated on the somas of the pyramidal cells; hence it has been concluded that these synapses belong to the basket cells, which have extensive axon ramifications that terminate exclusively on the cell bodies of the pyramidal cells[1]. Optimal conditions for the inhibitory control of cell firing are secured by location of inhibitory synapses on the cell soma, so it was suggested that this localization may be a general feature of synaptic organization in the central nervous system. The basket cells of the cerebellum provide a most remarkable concentration of synapses on the soma and axon hillock of Purkinje cells[2–5]. We have therefore chosen the Purkinje cell (*P*-cell) for our first investigation into the general proposition that the synapses responsible for postsynaptic inhibition are localized on the somas of neurones. Granit and Phillips[6] have referred to the occasional presence of spontaneous hyperpolarizing responses of Purkinje cells.

Fig. 1 is a simplified diagrammatic representation of the most important cellular elements in the cerebellar cortex and of the electrode arrangements used in the present study. The afferent mossy fibres (*mf*) synapse with the granule cells (*G*) which send their axons vertically into the molecular layer, where by a *T*-shaped junction each fibre divides into two branches which are called parallel fibres (*pf*) because they course strictly parallel to the surface of the folium for at least 1·5 mm in each direction; during this traject they penetrate a large number of *P*-cell dendritic trees all of which are oriented in a plane transverse to the long axis of the folium. The *P*-cell axons (*Pa*) represent the efferent link from the cerebellar cortex. Each of them has a number of recurrent collaterals said to end on the soma and initial dendrites of other *P*-cells[2,3,7]. In the lower part of the molecular layer there are a number of special cells, the so-called basket cells (*B*). These have extensive axon ramifications (*Ba*) that run largely transverse to the long axis of the folium and just above the *P*-cell layer. Numerous branches form basket-like plexuses around the somas of the *P*-cells, especially at the axonal poles, hence the name. The vast majority of synapses on the lower part of the somas of *P*-cells do, therefore, belong to the basket cell axons.

The *P*-cells have been excited in two ways, as indicated in Fig. 1, either by local stimulation exciting parallel fibres[8] or by antidromic activation through a concentric needle electrode[6]. Recordings were made by micro-electrodes filled with 4 M sodium chloride or 3 M potassium chloride or 2 M potassium citrate. The cerebellar cortex is extremely sensitive to mechanical or circulatory damage. By covering the surface with 4 per cent solution of agar in Ringer–Locke after the electrodes were positioned, the respiratory and circulatory movements of the cortex were controlled when the agar jelly had set. When agar covered, the cerebellar cortex remained in good condition for many hours. The microelectrode can be withdrawn and re-inserted through the agar gel.

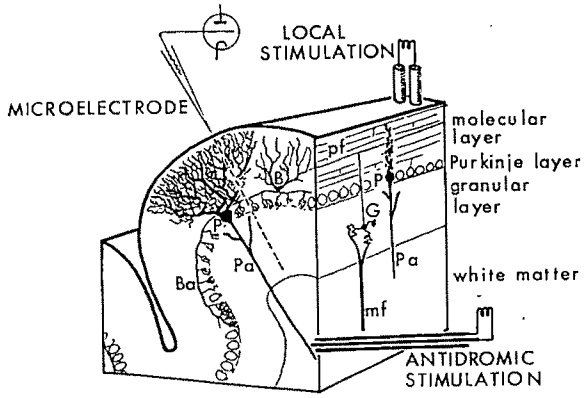

Fig. 1. Diagrammatic representation of cerebellar cortex with the electrode arrangement

When the depth of micro-electrode penetration was 0·3–0·4 mm, it frequently impaled nerve cells as shown by the recording of a resting potential, of repetitive spike potentials in the positive direction and of synaptic potentials. Usually these responses indicated extensive cell damage and there was rapid deterioration. However, resting potentials greater than −40 mV and large synaptic potentials have been recorded from several cells for a sufficiently long time to allow a discriminative investigation. Since the intracellular recording was always at the depth of the somas of the Purkinje cells, and since the intracellular responses conformed to a standard pattern, including antidromic invasion, it may be concluded that in fact our intracellular recording was restricted to Purkinje cells.

As shown in Fig. 2*A*, a weak local stimulation of a folium evoked, after a latency of about 4 msec, a prolonged hyperpolarization that had a rising phase of more than 10 msec and a total duration much in excess of 100 msec. In Fig. 2*B* there are two superimposed traces, the one set up by the stronger stimulation showing an additional depolarization with a latency about 1 msec briefer than for the hyperpolarization. These potentials correspond in every respect to excitatory and inhibitory postsynaptic potentials (EPSP's and IPSP's). The IPSP had the standard properties: reversal to a depolarizing response when a sufficiently strong hyperpolarizing current was passed out of the microelectrode; large increase during the passage of a depolarizing current; reversal to a depolarizing potential when Cl^- ions were injected out of a recording electrode filled with 3 M potassium chloride. Local stimulation produced these large and prolonged IPSP's in every *P*-cell from which we have recorded. In contrast, antidromic activation of *P*-cells by the stimulation as in Fig. 1 did not produce IPSP's, though with strong stimulation IPSP's were produced, presumably in response to the stimulation of the mossy fibres with serial synaptic activation of granule cells and basket cells.

The inhibitory action of the prolonged IPSP is illustrated in Fig. 2*C*, where the spontaneous rhythmic discharges of *P*-cells are inhibited for as long as 800 msec by the same surface stimulation of the folium that evokes the IPSP's. This powerful and prolonged inhibitory action on spontaneous discharges of a *P*-cell has invariably been produced by a surface stimulus that excited the parallel fibres projecting towards that *P*-cell.

The organization of the *P*-cells of the cerebellum gives ideal conditions for investigation of the location of synaptic action on them. The somas are arranged in a single layer parallel to the surface of the folium (Fig. 1) and are essentially bipolar with the dendritic trees projecting from one pole up to the surface and the axon from the other pole into the depths of the folium (Fig. 2*G*). In Fig. 2*D*, *E* are shown typical series of potentials recorded at the indicated depths along a microelectrode track and evoked by a weak (30 V) and a strong (50 V) local stimula-

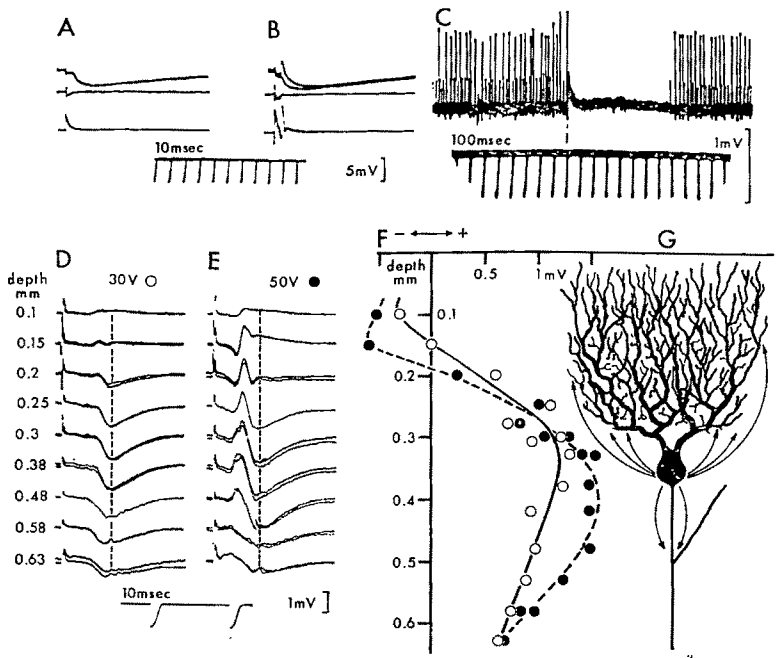

Fig. 2. *A*, *B*, Intracellularly recorded IPSP and EPSP from a Purkinje cell (*P* cell) in response to local stimulation; *C*, inhibition of the spontaneous discharges of two *P*-cells due to a single local stimulus; *D* and *E* show extracellular potentials evoked by local stimulation of 30 and 50 V and recorded at the indicated depths below the surface of the folium; *F*, plotting of measurements from *D* and *E* as described in text; *G*, diagram of a *P*-cell with current flow indicated by arrows

tion. The weak stimulation was remarkable in that it showed the development and the decline of an almost pure positive potential with progressive penetration. With the stronger stimulation there was at depths of 0·1–0·5 mm also an earlier negative response that overlapped with the onset of the positive potential. A trace of this negativity can be seen also with superficial records at the weak stimulation.

In order to obtain measurements of the field potential produced by the positive component relatively uncontaminated by this earlier negative component, measurements have been made at 6·7 and 5·7 msec after the stimulation at the stippled lines in *D* and *E*, respectively, and are plotted in Fig. 2*F*. The positive wave is seen to reach a maximum at a depth of 0·35–0·4 mm with both strengths of stimulation; and more superficially it rapidly diminishes and reverses to a surface negativity, which can be recognized as a distinct component following the initial surface negativity in Fig. 2*D*, *E* at depths of 0·1 and 0·15 mm. Beyond 0·4 mm the positive wave also declines, but much less rapidly, and no reversal is seen. The curves of Fig. 2*F* show that current is flowing outwards from the region of the somas of the *P*-cells very intensely up towards the dendrites all the way to the surface, and very weakly in the reverse direction towards the axon, as shown by the arrows in Fig. 2*G*. This is precisely the extrinsic current that would be generated by an inhibitory synaptic action concentrated on the *P*-cell somas. It cannot be due to depolarizing synaptic action on the *P*-cell dendrites, because in that case intracellular recording from the somas must give a depolarizing potential due to electrotonic spread of the EPSP, and not the hyperpolarization that is invariably observed.

From these various experimental investigations it may be concluded that powerful postsynaptic inhibition is exerted on the somas of the Purkinje cells. Since this is observed in all successfully impaled cells, there must be a concentration of inhibitory synapses on the somas of *P*-cells. Evidently the basket cells are the cells responsible for mediating this inhibitory action. This identification is further supported by the finding that stimulation of the folium may produce an inhibition virtually uncontaminated by a preliminary excitation of *P*-cells if it is off the direct line of parallel fibres to the recording electrode, which was the case with the weaker stimulation in Fig. 2*D*. Under these conditions the inhibition must be produced by mediation of interneurones having axons transverse to the folium, which is the case with basket cells. The parallel fibres traverse the dendritic trees of the basket cells as well as the *P*-cells, and probably synaptically excite both. This would explain the difference in latency of only about 1 msec between the EPSP's and the IPSP's (Fig. 2*B*).

In conclusion, the site of inhibitory synaptic action has been determined for Purkinje cells of the cerebellar cortex. Since the inhibitory synapses are concentrated on the somas, they must belong to the histologically identifiable basket cell, exactly as in the hippocampal cortex. However, this inhibition is not due to recurrent axon collaterals of *P*-cells, since antidromic stimulation of *P*-cell axons failed to give postsynaptic inhibitory potentials in spite of readily demonstrable antidromic invasion into the cell bodies of large numbers of *P*-cells. Taken together with the situation in the hippocampal cortex, the somatic location of inhibitory synapses may well be a generally occurring pattern, as proposed earlier[1]. An additional parallel between the basket cells of the hippocampus and the cerebellum is that synapses of both have the characteristics of synapses that Gray[9] designated Type 2 (refs. 10 and 11). This leads to the further suggestion that all postsynaptic inhibitory synapses may be of Type 2. [See also p. 699 of this issue of *Nature*.]

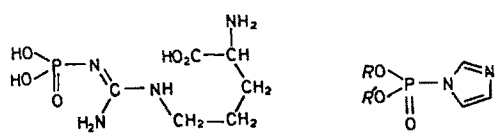
WHY DO PHOSPHAGENS FUNCTION AS PHOSPHORYL-TRANSFER REAGENTS?

By Dr. V. M. CLARK and S. G. WARREN

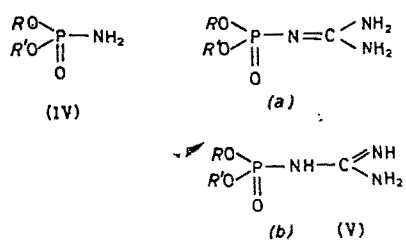


University Chemical Laboratory, Cambridge

N-Phosphoryl-creatine (I) was isolated from muscle by Fiske and SubbaRow[1] in 1927. Measurement of its heat of hydrolysis[2] led Lipmann[3], in 1941, to classify it as an 'energy-rich' phosphate, and its role in the formation of ATP from ADP (equation (1)) in muscle contraction[4] seemed to confirm this view.

(I) ....(1)

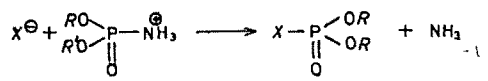
At approximately the same time, phosphoryl derivatives of other substituted guanidines, for example, *N*-phosphoroarginine (II), were identified as participants, with the adenine nucleotides, in phosphoryl transfer reactions and the term 'phosphagen' was applied to the group of naturally occurring phosphoroguanidates[5,6].



(II) (III)

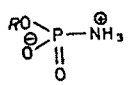
The transfer of a phosphoryl residue from a phosphoroguanidate (for example, I or II) requires cleavage of the phosphorus-nitrogen bond. Such a cleavage is known to be facile with the phosphoramidates (the simplest P—N system, for example, IV) and using this route ATP has been synthesized from ADP[7]; further development of this reaction has resulted in a highly flexible method of pyrophosphate synthesis[8,9].

A molecular system somewhat closer in structure to that of the phosphoroguanidates is to be found in the phosphoroimidazole (III) and this has been shown to be a powerful phosphorylating agent[10,11].



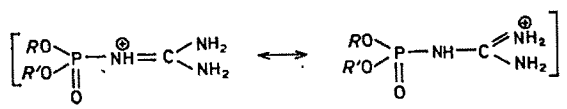
However, *in vitro*, a variety of phosphoroguanidates has failed to function as phosphorylating agents under conditions comparable with those used with the simple phosphoramidates[12].

The marked difference in lability between the phosphoramidate (IV) and the phosphoroguanidate (V: *a* or *b*) can be attributed to the nature of the P—N bond in the two series.



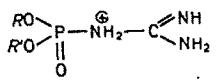
(IV) (a) (b) (V)

In (IV) the P—N bond order is enhanced by overlap of the orbital of nitrogen—occupied by the lone pair of electrons —with the *d* orbitals of the phosphorus atom. Thus, phosphoramidates, unlike carboxylic acid amides, are stable to caustic alkali, and, indeed, diphenyl phosphoramidate (IV : $R=R'=$Ph) is smoothly converted by caustic soda to the sodium salt of the acid (IV : $R=R'=$H) without cleavage of the P—N link[13]. On the other hand, protonation of the nitrogen atom removes this $p\pi-d\pi$ overlap and enhances the possibility of nucleophilic attack at phosphorus[14], providing, concurrently, a good leaving group, namely, the neutral ammonia molecule (equation 2). In consequence, phosphoramidates are



.. (2)

unstable under acidic conditions and can, for example, be converted to phosphorochloridates on treatment with gaseous hydrogen chloride ($X=$Cl)[15]. Moreover, in virtue of tautomerism to the zwitterionic structure (VI), phosphoramidic monoesters (IV : $R=C_6H_5.CH_2$, $R'=$H) are good phosphorylating agents[7,16].

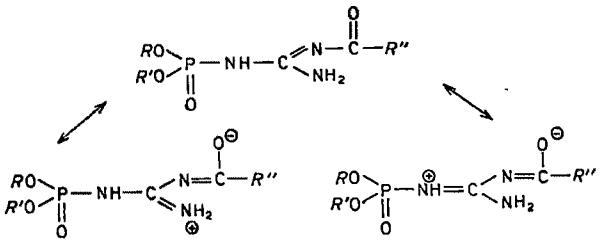


(VI)

Phosphoroguanidates present a more complicated picture, since at least two prototropic forms (V: *a* and *b*) are possible. In (V*a*) each of the two nitrogen atoms not attached to phosphorus has a lone pair of electrons which, on protonation of the nitrogen atom of the P—N bond, can facilitate the delocalization of the positive charge, as expressed in (VII): such delocalization inhibits the displacement reaction indicated in equation (2). On

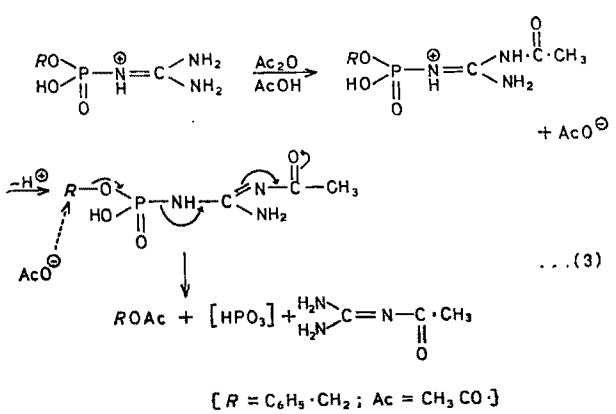
(VII)

the other hand, protonation of (V*b*) could yield (VIII),



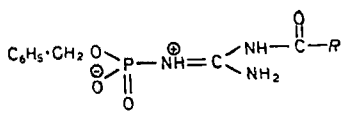
(VIII)

which would undoubtedly behave as a phosphorylating agent in accordance with equation (2).



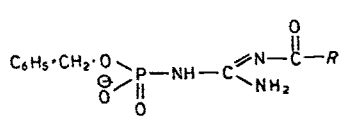
Our infra-red and nuclear magnetic resonance evidence shows that the normal esters of phosphoroguanidic acid have structures consonant with (V*a*). Their stability is not, therefore, unexpected. Structure (V*b*) is related to the phosphoroimidazole (III), which is highly reactive[10]. Thus, it seems likely that a phosphagen might be activated, *in vivo*, by a tautomeric shift of the type (V*a*→V*b*).

The sharp distinction between the chemical and biochemical lability of the phosphagens has led us to search for a structural modification which would convert Va to Vb. Acylation of one of the nitrogen atoms not attached to phosphorus could provide such a mode of activation since delocalization of electrons in the carboxylic amide group, for example (in IX), would militate strongly against the electronic distribution expressed in formula (VI).



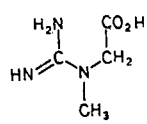
(IX)

Accordingly, a solution of benzyl hydrogen phosphoroguanidate (Va: $R=C_6H_5.CH_2$; $R'=H$) in a (1 : 1) acetic acid/acetic anhydride mixture was heated at 80° C for 2 h. Chromatography of the resultant solution revealed the presence of inorganic ortho-, pyro-, and trimetaphosphate (products of a hypothetical metaphosphate[17]), presumably formed in accordance with equation (3).

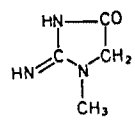


[$R = C_6H_5 \cdot CH_2$; Ac = CH_3CO·]

The dibenzyl ester (Va : $R=R'=C_6H_5.CH_2$) was (i) acetylated, and (ii) benzoylated, and in each case converted to the mono-benzyl ester by debenzylation in hydrochloric acid[12]. Infra-red and nuclear magnetic resonance spectra showed that, in both cases, the product possessed the structure (X : $R=CH_3$, or C_6H_5): however, in basic solution the ultra-violet spectrum[19] indicated that a proton had been removed to give (XI).



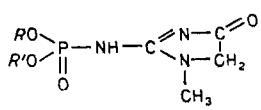
(X)



(XI)

In pyridine solution (XI) reacted to give a symmetrical product, namely, the $P^1 : P^2$ dibenzyl pyrophosphate dianion (cf. refs. 7 and 16).

In the phosphagens, a common structural feature is the presence of an additional acidic function attached directly to the carbon skeleton, for example, the carboxyl group in *N*-phosphoryl-creatine (I) and in *N*-phosphoryl arginine (II), the sulphonic acid residue in *N*-phosphorotaurocyamine[6], and the second phosphate residue in *N*-phosphoro-lombricine[6]. The remarkable increase in lability of the P—N link *in vivo* might then be ascribed to the further acylation of the guanidino-residue by this second acidic group. The cyclic form of one of these examples, namely (I), is well known. Creatine (XII) gives rise to creatinine (XIII) under just those conditions in which (I) is labile[20] (under acidic conditions *N*-phosphoryl creatine is hydrolysed 30 times faster than *N*-phosphoryl guanidine[21]), and in 0·1 N hydrochloric acid the

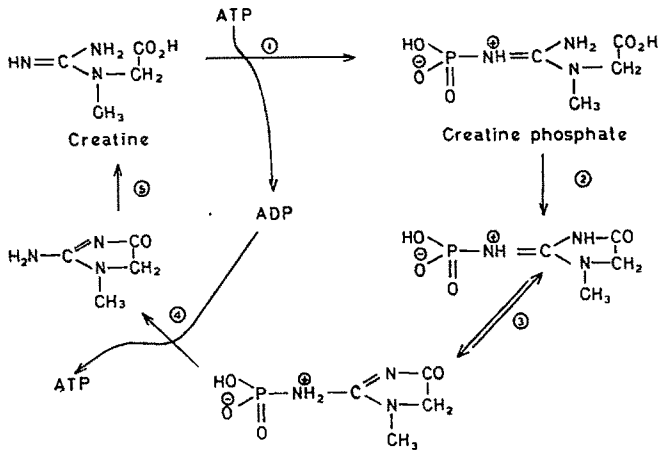


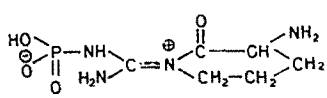
(XII)

(XIII)

cyclic form (XIII) is favoured to the extent of 96–97 per cent at equilibrium[22]. Moreover, *in vitro* hydrolysis of (I) appears[23] to give creatinine.

In order to test this hypothesis *N*-dibenzyl phosphoro-creatinine[24] (XIV : $R=R'=C_6H_5.CH_2$) was synthesized and monodebenzylated with hydrochloric acid to give the ester (XIV : $R=C_6H_5.CH_2$: $R'=H$). Both the mono- and the di-ester were phosphorylating agents undergoing reactions analogous to those of the acyclic acylated phosphoroguanidates (for example, IX and XI).

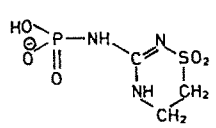




(XIV)

The experiments reported here lead us to propose a pathway for the ATP-creatine phosphotransferase catalysed reaction (Fig. 1) which can serve in a variety of organisms by the replacement of the *N*-phosphoryl creatinine by the cyclic compounds XV–XVII (cf. ref 6). The enzyme must hydrolyse the creatinine (XIII) formed in consequence of the phosphorylation of ADP, since rephosphorylation of the guanidinium moiety cannot be accomplished until the nucleophilicity of the guanidinium residue is restored by deacylation. Such a step would account for the absence of free creatinine in such systems (creatinine formation during *in vivo* phosphorylation has been reported[25] but this evidence may be discounted in the light of later reports[26]), the 'back reaction' being incomplete prior to the final hydrolysis to creatine.

The enzyme catalysing the transfer of a phosphoryl group from (I) to ADP is well known[27] and has been crystallized[28]. The phosphoryl transfer is known to be direct, that is, without any phosphorylated enzyme intermediate[29,30] and it requires at least one metal ion[31] (magnesium, manganese or calcium) bound to a phosphate group or groups in the nucleotide[32].



These biochemical data have led to considerable speculation[6,30,33] on the possible rôle (or rôles) of the phosphagens *in vivo*, but, thus far, no consideration has been given to the problem of the chemical stability of the phosphoroguanidates. The mode of action we suggest is in agreement with all the known data (and requires the features of general acid and general base catalysis already observed[34]). It accounts for the fact that the reaction can occur at all and also for the *in vivo* production of creatinine at a rate greater than that which could be accounted for by the cyclization of creatine itself[35].

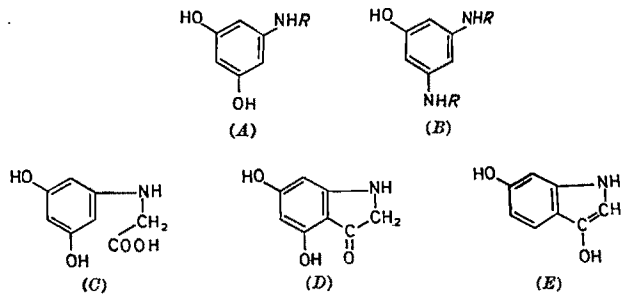
NON-ENZYMATIC BROWNING: BROWNING OF PHENOLS AND ITS INHIBITION BY SULPHUR DIOXIDE

By H. S. BURTON, Dr. D. J. McWEENY and P. N. PANDHI

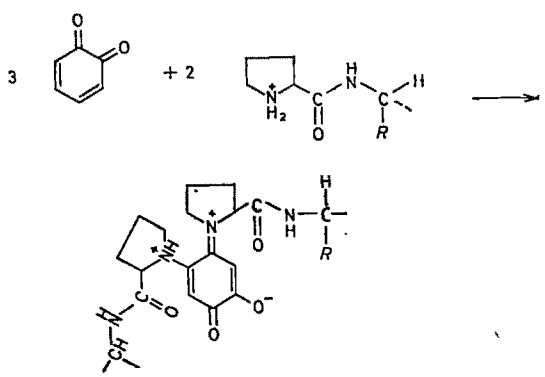


Food Science and Plant Health Division, Ministry of Agriculture, Fisheries and Food, London, S.W.1

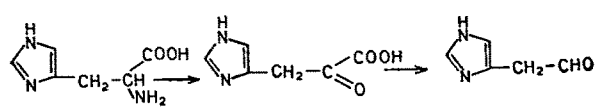
THE main pathway to non-enzymatic browning seems to begin with the reaction between carbonyl and amino groups to give an unsaturated carbonyl/amino derivative.

Most natural substances contain phenolic compounds, and some polyphenols enter into reactions leading to discoloration and, it is claimed, into melanin formation. It is known that sulphur dioxide and sulphites react with polyphenols; these sulphur compounds also retard the development of colour in sugar/amino compound systems and in phosphatide/amino systems, where the initial reactions are of the carbonyl/amino type.

Rinderknecht and Jurd[1] reported that polyphenols combine with amino-acids in aqueous solution at low temperatures to give a yellow colour. The colour was obtained on heating phloroglucinol with glycine, whereas catechol, resorcinol, eriodictyol and quercetin did not give the colour. It therefore appeared that all three hydroxyls must be free, as in phloroglucinol, for this type of reaction, since both quercetin and eriodictyol contain a combined phloroglucinol nucleus. In support of this contention, resorcinol was found to be inactive in this respect. Phloroglucinol is said to exhibit triketonic properties and is known to react with amines to give products (*A*) and (*B*).



It is possible that cyclization of a condensation product such as (*C*) occurs giving a hydroxyindole. 5,6, Dihydroxyindole-2-carboxylic acid is the product which is said to be an intermediate in melanin formation[2]. Oxidized polyphenolics react, for example, with proline



to give purple products[3]. Catechol, when oxidized reacts with glycine[4], and *O*-benzoquinone reacts with glycine ethyl ether to give a black solid.

Cresols, and homocatechol, give brilliant colours with aniline[5]. *O*-dihydroxy acids react via the *O*-quinone with NH_2 groups to give cross-linked structures, the N-function becoming attached directly to the aromatic nucleus[6]. The first step here is believed to be a N-substitution to the quinone nucleus in the 4 or 5, or both positions.

It is noteworthy that the following mechanism has been proposed for the enzymatic *O*-quinine/salmine reaction[7]:

Oxidized polyphenols may also de-aminate amino-acids with the formation of keto acids, which lose carbon dioxide to form aldehydes[8], for example:

Such aldehydes would also react with $-NH_2$ groups, and undergo condensations with substances likely to be present in naturally occurring materials, and in foodstuffs. The reactions of aldehydes in the presence of food substrates has not been fully explored, but they may well undergo condensations in the presence of other substances likely to be present in foodstuffs to give intermediates of high browning potential (cf. Overend and Stacey[9]).

In the presence of sulphites, such carbonyl reactions would be limited[10–12]. The effect of sulphites in retarding non-enzymatic browning and on the carbonyl-amino system has been reported on in a number of publications[11–15] and it was decided to examine its effect on the phloroglucinol/glycine system. The concentration of both reactants was 0·05 M, and the incubation was carried out at 19° C. In the sulphited series the concentration of sulphur dioxide was 2 mg/ml., added to the solutions as sodium metabisulphite, with an initial *p*H 6. The colour of the incubated solutions was measured by means of an EEL colorimeter at 460 mμ. Results are shown in Table 1.

Two things are at once apparent. The first is that even at low concentrations, the effect of the nitrogen function on the development of chromophores was marked, which runs parallel to our recent findings in related browning systems[10,12,13]. The second is that sulphites are effective

Table 1. Browning of Phloroglucinol/Glycine

Both reactants 0·05 M. *p*H 6·0. Incubated at 19° C. Concentration of sulphur dioxide, where present, 2 mg/ml.

Incubation period (days)	Colorimeter readings at 460 mμ: Phloroglucinol/glycine not sulphited	Phloroglucinol/glycine sulphited	Phloroglucinol not sulphited	Phloroglucinol sulphited
4	0·4	0·3	0·4	0·3
6	1·0	0·3	0·8	0·4
12	1·7	0·4	1·0	0·4
19	2·6	0·6	1·2	0·5
26	5·4	0·6	1·3	0·5
33	11·0	1·1	1·5	0·6
41	15·6	1·1	1·5	0·6
47	20·6	1·3	1·6	0·8
54	27·3	1·6	1·7	0·9
61	33·3	1·8	1·8	0·0
68	38·6	2·1	1·9	1·2

in retarding the development of chromophores in the phenol/amino-acid system, where presumably the phenolic groupings become oxidized.

Sodium sulphate had no such effect in retarding browning, and when incubated at 50° C with 0·05 M phloroglucinol/glycine at 0·03 M concentration the readings given in Table 2 were obtained.

Table 2. Browning of 0·05 M Phloroglucinol/Glycine in the Presence of Sodium Sulphate at 50° C

Incubation period (days)	Phloroglucinol/glycine	Phloroglucinol/glycine + Na_2SO_4
5	20·0	22·0
10	48·0	54·0

The effect of the nitrogen function, and of the effect of *p*H on the system is well demonstrated by the results shown in Table 3.

Table 3. Browning of Phloroglucinol and Phloroglucinol/Glycine (0·05 M) over the *p*H-range 3–8

Incubation temperature 50° C

Incubation period (days)	Colorimeter readings at 460 mμ after incubation at *p*H 3·0 Phlor./gly.	3·0 Phlor.	5·0 Phlor./gly.	5·0 Phlor.	7·0 Phlor./gly.	7·0 Phlor.	8·0 Phlor./gly.	8·0 Phlor.

10	2·3	0·9	19·0	1·96	88·6	6·2	270·0	166·0

There was again a great difference between the browning of phloroglucinol in the presence, as compared with the absence, of a nitrogen function at all acid *p*H's. The browning rate rose with increase in *p*H and once the solution became alkaline an enormous increase in browning occurred. A similar effect has already been recorded by us for the carbonyl/amino reactions[16]. It is known that alkaline treatment causes rapid autoxidation of polyphenols to give dark-coloured polymers.

Similar results were obtained with resorcinol in the presence and absence of glycine, as shown in Table 4.

Table 4. Browning of 0·05 M Resorcinol with and without Glycine, and of 0·05 M Phloroglucinol/Glycine in the Presence and Absence of Calcium Chloride ($CaCl_2.6H_2O$ = 0·545 g/l)

Incubation temperature 50° C

Incubation period (days)	Colorimeter readings at 460 mμ: Resorcinol/glycine	Resorcinol	Phloroglucinol/glycine	Phloroglucinol/glycine + $CaCl_2$
1	0·6	0·6	1·83	1·8
3	4·3	0·73	4·7	5·4
6	32·0	0·8	13·0	16·3
10	117·0	0·9	28·0	33·0

The effect of calcium on the browning of sugar systems[13,16–18], and carbonyl systems[10,12,18] ascorbic acid[19] systems and phosphatide systems[15] has already been examined. Calcium appears to retard somewhat the early browning of sugar systems but does not retard the browning of the other components. Calcium chloride is important in the retardation of non-enzymatic browning of some products, for example, White Rose potatoes brown too rapidly in the presence of statutory levels of added sulphite, but respond to conjoint treatment with the calcium salt. It does not appear to retard the browning of aqueous phenol systems. Table 4 shows that in the presence of calcium chloride, the colour developed by

phloroglucinol and glycine on incubation in aqueous solution was, if anything, somewhat enhanced.

Polyphenols containing ortho-dihydroxy and vicinal trihydroxy groupings have the ability to bind metal ions to form coloured complexes. Where such polyphenols occur in foodstuffs, or during the storage of foodstuffs, in the presence of metals, darkening effects may well be produced. Calcium has been known to cause such an effect[20], but it would appear that in some systems one ion may be preferable in the complexes to others due to the lower degree of coloration produced.

In the solid-state, the effect of metabisulphite in retarding colour development was examined by incubation at 50° C of slurries of phloroglucinol and phloroglucinol/glycine, with and without potassium metabisulphite, dried over phosphorus pentoxide *in vacuo* prior to incubation.

While in the dry solid-state the greatest red discoloration as observed visually occurred in the absence of glycine, when the phenol presumably underwent autoxidation and self-condensation. It is well known that polyphenols, particularly those with vicinal hydroxy groups, when absorbed on to a surface and exposed to air or sunlight, will brown rapidly. This was prevented to some extent by the presence of sulphite. When glycine was present the discoloration which occurred was yellower and less red in shade when observed by eye in the dry state, and the discoloration was only very slight in the presence of metabisulphite after five months' incubation. The incubated mixtures were dissolved in water and examined by means of the EEL Colorimeter using a range of filters. Some results are given in Table 5.

Table 5. BROWNING OF PHLOROGLUCINOL AND PHLOROGLUCINOL/GLYCINE (EQUIMOLAR) IN THE SOLID-STATE AT 50° C

Metabisulphite where added to give 1/10 mole SO_2/mole. Dilution 0·2 g of incubate in 10 c.c. water

Incubate	Colorimeter readings after incubation for 150 days (mμ)							
	570	540	520	490	460	450	690	600
Phloroglucinol	1·6	2·3	2·7	3·5	4·2	3·7	0·8	1·2
Phloroglucinol/sulphite	1·0	1·5	2·6	2·0	2·5	2·2	0·6	0·8
Phloroglucinol/glycine	1·5	2·3	2·6	3·6	4·5	3·9	0·9	1·2
Phloroglucinol/glycine/sulphite	0·8	1·2	1·4	1·9	2·45	2·3	0·4	0·6

Over the range examined, the colour produced by the equimolar phloroglucinol/glycine mixture was somewhat greater than that produced by the phloroglucinol alone, but the reduction in colour density effected by the metabisulphite was greater in the glycine series. Some phenolic compounds may, however, cause sulphite loss by a different mechanism to that postulated for carbonyl/amino systems[13], dihydroquercetin, for example, converting bisulphite to thiosulphate, which in turn catalyses the decomposition of bisulphite to thiosulphate and sulphate[21]. When oxidized to the quinone form, many phenolic compounds and phenol acids couple with amino groups of amino-acids to yield darker compounds than those produced by self-condensation[22–24], and even the addition of hydroquinone to dehydrated vegetables produces some increase in degree of browning on storage[14]. Such discoloration was still much reduced in the presence of sulphite, and acid hydrolysable sulphur dioxide still remained in such products after 2½ years storage in nitrogen[14]. In the storage investigations, the sulphitation was carried out at the same time as the blanching, but observations in other fields[25,26] suggest that careful control of *p*H conditions might be necessary for some products depending on the predominance of certain reactive species.

From these observations it is clear that whether in the solid-state or in weakly acid solution, the non-enzymatic browning of phenolic compounds in the presence of a nitrogen function is faster than non-nitrogenous browning, and that sulphite is effective in retarding the onset and development of such browning. Effective browning retarding agents are both carbonyl group reagents and reducing agents, and this is clearly an example of browning associated with carbonyl and amino groupings which sulphites help to prevent developing in some foodstuffs.

MECHANISM OF SOLANESOL BREAKDOWN DURING PYROLYSIS

By J. D. GROSSMAN, R. M. IKEDA, E. J. DESZYCK and A. BAVLEY

Philip Morris, Inc., Richmond, Virginia

THE aroma of tobacco smoke has not been fully explained on the basis of the flavour constituents naturally present in tobacco. A number of the steam-volatile constituents in tobacco has been described by Onishi in several publications[1]. Several other workers in this field, particularly Weybrew[2] and Stedman[3], studied the differences in the volatile components of various grades of tobacco. However, tobacco resins, because of their complexity, have been studied only cursorily. As a part of a programme to determine the contribution of tobacco resin constituents to the overall flavour of smoke, we investigated the pyrolysis products of solanesol. Solanesol was selected because it was the first of such tobacco resin constituents to be isolated and described in terms of its chemical structure. The structure of solanesol was established by two groups of investigators: Rowland,

Latimer, and Giles in 1956[4] and Folkers and co-workers[5] in 1959. They proved that it had the following structure:

Fig. 1. Solanesol

During our investigation of the pyrolysis of solanesol, we isolated and identified several C_{10}-terpenoid hydrocarbons. We showed that these hydrocarbons are formed partially by dimerization of isoprene, one of the pyrolysis products of solanesol[6]. After establishing the structure of the products present in the C_{10}-hydrocarbon fraction and correlating them with the products formed by the pyrolysis of isoprene and dipentene under identical conditions, it became evident that the products formed during the pyrolysis of solanesol could not be explained fully as being formed by the dimerization of isoprene. Higher yields of dipentene than would be expected led us to believe that other mechanisms of breakdown were involved. By pyrolysing solanesol in atmospheres of hydrogen versus nitrogen, we found quantitative differences in the yields of the C_{10}-hydrocarbons. These differences confirmed our belief that solanesol might be breaking up by other routes.

In a recent publication by Johnstone[7], a mechanism was proposed for the formation of a C_{10}-biradical during the pyrolysis of solanesol with subsequent cyclization to give products such as 1,3-dimethyl-1-vinyl *cyclo*hexene and dipentene. We postulated that this mechanism could account for some of the quantitative differences in the yields of the C_{10}-hydrocarbons. It had been shown in the recent work on the pyrolysis of toluene and of deuterated toluenes[8] that the free radicals which are formed during pyrolysis can be terminated by hydrogen. It occurred to us that, in a hydrogen atmosphere, an intermediate free radical formed during the pyrolysis of solanesol can terminate by capturing hydrogen, giving different yields of C_{10}-hydrocarbons. At this time we want to present evidence that supports our theories that solanesol might be breaking up: (1) through the formation of a C_{10}-biradical which is terminated by capturing hydrogen; (2) through the direct breakdown of solanesol to give dipentene.

First, it was necessary for us to develop a method for isolating solanesol in large quantities from tobacco. Although solanesol has been synthesized[9], it is difficult to produce in large quantities. Instead of using the conventional method of adsorption chromatography[4] for its isolation we developed a simplified procedure by which tobacco was extracted with an appropriate solvent and the solanesol isolated by molecular distillation and crystallization.

Ten pounds of aged tobacco was exhaustively extracted with petroleum ether. The extract (4·5 l.) was washed twice with 1-l. portions of a 10 per cent hydrochloric acid solution, and then with water until it was neutral. All washes were discarded. The same procedure was repeated, using a 5 per cent sodium hydroxide solution. The neutral extract was dried over anhydrous magnesium sulphate, filtered, and the solvent removed under reduced pressure at 40° C. The residue was dissolved in 2 l. of hot acetone, cooled overnight at 4° C, and filtered to remove the solids.

The de-waxed solution was concentrated to a syrup under the conditions previously mentioned, leaving 400 ml. of a dark brown residue. The residue was transferred into a 2-in. molecular still (Arthur K. Smith, Inc.) and, after removal of traces of the solvent, it was subjected to distillation at 300° C and 100–200μ pressure. Two-thirds of the material was distilled under these conditions as a viscous, orange-coloured liquid. Solanesol was crystallized by dissolving the distillate in a minimum amount of ether (200 ml.), covering the solution with methanol (300 ml.) without mixing the two layers, and cooling overnight at 4° C. By recrystallizing three times, we obtained 20 g of solanesol (a crystalline white material, m.p. 33°–34° C) and identified it by its infra-red spectrum. The acetate of the crystalline material melted at 31°–32° C and the 3,5-dinitrobenzoate at 55°–56° C.

All samples of solanesol prepared in this way showed excellent stability, and did not decompose for several weeks on storage under ordinary conditions.

Solanesol was passed under nitrogen through a 30-cm 'Vikor' tube filled with porcelain chips which were heated to the desired temperature. The pyrolysis was carried out in a nitrogen atmosphere, maintaining a constant dropping rate of material into the apparatus. The pyrolysis products were collected in a trap cooled with a dry ice–acetone mixture. The total pyrolysis product was separated into the volatile components by distillation at 40° C. The remainder of the mixture was then separated by fractionation on silica gel into a hydrocarbon and an oxygenated fraction. The hydrocarbon fraction was then separated into various components by gas chromatography.

We established that temperature is a critical factor in the production of the hydrocarbon components; namely, at temperatures up to 550° C the hydrocarbon fraction was composed mainly of monoterpenoids with traces of aromatic products being present. At higher temperatures, aromatization is favoured. This has been previously established with other compounds[10–12]. We observed no formation of terpenoids from solanesol at temperatures above 650° C. Instead, various aromatic compounds were formed. It has been shown[11] that at high temperatures even such compounds as acetylene and butadiene give rise to mixtures of aromatic hydrocarbons.

Our method of isolation of the pyrolysis products is outlined in the following diagram:

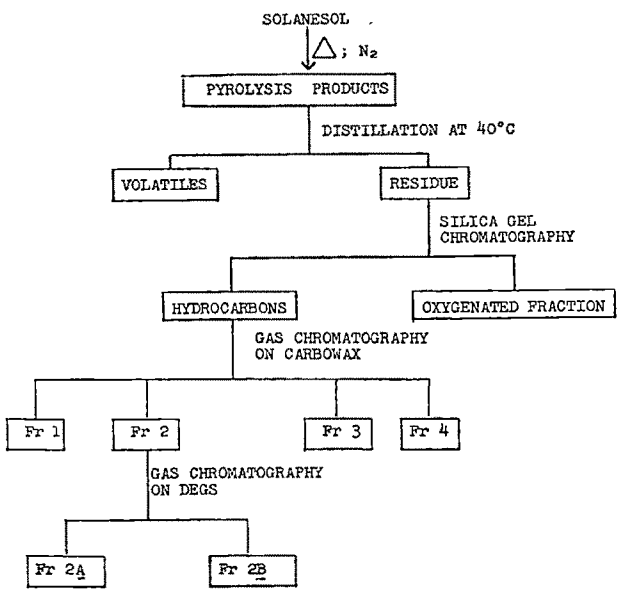

Fig. 2. Scheme of isolation of products from pyrolysis

From work described in the literature, only the mechanisms of pyrolysis of α- and β-pinene[13], *d*-limonene[1], and allo-ocimene[14] have been described. These investigations were significantly helpful to us in the interpretation of solanesol pyrolysis data.

Examination of the volatile pyrolysis constituent by mass spectroscopy, infra-red, and ultra-violet analyses established that the main products in this mixture are isoprene and 2-methyl-2-butene. Several other not yet identified dienes were also present.

The terpenoid fraction was separated by preparative gas chromatography into five fractions.

Fraction No. 1. This fraction was identified by ultra-violet, infra-red, and mass spectroscopy as consisting of a mixture of α- and β-pyronenes. It had been reported previously that these compounds arise from the pyrolysis of terpene hydrocarbons[10,14]. Rechromatography of component No. 2 separated the material into two fractions.

Fraction No. 2A. This material had a molecular weight of 138. Infra-red spectra indicated a tri-substituted double bond. On hydrogenation this material absorbed 2 moles of hydrogen. The resulting product did not have a menthane structure. The hydrogenated product was different from synthetic 2,6-dimethyl-octane prepared by hydrogenation of myrcene and slightly different from synthetic 2,7-dimethyloctane prepared by coupling 3-methyl-1-butene with sodium borohydride-BF_3 and treating it with silver nitrate. Mass spectrometric analysis of the hydrogenated product isolated from the pyrolysis showed that we had obtained a 60–40 per cent mixture of the two dimethyloctanes. Therefore, we conclude that our pyrolysis sample must be a mixture of 2,6-dimethyl and 2,7-dimethyl octadienes. The 2,7-dimethyl octadiene must arise by dimerization of isoprene formed during the pyrolysis process.

Fraction No. 2B. This fraction was characterized by infra-red, nuclear magnetic resonance and mass spectroscopy as being similar to dimethyl-vinyl *cyclo*hexene, which arises from dimerization of isoprene[7]. On hydrogenation, it absorbed 2 moles of hydrogen, giving a product with a different mass spectroscopic pattern of the dimethyl-vinyl *cyclo*hexene hydrogenated product obtained by the dimerization of isoprene. We think that the difference in these two compounds is due to the position of the substituents on the *cyclo*hexene ring. Thus, in the case of isoprene, the compound which is formed is probably the 1,4-dimethyl, 1-vinyl *cyclo*hexene. Our solanesol pyrolysis product, on the other hand, was identical with one formed during the pyrolysis of dipentene and must have been formed through a 2,6-dimethyl-octadiene free radical to give the 1,3-dimethyl, 1-vinyl-isomer.

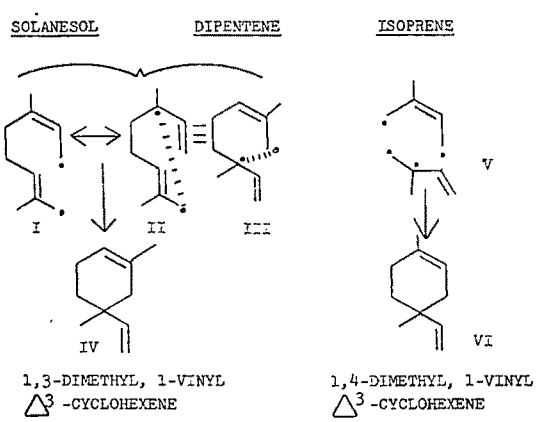

Fig. 3. C_{10} Hydrocarbons (Fr. 2*B*)

Fraction No. 3. Purification of this fraction resulted in the isolation of Δ-1-menthene identical with a reference standard.

Fraction No. 4. This was identified as dipentene, as was reported previously[6].

The pyrolysis of solanesol in a hydrogen atmosphere was accomplished by following essentially the same procedure as that for the pyrolysis in a nitrogen atmosphere. The whole apparatus was flushed thoroughly with nitrogen, and then was flushed thoroughly for half an hour with hydrogen. The pyrolysis was accomplished in a hydrogen atmosphere. The C_{10}-hydrocarbons were isolated, following the same fractionation procedure. Examination of the volatile pyrolysis constituents by mass spectroscopy and gas chromatographic analysis established that they were a mixture consisting of 64 parts isoprene, 8 parts 2-methyl-2-butene, 1 part each of 2-methyl-1-butene and 3-methyl-1-butene, with a trace of isopentane being present. The C_{10}-hydrocarbon fraction obtained during pyrolysis in the hydrogen atmosphere was compared quantitatively with the products obtained during the pyrolysis of solanesol in nitrogen.

The results are given in Table 1.

Table 1

Fraction (pyrolysis of 500° C)	H_2 atm (% of total C_{10}-terpenes)	N_2 (% of total C_{10}-terpenes)
1, Pyronenes	4·17	7·13
2*A*, (Dimethyloctadiene)	19·12	11·82
2*B*, (Dimethyl vinyl *cyclo*hexene)	7·01	12·20
3, Δ^1-Menthene	8·54	12·84
4, Dipentene	52·72	45·31

As can be seen from the results given here, there is a considerable increase in the dimethyloctadiene formed during pyrolysis of solanesol in a hydrogen atmosphere and a decrease in pyronenes, dimethyl-vinyl-*cyclo*hexene and Δ^1-menthene. This confirms one of our suggested mechanisms of breakdown of solanesol; namely, by the formation of a dimethyloctadiene biradical which in a hydrogen atmosphere terminates by capturing two hydrogens, thus forming dimethyloctadiene. This, consequently, caused a lower yield of dimethyl-vinyl-*cyclo*hexene and the other products which are formed through this intermediate biradical.

The increase of dipentene formed during the pyrolysis of solanesol in the hydrogen atmosphere tends to support the third mechanism of its pyrolysis. This mechanism gives dipentene directly through an 'unzipper' type of mechanism illustrated in Fig. 4.

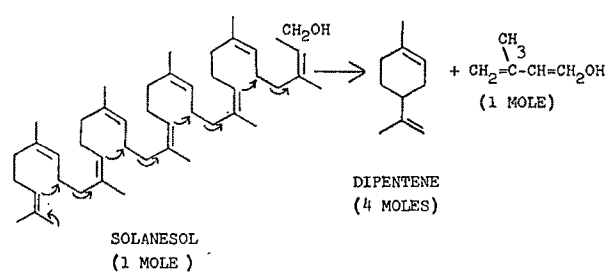

Fig. 4. Direct breakdown of solanesol to dipentene

C_{10}-terpenoid hydrocarbons are formed during the pyrolysis of solanesol by several routes. These pathways of formation have been established: (1) Through the dimerization of isoprene into dipentene and other C_{10}-hydrocarbons. (2) Through the formation of a C_{10}-biradical which is terminated by capturing hydrogen in a hydrogen atmosphere. (3) Through the direct breakdown of solanesol to give dipentene.

REPLICATIVE FORM OF ENCEPHALOMYOCARDITIS VIRUS RIBONUCLEIC ACID

By Dr. L. MONTAGNIER and Dr. F. K. SANDERS
Virus Research Unit, Medical Research Council Laboratories, Carshalton, Surrey

INFECTIVE ribonucleic acid (RNA) molecules, extracted from encephalomyocarditis (EMC) virus preparations, each have a size corresponding to the whole RNA content of one virus particle[1,2], as well as physical properties indicating that they exist in solution as single-stranded chains, thus resembling ribosomal and other viral RNA's[3]. Stirred suspensions of Krebs-II ascites tumour cells, infected *in vitro* with EMC virus[4], have been used to investigate the mode of replication of such a single-stranded viral RNA. We now have evidence that an unusual kind of infective RNA, the properties of which are consistent with a double-stranded structure, may be present in Krebs-II cells during infection by EMC virus.

The use of specific inhibitors has led to the conclusion that the replication of small RNA viruses is not dependent on the integrity of host DNA[6,7]; nor does it require DNA synthesis[5,7]. Actinomycin, which suppresses DNA-dependent RNA synthesis[8], also fails to inhibit EMC[7], Mengo[6], or poliovirus[9] multiplication. Moreover, replication of the RNA of bacteriophage *MS*-2 in *E. coli*[10], and Mengo virus RNA[11] in *L* cells, follows the appearance of a specific polymerase able to synthesize RNA directly on an RNA model. Cline, Eason, and Smellie[12] have also observed stimulation of an RNA-primed RNA transferase in our system of Krebs-II ascites cells infected by EMC virus.

These observations suggest that the RNA of the invading virus particle somehow serves directly as a model for the synthesis of new viral RNA. How, then, does this occur? Double-stranded DNA almost certainly replicates by a mechanism involving progressive separation of the two strands, and the formation on each of a further complementary chain[13] in which the sequence of bases is determined by the rules of base pairing laid down by Watson and Crick[14]. The same scheme can be applied to the replication of single-stranded DNA, phage $\varphi X174$ DNA being double-stranded when in its replicative form[15].

Whether viral RNA also first makes a complementary chain, so that the duplex can then replicate like DNA, or whether it utilizes some peculiar mechanism without base pairing[16] is at present unknown. If the first suggestion is correct, an RNA of double-stranded structure should be found at some stage of viral replication. The physical properties of such an RNA in solution should resemble those of DNA, since the structure deduced from X-ray diffraction patterns of the helical hairpin-like portions of transfer RNA does not differ fundamentally from that of a DNA double helix[17]. Moreover, such an RNA duplex should exhibit a sharp thermal transition, and show some resistance to degradation by ribonuclease[18]. We believe that the material we have isolated has a sufficient number of these properties to identify it as a double-stranded RNA of viral origin. No similar double-stranded RNA has as yet been found in uninfected cells, and we suggest that the material present in infected cells may be the replicative form of the viral RNA.

Separation of the bulk of infective RNA extracted from infected Krebs-II cells into two components. Infective RNA can be extracted from infected cells with phenol some time before mature virus particles appear[19]. This RNA sediments just like RNA extracted from purified virus, although it shows up as a broader band on a sucrose gradient[2]. To show that this band contains replicating, in addition to finished, viral RNA, we have first to establish that the replicative form of viral RNA is, in fact, extracted by phenol; in mammalian cells a nuclear RNA fraction associated with DNA, and rapidly labelled by radioactive precursors, is not extractable by phenol alone, but only when a detergent is present[20,21]. Since viral RNA replication is likely to occur in nuclei[22,23], nuclear RNA has to be considered in this context. Thus a technique has been developed for extracting all possible fractions of infective RNA from EMC-infected Krebs-II cells. Two forms of this technique have been used in the experiments to be described.

(1) DNA, as well as all the RNA components, are first extracted from cells without previous separation. Infected, washed, Krebs-II cells are treated with 1 per cent sodium dodecylsulphate in presence of bentonite (0·1 per cent) and 0·05 M EDTA, at room temperature; the viscous homogenate resulting is deproteinized by three phenol extractions, and the mixed nucleic acids treated as described earlier for cellular RNA extracted with aqueous phenol[2]. DNA is then destroyed by treatment with deoxyribonuclease (previously freed from traces of ribonuclease by the technique of Polatnick and Bachrach[24]) (Worthington, 4 μg/ml., 30 min 22° C, in sodium chloride 0·1 M, magnesium chloride 0·01 M). DNase treatment is halted by the addition of EDTA to a concentration of 0·01 M, and after a new cycle of deproteinization by phenol and bentonite, nucleic acids are precipitated twice with ethanol. The precipitate contains all RNA fractions in a natural state, as well as oligodeoxyribonucleotides. (2) Here we make an initial separation between RNA's extractable by aqueous phenol, and that closely associated with DNA. Infected cells are first extracted with phenol, which releases ribosomal and transfer RNA into the aqueous phase. After centrifugation at low speed the aqueous phase is decanted, the phenol layer discarded, and the interface carefully washed and re-extracted 2–4 times with aqueous phenol. Addition of 1 per cent of sodium dodecylsulphate at this stage releases the majority of the DNA and its associated RNA into the aqueous phase. The separate fractions are then further treated as in (1).

To obtain a picture of the appearance of infective RNA, a series of extractions of cells infected with purified virus[25] was carried out at various times during the cycle of virus growth using variant 1 of the technique. The extracted RNA's were then centrifuged on a sucrose gradient[2], and the gradient fractions assayed for infectivity and ultra-violet absorbance, as described by Montagnier and Sanders[2]. As shown in Figure 1*a*, most of the infectivity sediments in front of the 30 *S* ribosomal component, just like RNA extracted from purified virus[2]. As already stated, at all times after infection this infectivity band is broader than that given by RNA from pure virus; sub-fractionation of the sedimentation band shows a definite heterogeneity, some portions sedimenting faster than 37 *S*. A similar heterogeneity was also found in very early stages of infection—immediately after virus adsorption in the cold, when most of the recorded infective RNA comes from virus particles which have adsorbed

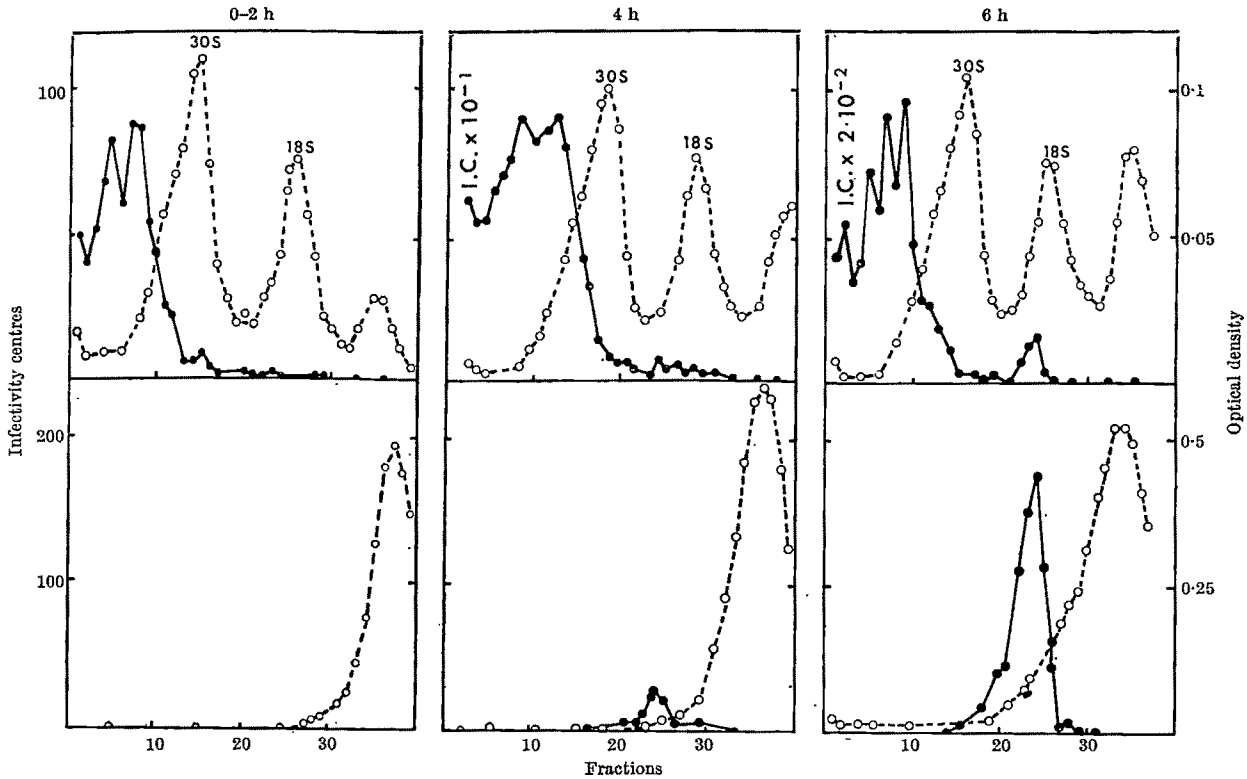

Fig. 1. Sedimentation in sucrose gradient (10–20 per cent) of RNA extracted from Krebs II cells at different intervals after infection by EMC virus (15*H*30, 22,500 r.p.m., in *tris*-hydrochloric acid 0·005 M, EDTA 0·02 M, *p*H 7·2). Top row: (*a*), untreated; bottom row: (*b*), same samples treated by ribonuclease (10^{-1} μg/ml., 30 min 22° C) immediately before centrifugation. Continuous line, infectivity; dotted line, optical density at 260 mμ. The scales of the ordinates in the top and bottom rows are different

on cell membranes, but not yet begun to replicate. It is therefore unlikely that this 'heavy' RNA represents the replicative form.

However, Fig. 1 also shows, and only at times after which viral RNA has begun to replicate, a second peak of RNA infectivity sedimenting in front of the 18 *S* ribosomal RNA component. Its position in the gradient suggests a sedimentation coefficient of about 20 *S*. Though the 20 *S* peak represents only a small proportion of the total infectivity, the amount of this fraction increases with time, especially at the end of the cycle of infection, when cells are dying and releasing virus (Fig. 1 and Table 1).

Table 1. Appearance of Ribonuclease-resistant 20 *S*-Sedimenting Material (Infectivity in Percentage of Control not treated by RNase) in Krebs-II Cells infected with EMC Virus (Multiplicity 10)

Time after infection (h)	Experiment I RNA extracted by variant 1 (%)	Experiment II Extraction variant 2	
		Fraction extractable by phenol (%)	Remaining fraction extractable by sodium dodecylsulphate (%)
0*	0 (< 0·1)	—	—
2	0 (< 0·1)	—	—
4	0·1	0·05	—

* Immediately after adsorption of virus at +4° C.
RNase treatment: Armour crystallized RNase (10^{-1} μg/ml., 30 min, 22° C in *tris* 0·005 M EDTA 0·02 M *p*H 7·2).

Treatment by pancreatic ribonuclease (0·1 μg/ml., 22° C, 30 min) results in a dramatic disappearance of the 37 *S* infective peak, while the infectivity of the 20 *S* component is unaffected (Fig. 1*b*). Moreover, its slow sedimentation and ribonuclease resistance allow separation of this RNA from the rest of the RNA present.

Similar experiments performed with RNA's extracted by variant 2 of the method described show that only a small part of the total infectivity lies in the fraction not extractable by phenol. Up to 5 h after infection, the infectivity recoverable from this fraction has similar properties of sedimentation and RNase sensitivity to the bulk of the infective RNA extracted by phenol. However, in the later stages of infection, accumulation of the 20 *S* form occurs faster here than in the fraction extractable by phenol (Table 1).

Physical and chemical properties of the 20 S infective form. Sufficient amounts of impure 20 *S* material have been obtained from batches of dying infected cells to enable its physical properties to be measured. Variant 1 of the extraction technique was used, and the product centrifuged on a sucrose gradient. Infective fractions sedimenting in the 20 *S* region were pooled together and concentrated by ethanol precipitation. Studies using biological criteria were performed without further purification.

(i) *Ribonuclease resistance.* In solutions of moderate ionic strength, the infectivity of the 20 *S* form totally resists destruction by the enzyme up to a concentration of 1 μg/ml. in the conditions of time and temperature mentioned here. Under the same conditions, the infectivity of RNA sedimenting in the 37 *S* region, whether extracted from infected cells or from purified virus, is reduced to a value of less than 0·001 per cent of that of control untreated preparations. At lower ionic strength and higher temperature, the 20 *S* form becomes more sensitive to RNase.

(ii) *Effect of formaldehyde.* Preliminary results indicate that the infectivity of the 20 *S* form resists treatment with formaldehyde, in conditions where 37 *S* form has lost 98 per cent of its original infectivity.

(iii) *Solubility in sodium chloride.* The 20 *S* form is soluble in 1·5 M sodium chloride, like DNA and transfer RNA, while the 37 *S* infective form is insoluble, like ribosomal RNA.

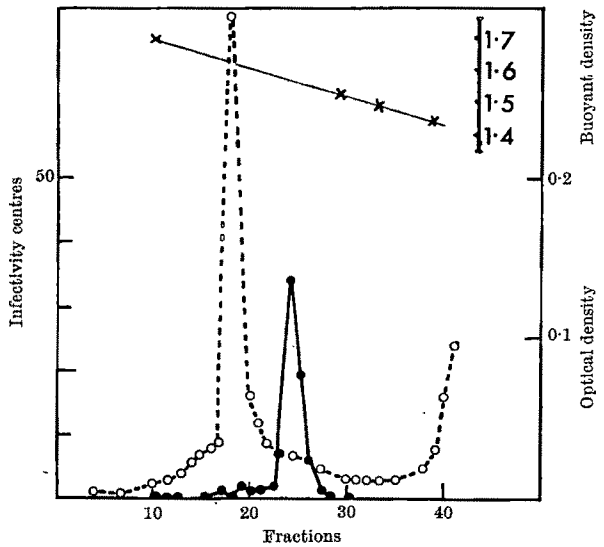

Fig. 2. Equilibrium density centrifugation in cæsium sulphate of 20 *S* infective RNA mixed with an excess of Krebs II ribosomal RNA. (44 h, 33,500 r.p.m. in *SW*39 head.) Continuous line, infectivity; dotted line, optical density at 260 mμ. Density measurements by refractometry

(iv) *Buoyant density in cæsium sulphate.* When centrifuged to equilibrium in concentrated cæsium sulphate, solutions of DNA (double-stranded) have a buoyant density of 1·42 [26], single-stranded ribosomal RNA 1·63 [26]. The latter forms aggregates at high concentration, so that its band-width is narrower than would be expected from its molecular weight. The 20 *S* infective RNA forms a band at a density of 1·57 (Fig. 2) and does not aggregate. Its band-width is comparable with those given by cellular DNA with a molecular weight of 6 millions under the same conditions of centrifugation. The 37 *S* component bands at the place of single-stranded ribosomal RNA.

(v) *Effect of heating on the absorbance of* 260 *mμ.* Only double-stranded DNA and helical polynucleotides exhibit a sharp thermal transition[27]. EMC virus RNA, like ribosomal or tobacco mosaic virus RNA, shows a broad thermal transition owing to the melting out of short intramolecular helical regions (Fig. 3).

To study the effect of heating on the 20 *S* form, we attempted further purification of the material with associated infectivity. The DNase treated product of extraction was precipitated by 1·5 M sodium chloride to remove ribosomal and 37 *S* viral RNA. The supernatant containing oligodeoxyribonucleotides, transfer RNA and the 20 *S* infective form, was precipitated with ethanol, redissolved in 0·15 M sodium chloride, 0·015 M sodium citrate and treated with pancreatic ribonuclease (1 h, 25° C, 0·1 μg/ml.). After removal of ribonuclease by addition of 0·1 per cent of bentonite and centrifugation at high speed, alcohol precipitation and redissolution of the pellet in 0·015 M sodium chloride, 0·0015 M sodium citrate, the final product was fractionated on a column of 'Sephadex *G*200'. The first peak to appear, judged by ultra-violet absorbance at 260 mμ, contained all the infectivity, had ratios $\frac{260}{230}$ and $\frac{260}{280}$ of 2·0, and was orcinol-positive and Dische[28]-negative, indicating the presence of ribose rather than deoxyribose.

The thermal transition of 260 mμ absorbance was examined on the fraction having the highest specific infectivity (5×10^4 plaque-forming units/μg). After a gradual increase up to 70° C, there was a very sharp transition (Fig. 3). The T_m's (melting temperature) were, respectively, 96° C, in 0·15 M sodium chloride, 0·015 M sodium citrate; and 84° C, in 0·015 M sodium chloride, 0·0015 M sodium citrate.

Discussion

All the properties of the 20 *S* infective component are those typical of a molecule having highly organized secondary structure. Before we can be reasonably sure that this is double-stranded RNA, made from a single-stranded chain of viral RNA bound by base pairing to a complementary chain, we must consider whether this molecule could be a DNA-viral RNA hybrid, which would also be resistant to nucleases. However, the buoyant density in cæsium sulphate of such a hybrid would be considerably lower (1·49 [29]); no deoxyribose is detectable; the melting temperature is very high. All these facts, as well as the results of experiments using inhibitors mentioned at the beginning of this article, are against the hybrid hypothesis. Assuming that the material we have found has similar hydrodynamic properties to double-stranded DNA, its molecular weight, calculated from a sedimentation coefficient of 20 *S*, would be $6{\cdot}7 \times 10^6$ (ref. 30). This is about twice the value of the molecular weight found for the single-stranded RNA from purified virus[1,2].

Unfortunately, confirmation of the double-stranded nature of this RNA by determination of its base composition cannot be done with EMC virus, where single-stranded RNA already has ratios adenine/uracil guanine/cytosine very close to one[25]. The necessary confirmation could perhaps be obtained with poliovirus, where adenine/uracil and guanine/cytosine ratios in the single-stranded viral RNA differ from one[31].

If we assume that the double-stranded nucleic acid isolated from our system is really concerned in virus replication, some of its other unusual features have to be accounted for; for example, unlike the double-stranded replicative form of single-stranded φ*X*174 DNA[15], double-stranded EMC RNA only comprises a small proportion of the infective RNA found in infected cells; most of the latter is single-stranded. Experiments in which infected cells have been labelled with radioactive RNA precursors in the presence of actinomycin gave similar results to experiments where RNA was identified by the criterion of infectivity; most of the label becomes incorporated in single-stranded viral RNA, and only a very small amount in the double-stranded material.

So if the mechanism of replication was strictly semi-conservative (all the newly produced chains replicating

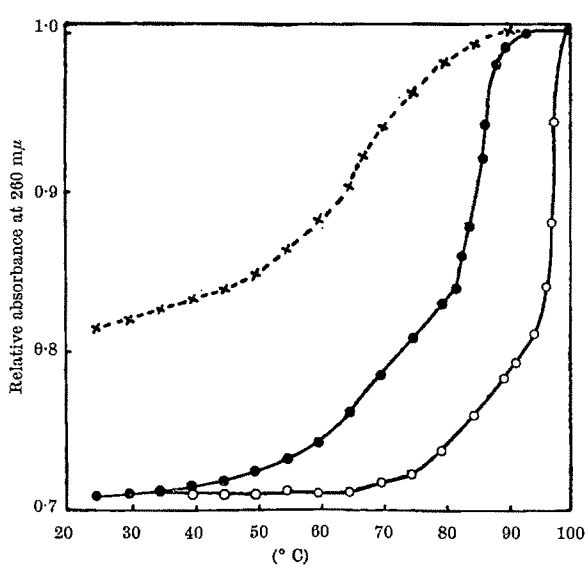

Fig. 3. Absorbance at 260 mμ as a function of temperature. Filled circles, infective 20 *S* material in sodium chloride 0·15 M, sodium citrate 0·015 M; open circles, the same in sodium chloride 0·015 M, sodium citrate 0·0015 M; crosses, single-stranded 37 *S* RNA extracted from purified EMC virus, in sodium chloride 0·15 M, sodium citrate 0·015 M

as well as the infecting chain) it would be necessary to assume that the double-stranded stage has a very transient existence compared with the single-stranded stage. Alternatively, the number of double-stranded molecules may remain very small during active replication; the greater part of the new duplexes formed may be immediately split into their two constituent chains, only one containing the viral information serving to initiate specific protein synthesis on the ribosomes.

In either case, the fate of one of the chains is uncertain. It is unlikely that they both contain the necessary base sequences to direct synthesis of viral protein via the ribosomal system[32]. In HeLa cells infected with poliovirus, the base ratios of RNA, newly synthesized in the presence of actinomycin, resemble those of purified virus RNA, and so do not reflect an equal synthesis of complementary RNA[33,34]. This suggests that the complementary chain may be destroyed soon after replication without attachment to ribosomes.

Bellett and Burness[22] found that infective RNA (presumably single-stranded) extractable from Krebs cells by phenol was at first mostly located in the nuclear fraction, and Zalta *et al.*[23] have reported an increase of infectivity after incubation *in vitro* of nuclei from infected Krebs-II cells. The high proportion of the double-stranded form found in the nuclear fraction of RNA which resists extraction by phenol also suggests that the replication, as well as the opening of the strands, may occur in the cell nucleus. This hypothesis is not incompatible with the results of Franklin[35], which show radioactive precursors located mostly in the cytoplasm of *L* cells infected with Mengo virus; in these rapidly growing cells the nuclear stage of virus replication may be very short compared with the cytoplasmic stage, as has been pointed out by Dulbecco[36]. Indeed, experiments in progress show that in *L* cells also double-stranded material accumulates during the later stages of the cycle.

We thank Mrs. B. Burford and Mr. J. Biffen for assistance. One of us (L. M.) has been supported by the "Délégation Générale à la Recherche Scientifique—Comité de Biologie Moléculaire".

DIURNAL RHYTHMS OF ELECTROLYTE EXCRETION IN DEPRESSIVE ILLNESS

By MARY LOBBAN and BARBARA TREDRE
National Institute for Medical Research, London, N.W.3
AND
DR. A. ELITHORN and DR. P. BRIDGES
Royal Free Hospital and National Hospitals for Nervous Diseases, London

THE term "manic-depressive insanity" was first used by Kraepelin[1] in 1899, although the disease had been previously described by Falret[2] and Baillarger[3] in 1854, who independently reported recurring attacks of mania and depression in the same patient. From their observations, the concept has developed of an endogenous or physiological type of depressive illness which can be distinguished ætiologically and clinically from an exogenous, reactive illness determined primarily by psychological events. In spite of the genetic evidence presented by Slater[4], Kallmann[5] and other workers however, this concept has remained controversial: recently the evidence derived from the exploitation of physical treatments has forced a revaluation of the position and established the need for a careful examination of the physiological status of psychiatric patients.

A classic symptom of endogenous depression, first described by Schneider[6] in 1920, is a diurnal variation of mood in which the depressive process is typically at its maximum in the early hours of the morning and tends to improve during the day. This contrasts with the findings in psychogenic depression where very frequently each new day starts more hopefully than it finishes. It is also claimed that the sleep disturbance in the two types of depression is characteristically different so that in the endogenous depression sleep is most difficult in the early hours of the morning. These diurnal variations in symptomatology and the disruption of the normal pattern of sleep and wakefulness suggest that it might be worth looking for abnormalities in other physiological functions normally showing diurnal rhythms. Such rhythms in the renal excretion of water and electrolytes have intermittently attracted the interest of physiologists since Quincke[7] reported in 1877 that the volume of urine excreted at night is reduced compared with that excreted during the daytime.

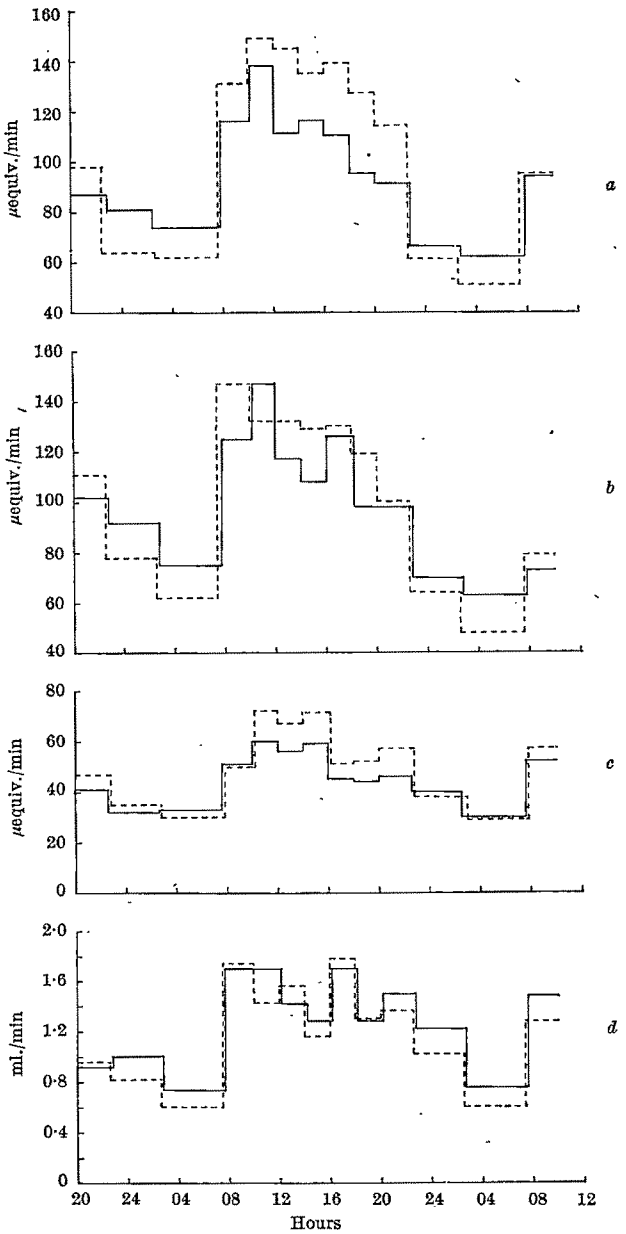

Fig. 1. —, Depression; – – –, neurosis: *a*, chloride; *b*, sodium; *c*, potassium; *d*, urine volume

This article describes briefly the result of an investigation of the renal diurnal rhythms of 20 "endogenously depressed" patients treated in the psychiatric ward at the Royal Free Hospital. These findings are related to similar observations obtained with 25 "neurotic" controls. Observations were made consecutively on all admissions.

The diagnoses were those derived on clinical grounds in the absence of any knowledge of the experimental findings and patients in whom there was any suspicion of schizophrenia or organic disease were excluded from the analysis.

Shortly after admission each patient was placed on a standard régime, which started at 20.00 h when the patient emptied his bladder. The bladder was again emptied at the following times: 22.30; 02.30; 07.30; 10.00; 12.00; 14.00; 16.00; 18.00; 20.00; 22.30; 02.30; 07.30; 10.00. On each occasion the volume and the actual time at which urine was passed were recorded and a specimen kept for analysis. In addition, observations were made on oral temperature, pulse, blood pressure and reaction time. Throughout the test period the patients were kept on a standard hospital metabolic diet.

Fig. 1 shows the mean rates per minute of water and electrolyte excretion for the group of neurotic and for the group of depressive subjects over the different periods of the 38 h of the investigation. In all cases a clear diurnal rhythm is seen with rates higher between 07.30 h and 22.30 h than during the preceding and succeeding night periods. In the case of sodium and chloride, and to a lesser extent potassium, but not water, the amplitude of this diurnal variation is greater in the neurotic group than in the depressives. This difference is not present in the excretion of water and this excludes the possibility that it is brought about by differences in the efficiency of the collection procedures for the two groups. There are no important differences in overall excretion rates, but if the first night is compared with the second, both groups show a tendency to sodium and chloride retention during the second night. This is probably a consequence of the standard diet which had a relatively low sodium content (80 m.equiv./day) and could have influenced excretion rates during the latter half of the test period. Both groups were equally affected and the effect therefore is not relevant to differences between the day/night partitions for the two groups. As would be expected, the results for sodium and chloride excretory patterns were very similar. The depressives when compared with the neurotics excrete less of these electrolytes during the day and more by night. For potassium, the night excretory rates are very similar for the two groups; but by day the excretory rate is greater for the neurotics, giving again for this group a diurnal rhythm of greater amplitude.

In order to assess the significance of these findings and the importance of differences in medication and age, we have expressed the results as day/night ratios for each of the three electrolytes. For each subject the total amount of electrolyte excreted between 08.00 and 20.00 h has been calculated as a percentage of the total excretion

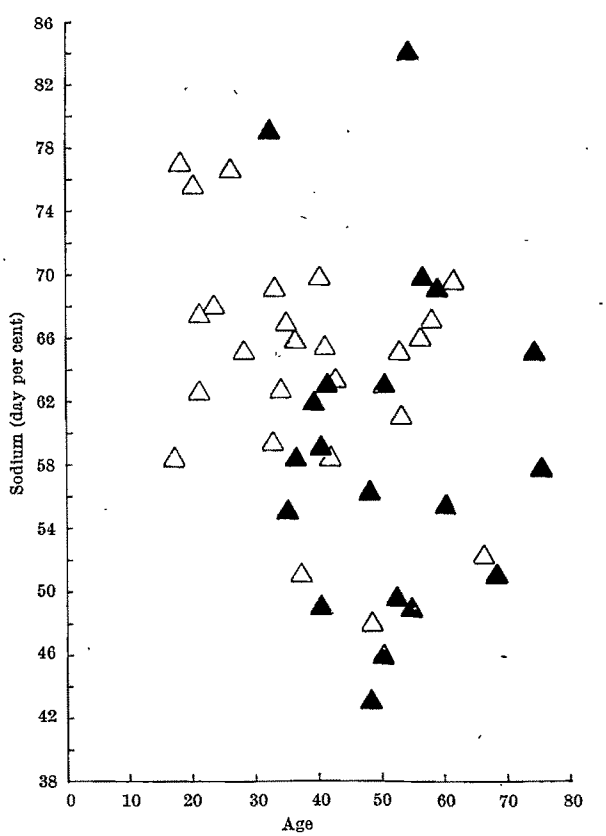

Fig. 2. ▲, Neurotics; △, depressives

over the period of 24 h. The figure for the night is the mean of the two night periods. Since the early morning specimen was collected at 07.30 the 12-h figures have been prorated from the two periods 02.30–07.30 and 07.30–10.00. Ranking these ratios the Mann–Whitney U test shows that the differences between the two groups are statistically significant for sodium ($P = 0{\cdot}012$) and for chloride ($P = 0{\cdot}035$) but not for potassium ($P = 0{\cdot}08$).

Unfortunately, the condition of many patients precluded the possibility of their ceasing treatment for the test and we have therefore assessed the relationship of the day/night ratios to medication. Patients having drug treatment ($n = 15$) were compared with those having no drug treatment of any kind ($n = 30$), those having antidepressant drugs ($n = 11$) with those not having these drugs, and those having phenothiazines ($n = 10$) with those not. In no case was the difference significant nor were any of the differences marked.

Another difference between the two groups of patients which needs to be considered is that of age. The mean age of the depressive group was 50·3 years and that of the neurotic group 37·6 years (Mann–Whitney U test, $P = 0{\cdot}003$). So far as we are aware there is no published data on the relationship of the diurnal excretory rhythm to age. For the present subjects the relationship between the day/night ratios for sodium and age and diagnosis is shown graphically in Fig. 2. Since the distribution of the ratios is reasonably normal, we have calculated the product moment correlations of their ratios with age for the two groups. For the neurotics $r = -0{\cdot}37$; for the depressives $r = -0{\cdot}09$. Neither of these coefficients is significant but that for the combined group ($r = -0{\cdot}308$) just reaches the 0·05 level of confidence. While the regression on age does not account for all the difference between the two groups, there is insufficient data to decide whether the ratios for the two groups are different if age is taken into account. Further observations are being made and will be reported elsewhere. In the meantime it may be observed that the range and the variance of the day/night ratios are greater for the depressives, and that while increasing age might well be associated with a reduction in the amplitude of the diurnal rhythm, there is no reason to suppose that it would produce an actual reversal. Six of our patients showed such a reversal and of these five were diagnosed as depressive.

It seems likely therefore that there are in depressive illness disturbances of the diurnal rhythm of electrolyte excretion which are not secondary to changes in behaviour or diet.

We thank Dr. S. W. Hardwick, Sister Guiver and other members of the staff of the Royal Free Hospital, and Mrs. M. Kerr for advice with statistical analysis. One of us (A. E.) was supported by the Medical Research Council and another (P. B.) by the Mental Health Research Fund.

USE OF PAPER IMPREGNATED WITH ESTERS OF *O*-PHENYLPHENOL TO REDUCE THE ROTTING OF STORED FRUIT

By Dr. R. G. TOMKINS
Ditton Laboratory (Agricultural Research Council), Larkfield, Maidstone

In recent years the use of wraps or liners impregnated with diphenyl has become one of the standard methods for reducing the rotting of oranges. Diphenyl wraps cannot, however, be used to reduce the rotting of fruits other than citrus. All deciduous fruits take up diphenyl from diphenyl treated wraps and acquire an unpleasant taste and attempts to find other volatile fungicidal compounds which could be used instead of diphenyl to reduce the rotting of all stored fruits have so far been only partially successful.

The use of diphenyl was first suggested in 1936 [1,2]. I had previously found that wraps impregnated with iodine[3] reduced the rotting of grapes and of tomatoes, and later found that *o*-phenylphenol alone, or in mineral oil[4], or with hexamine[5] reduced the rotting of citrus and some other fruits. Iodized wraps were found to be effective under commercial conditions, but because they stained the wood wool packing they were commercially unacceptable. Wraps containing *o*-phenylphenol when used on a large scale were found to be unsatisfactory because they often caused damage to fruit. More recently Spenser and Wilkinson[6] found that lentical rotting of apples caused by *Gloeosporium* could be reduced by storing them in trays to which liners impregnated with 2.4.5-trichlorophenoxytrichloromethane had been fixed. Direct contact with the treated liners caused damage to the fruit. Eckert and Kolbezen[7] were able to control the spread of *Rhizopus* in packed tomatoes with paper wraps impregnated with active halogen compounds such as dichloro- or dibromodimethylhydantoin or dichloroisocyanuric acid.

It has now been found that it is possible to reduce the rotting of tomatoes, citrus and some other fruits by the use of paper impregnated with certain esters of *o*-phenylphenol, many of which are both volatile and fungicidal, and if introduced in small quantities into the lid of an inverted Petri dish will inhibit or reduce the rate of growth of fungi on the nutrient medium contained in the upper part of the Petri dish.

The extent of damage caused to fruit by contact with paper impregnated with esters of *o*-phenylphenol varies considerably. Some esters caused an extensive browning or pitting of the surface of some fruit within 3–5 days, though with other fruit there was no damage or so little damage as to warrant small scale trials of the extent to which these esters could reduce rotting of these fruits.

In preliminary trials, wraps (10 in. × 10 in.) containing 50 mg of the *o*-phenylphenol esters of caproic, methoxyacetic, benzoic or crotonic acids were not effective in reducing rotting and did not cause damage. But wraps containing 50 mg of the esters of acetic, propionic, butyric or isobutyric acids considerably reduced the rotting of samples of oranges which had been wounded and loaded with spores of *P. digitatum*. The wraps containing isobutyrate caused no damage to the surface of the oranges, those with acetate or butyrate caused a slight pitting and browning of the surface while those with the propionate caused extensive damage.

In other trials, wraps impregnated with the *o*-phenylphenol esters of acetic, butyric or isobutyric acids were found to be as effective as diphenyl wraps in reducing the rotting of citrus; Table 1, for example, shows the relative effects of paper impregnated either with *o*-phenylphenyl acetate or with diphenyl. In this experiment the *o*-phenylphenyl acetate paper caused slight pitting of the

Table 1. No. (per cent) of Oranges rotting (in Samples of 30), wrapped in Plain Wraps or Wraps impregnated with *o*-Phenylphenyl Acetate, or with Diphenyl

(50 mg per 10 in. × 10 in. wrap)

Temperature of storage	Type of wrap	Days in store 6	11	18	27
20° C	Untreated	97	100		
	Diphenyl	40	97		
	o-Phenylphenyl acetate	23	33	80	90
12° C	Untreated	—	100		
	Diphenyl	—	33	84	84
	o-Phenylphenyl acetate	—	26	67	70
5° C	Untreated	—	—	33	100
	Diphenyl	—	—	10	70
	o-Phenylphenyl acetate	—	—	13	50

oranges. The extent of damage caused by *o*-phenylphenol esters depends in part on the amount contained in the wrap and when the amounts per wrap were reduced from 50 to 25 or 12·5 mg the damage was reduced without their effect on rotting being seriously reduced.

The possibility of reducing liability to damage by dissolving the esters in some mineral or vegetable oil, or other carrier before incorporation in the paper has been considered, but a suitable one has not so far been found.

Table 2 shows the extent to which the rotting of English glass-house tomatoes stored under conditions of high humidity was reduced by the use of wraps impregnated with *o*-phenylphenyl acetate. The wraps were effective even at 40° F, a temperature at which tomatoes suffer low temperature injury and are rendered more liable to rotting. The tomatoes suffered neither damage nor taint. Grapes and some soft fruits appear not to be damaged by contact with paper impregnated with *o*-phenylphenyl acetate. Apples and pears are susceptible to injury but

Table 2. No. (per cent) of Tomatoes rotting (in Samples of 25), wrapped in Plain Wraps and in Wraps containing 12·5 mg of *o*-Phenylphenyl Acetate

Temperature of storage	Type of wrap	Days in store 14	17	21	24	28
15° C	Plain	28	64	84	92	92
	Treated	0	0	0	4	12
10° C	Plain	8	20	48	64	68
	Treated	4	4	4	4	4
5° C	Plain	0	0	44	88	96
	Treated	0	0	0	0	0

in some instances rotting has been reduced without damage to the fruit. Hence it appears that *o*-phenylphenyl acetate (12–25 mg per 10 in. × 10 in. wrap) may well prove a substance which could be used in paper to prevent the rotting of tomatoes and some other deciduous fruits, and that it may also prove as effective as diphenyl in reducing the rotting of citrus.

It may be possible that on further investigation some slightly less volatile ester will be found to be generally more suitable than the acetate and further esters are being examined. The isobutyrate, for example, appears to be less damaging to citrus than the acetate. One reason for exploring the use of *o*-phenylphenol compounds is that data already exists on the extent to which *o*-phenylphenol is taken up by fruit[8] and on the toxicity of *o*-phenylphenol[9]. Dipping in a solution of sodium *o*-phenylphenate alone or with the addition of hexamine or excess sodium hydroxide is extensively used to reduce the rotting of fruit and limits have been fixed in the United States and in England to the amounts of *o*-phenylphenol treated fruits may contain.

It is, of course, possible that esters of *o*-phenylphenol could be used in dips, wax coatings, etc., for the preservation of fruits or other materials of biological origin, but it is their use in paper wraps which appears to be of greatest interest.

The *o*-phenylphenol esters were supplied by Borax Consolidated, Ltd., and Theodore St. Just, Ltd. A provisional patent application (*U.K. PA* 25694/63) covering the use of these esters has been filed jointly by the National Research Development Corporation (acting on behalf of the Agricultural Research Council) and Borax Consolidated, Ltd.

A COMMON LINK BETWEEN PHOTOSYNTHESIS AND RESPIRATION IN A BLUE-GREEN ALGA

By LARRY W. JONES and JACK MYERS

Department of Botany and Zoology, University of Texas, Austin

CONTINUING investigations of the Emerson enhancement effect have revealed in the blue-green alga *Anacystis nidulans* a new phenomenon which appears important to the formulation of a two-light-reaction mechanism for photosynthesis. At wave-lengths absorbed predominantly by chlorophyll *a* the light-intensity curve of photosynthesis shows two distinct linear segments as observed in terms of net rate of oxygen evolution. The phenomenon is far more dramatic and more easily measurable than the minor 'non-linearities' previously observed in *Chlorella*[1].

Independent and prior observation of the same phenomenon has been communicated to us by Hoch, Owens and Kok[2]. Their measurements with a mass spectrometer and oxygen isotopes permitted simultaneous measurement of oxygen uptake and oxygen evolution and provide the key to interpretation. In *Anacystis* they could distinguish between two effects of increasing intensity at 700 mμ: (1) a linearly increasing rate of oxygen production; (2) a depression in rate of oxygen uptake which became saturated at about 50 per cent of the rate in darkness.

Our investigations are carried out with a modified Blinks–Haxo polarographic electrode[3], and therefore are less definitive in measuring only changes in net oxygen exchange. At the same time our precision and rapidity of measurement and our use of two symmetrical light beams of 4·3-mμ half band-width[1] have allowed measurements which broaden the interpretation.

Our electrode is a platinum strip, maintained at 0·5 V (versus saturated calomel electrode), which forms the floor of a chamber 250μ deep and separated from flowing nutrient solution above by a 'Cellophane' membrane. Any change in net rate of oxygen exchange by an algal film, as between light and darkness, is reflected by a proportionate change in current flow. In work with *Chlorella* a film of algal cells was deposited directly on the platinum surface; however, blue-green algae deposited in the same way showed a decaying response to a standard illumination. Analysis of concentration profiles in the electrode chamber leads to the belief that algal cells on the cathode surface experience a very low oxygen concentration, a high OH^- ion concentration, and hence a potentially low concentration of carbon dioxide. We were able to obtain

reasonably stable day-to-day response with *Anacystis* by depositing the cells on an agar layer which held them about 100μ above the platinum cathode surface. One cell preparation then provided stable material over a period of a week although within a series of measurements on one day there was a small measurable decay.

Figs. 1 and 2 show the results of a set of experiments which have been repeated several times with variations only in detail. At a wave-length absorbed predominantly by phycocyanin the rate of net oxygen evolution increases linearly with intensity and the curve extrapolates approximately to the origin (curve *D*). At wave-lengths absorbed predominantly by chlorophyll *a* the corresponding curves (*A*, *B*, *C*) always show two linear segments: a high initial slope at low intensity followed by a lower secondary slope at high intensities. From the analysis of Hoch, Owens and Kok[2], we attribute the high initial slopes to the combined effects of a decreasing rate of oxygen uptake and an increasing rate of oxygen production. The lower slopes at higher intensities represent only the actual rate of oxygen production superimposed on a lowered but now constant rate of oxygen uptake.

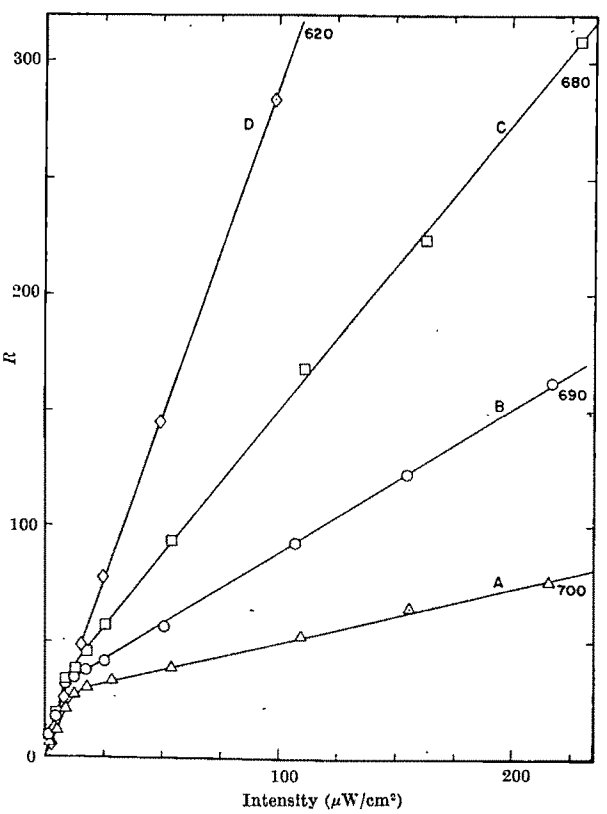

Fig. 1. Net rate of apparent oxygen production, *R*, of *Anacystis nidulans* as a function of light intensity. *R* is measured in relative units of 1×10^{-8} amp change in polarographic current. Each of the curves describes response to the wave-length indicated in mμ. The relatively thick algal film used gave nearly complete light absorption. Experimental temperature was 26° C; the cells had been grown at 37° C under conditions of high cell concentration and high tungsten illumination

Fig. 2 shows the change in rate of net oxygen evolution in response to intensity at 700 mμ when added to a constant background intensity. The reference curve *A* (dark background) is taken from the first set of experiments of Fig. 1. Its slopes are somewhat higher than those of the other curves only because of a measured 10 per cent decay in response which occurred between the two sets of experiments. Curve *E*, obtained with a constant background of 700 mμ, shows only one linear segment extrapolating to zero but otherwise corresponding to the second and lower slope of curve *A*; the low intensity effect has been saturated and obscured by the 700 mμ background.

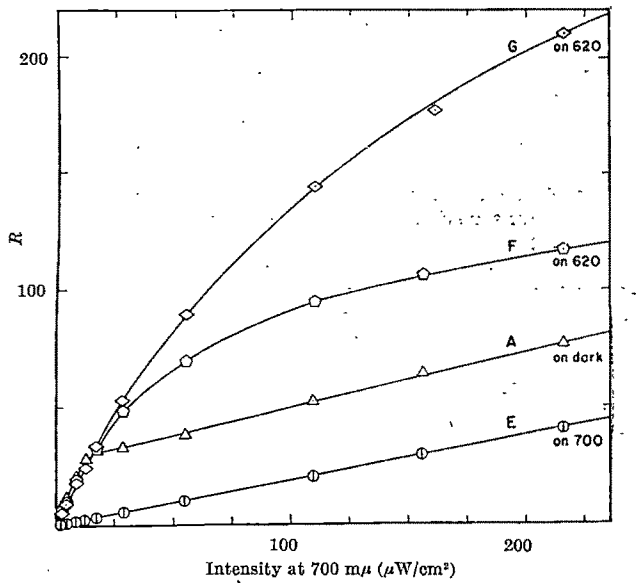

Fig. 2. As Fig. 1, but for response to 700 mμ when superimposed on various background illuminations of constant intensity: *A*, on dark, repeated from Fig. 1 and without correction for small decay in response between the two sets of experiments; *E*, on 180 μW/cm² 700 mμ; *F*, on 35 μW/cm² 620 mμ; *G*, on 145 μW/cm² 620 mμ

Conversely, curves *F* and *G* (620 mμ background) follow the higher initial slope of curve *A* and prolong its duration to an extent dependent on intensity of the 620 mμ background. Curves *F* and *G* demonstrate enhancement. Curve *F*, for the lower level of 620 mμ background, reaches the same final slope common also to curves *A* and *E*; 620 mμ background becomes limiting so that added increments of 700 mμ are not enhanced.

Further treatment of the results is presented in Table 1. The ratio of the slopes of the two linear segments of each of the three wave-lengths is the same as the maximum enhancement attainable at these wave-lengths (columns 2 and 3). The initial high slope at each wave-length (curves *A*, *B*, *C*) is the same as the corresponding slope of its curve when enhanced by 620 mμ background (for example, curve *G*). Columns 4 and 5 demonstrate that for all three of the long wave-lengths chosen there is a common limit to the decrease in oxygen uptake. The actual magnitude of this figure has varied between experiments, apparently depending on thickness of the film and past history of the cells.

Table 1

λ (mμ)	Ratio of slopes initial/ sec	Maximum enhancement*	Magnitude of decrease in oxygen uptake† extrapolated intercept	measured directly‡
680	3·2	3·2	25	28
690	6·2	6·2	27	26
700	10·3	10·6	26	27

* Calculated as $(R_\lambda)_{620}/(R_\lambda)_{700}$.
† In relative units as used in Figs. 1 and 2.
‡ Measured as $(R_\lambda)_{dark} - (R_\lambda)_{700}$ at 25 μW/cm².

Several different lines of investigation[4–7] provide evidence for two light reactions separated by an electron transport system, as originally envisaged by Hill and Bendall[8]. One light reaction, driven by quanta absorbed by accessory pigments, delivers to an electron transport system electrons ultimately derived from the oxidation of water. Electrons pass through the electron transport system in dark reactions and are furnished to a second light reaction. The second light reaction, driven by quanta absorbed by, or transferred through chlorophyll *a*, delivers electrons at a potential capable of phosphopyridine nucleotide reduction.

A low net quantum yield occurs at long wave-length and enhancement becomes possible when the chlorophyll *a* reaction receives quanta at a rate greater than its supply

of electrons. Supplementary light of wave-length absorbed predominantly by accessory pigments increases the rate of the first light reaction and delivers electrons to the second light reaction at a rate potentially in excess. Excess long-wave quanta absorbed by the chlorophyll *a* system then can be used, giving enhancement as measured by oxygen production[1].

In *Anacystis* a higher intensity increment of 700 mμ can be enhanced about 10 times by background light at 620 mμ (Table 1). Hence we estimate that, in the absence of 620 mμ background, approximately 90 per cent of the quanta available to the chlorophyll *a* reaction at 700 mμ is ineffective as measured by oxygen production. However, the effect of a low-intensity increment of 700 mμ light cannot be enhanced as observed in terms of net oxygen exchange. We conclude, therefore, that at long wave-length a large fraction of the quanta available to the chlorophyll *a* reaction can be used effectively in suppressing oxygen uptake. It appears that the electron acceptor for the chlorophyll *a* reaction, the P_{700} of Kok[6], is at least partially a competitor of oxygen as an electron acceptor.

Preliminary experiments with *Anabaena variabilis* show the same phenomenon presented in Fig. 1 except that the initial slopes extend to higher intensities, as might be expected in an alga with a much higher rate of respiration[9]. However, repetition with *Chlorella pyrenoidosa* under present conditions revealed only the minor 'non-linearity' noted previously. Apparently the phenomenon is not general to all photosynthetic systems, but may be common in the blue-green algae. Other observed anomalies[10–12] of effects of light on oxygen exchange do not fit the pattern suggested herein. It seems likely that other interactions between pathways of electron transport for photosynthesis and respiration will be discovered.

For the chlorophyll *a* reaction in algae there now appear to be three possible sources of electrons: (1) the accessory pigment reaction; (2) hydrogen via hydrogenase[13]; (3) respiration.

ASSYNT DYKES AND THEIR METAMORPHISM

By J. TARNEY
Department of Geology, University of Birmingham

FOR many years the unravelling of the history of the metamorphic complexes of the Lewisian rocks of the north-west Highlands of Scotland and the Hebrides has been greatly aided by a swarm of dolerite dykes, commonly known as the 'Scourie' dykes. At the beginning of the century, the Geological Survey workers[1] recognized that these dykes, intruded into the Early Gneiss Complex, were later affected by the 'Pre-Torridonian Movements'. Sutton and Watson[2] elaborated on these events and used the terms 'Scourian' and 'Laxfordian' to describe the two metamorphic periods separated by the period of dyke intrusion.

The intrusion of basic dykes with chilled margins into the 'Scourian' complex was thought indicative "that this section of the crust had become rigid enough to fracture and cool enough for basaltic magma to chill rapidly", and that "when the dolerites were intruded all metamorphism had ceased"[2]. Absolute age determinations by Giletti *et al.*[3] showed that at least 800 m.y. separated the two metamorphisms, but the exact position of the dolerite dykes on this extended time scale has until very recently remained unknown.

During the past two years, however, the re-interpretation of these early generalizations by various workers has aroused much controversy. O'Hara[4] has regarded the development of a hornblende-plagioclase ± garnet assemblage in the chilled margins of the basic dykes in the Scourie area as being an autometamorphic effect, best explained by intrusion of the dolerite magma into the gneiss "at a time when the rocks were still deeply buried and relatively hot (a temperature of 300°–500° C would be consistent both with chilling of the magma and with the generation of amphibolite facies assemblages)". Dearnley[5], on the other hand, has suggested that these margins may record the existence of an 'Early Laxfordian' granulite facies metamorphism which he recognizes in the Outer Hebrides.

Evidence that there may be more than one series of basic dykes in the Lewisian has been advanced by Park and Bowes[6] on the basis of the structural relations at Gairloch and they regard the later set as being contemporaneous with the Laxfordian metamorphic event. Wright[7] has put forward similar suggestions. Other workers have, however, expressed disagreement with such interpretations.

O'Hara[8] has described four different types of dykes—an amphibolite, a norite, a typical 'Scourie' dolerite, and thin ultrabasic dykes—in close association near Badcall, Sutherland, and again reiterates his view that these dykes were intruded into hot country rock and that there was no great period of uplift coincident with the intrusion of these dykes.

Thus the main arguments seem to centre on the age or ages of the basic dykes, the conditions under which they were intruded and the variety of dyke types represented. It is the purpose of this article to summarize some of my observations which may be of interest in these respects.

The Assynt district is favoured by perhaps the greatest concentration of intrusive dykes on the whole foreland and has been commonly regarded as an area little modified by the effects of the Laxfordian metamorphism[2,5]. At least eight types of dykes can be recognized in the area:

(1) *The 'Epidiorites' of the Survey.* Quite abundantly represented, thick quartz dolerites with distinctive coarse gabbroic texture. Rather rarely fresh central parts of these dykes are preserved; otherwise the whole suite is completely amphibolized and usually recrystallized in the lower amphibolite facies.

(2) *Dolerite dykes.* Similar to (1), but richer in pyroxene and with less quartz. Two pyroxene types are also represented. As with the epidiorites much of the suite is completely altered.

(3) *Loch Crocach 'Peridotite'*. This dyke and its branches is completely altered throughout its length. Ghost textures in the tremolite–biotite–plagioclase assemblage suggest an original pyroxene-rich dolerite.

(4) *Picritic dykes.* Olivine–orthopyroxene–augite–plagioclase–biotite dykes which are often wide and rather coarse grained. The margins of these dykes are orthopyroxene-rich and not chilled. These dykes are all slightly different from each other, so were probably not intruded simultaneously. They are considerably less altered than the basic dykes in the same areas, though nevertheless altered rock is more abundant than fresh rock.

(5) *Olivine gabbro dykes.* Olivine–augite–orthopyroxene–plagioclase–biotite–kaersutite–ore dykes, probably related to the picrites. These dykes have finer grained augite-rich margins, but are not chilled. Their state of alteration is comparable with that of the picrites.

(6) *Thin finer-grained dolerites found in the vicinity of Loch Assynt.* These dykes have a similar mineralogy to the earlier dolerites—augite–plagioclase–quartz–primary green hornblende–biotite–ore—but the plagioclase displays a characteristic deep brownish clouding. In spite of their narrow width these dykes are considerably less altered than the earlier basic dykes in comparable areas. Occasional chilled veins of these dykes are seen to cut the picrites.

(7) *Two pyroxene dolerites, with minor olivine, which is largely enclosed by the orthopyroxene.* One dyke on the south side of Loch Assynt is completely fresh and has unaltered chilled margins. Some probably related dykes on the north-east side of Loch Assynt show low-grade alteration.

(8) *Thin basic dyke running to the south of and parallel to the picrite ('Teall's Dyke') west of Loch Assynt.* This is an olivine–augite–plagioclase–biotite–ore rock and the absence of quartz and hypersthene, the sodic character of the plagioclase and the high content of biotite suggest that it may be of alkali type. The dyke is unusually fresh, the development of secondary amphibole being limited to an inch or so at the margins.

The order given here is, on the available evidence, the order of intrusion as found in the field, except that there is no evidence as to the relative order of intrusion of the last three dyke types.

What is significant is that the various dyke types have undergone different degrees of alteration and recrystallization, and that the extent of this is roughly related to the order of intrusion, with the earlier dykes being more altered. These features are difficult to reconcile with a period of metamorphism after the intrusion of the various dykes, but the relations become more feasible if it is postulated that the dykes were intruded during and towards the close of a metamorphic episode, with the degree of alteration being dependent on the length of time being spent under metamorphic conditions. It may be mentioned in passing that a high proportion of the gneisses in Assynt have a lower amphibolite or upper greenschist facies mineralogy; pyroxene gneisses have a very limited distribution. Most of the altered basic dykes belong to the lower amphibolite or upper greenschist facies (see also ref. 9).

Confirmatory evidence that the picritic and olivine–gabbro dykes were intruded into hot country rock is provided by the coarse-grained margins of these dykes and also by the complex crystallization history which they have undergone which is difficult to interpret except under conditions of slow cooling at depth. The chilled margins of the basic dykes are probably more a function of the higher viscosity of the magma than of the temperature of the country rock.

Some idea of the relative temperature of the gneiss at the time of intrusion and alteration of the picrites is afforded by the common occurrence of the assemblage olivine–tremolite–chlorite ± talc in the thoroughly altered picrite dykes wherever the original rock contained an excess of olivine. Serpentine is not developed. This stability of olivine in a hydrous environment would indicate temperatures of about 500° C according to the experimental data of Bowen and Tuttle[10] on the MgO–SiO_2–H_2O system.

Another interesting feature of the picrites, particularly with regard to the high proportion of olivine and orthopyroxene they contain, is the complete absence of any indication of the common reaction relationship between these two minerals, as seen in near surface intrusions. Boyd and England[11] have recently shown that the reaction relation is eliminated at high pressures and their experiments suggested a pressure of about 5–6 kbar as the minimum necessary to overcome the relationship. The depths of the Earth's crust corresponding to these pressures would be about 15–20 km, and temperatures at these depths would be about 500° C under typical values for the geothermal gradient of 25°–30°/km. This temperature is not in conflict with that suggested here by the stability of the dyke olivines. Hence these values serve to confirm the view that the Assynt dykes (except perhaps the later three types) were intruded at considerable depth into hot country rock, and that their intrusion clearly does not mark a period of great uplift of the basement rocks.

The effects of the early metamorphism of the basic and ultrabasic dykes are most widespread in the western part of the area, particularly near the belt of west-north-west–east-north-east trending vertical gneisses north of Lochinver. Here the ultrabasic dykes have suffered considerable chemical interchange at their margins with the gneisses or adjacent basic dykes, and the typical assemblage tremolite–chlorite ± anthophyllite of the centre gives way at the margins to a conspicuous green actinolite ± plagioclase rock. However, carbon dioxide has also been an important and widespread influence during the metamorphism such that dolomite becomes a common phase in the assemblages developed, and the anthophyllite and even tremolite are replaced by talc and dolomite. The carbon dioxide has also caused widespread development of scapolite from plagioclase in the green actinolitic margins of the ultrabasic dykes, in some basic dykes, and, in favourable structural situations small masses of gneiss may even be completely replaced by scapolite. Tourmaline is found locally in the dyke margins.

Much of this alteration and metasomatic activity predates the strong shearing characteristic of the Laxfordian. One major shear belt recognized by the Survey workers[1] runs south-eastwards from Clachtoll, following the belt of vertical gneisses, towards Glen Canisp. In this belt the central parts of the ultrabasic dykes have been converted to soft talc–carbonate schists while the green margins remain as more massive actinolite schists. In some extreme cases the central parts of the dykes may be largely sheared out, leaving lenses of green actinolite rock in a matrix of talc schist. All scapolite is destroyed in the sheared rocks.

The three later dyke types listed here have largely escaped the effects of the hydrous metamorphism and the later shearing, though type 6 has suffered marginal shearing in one locality. Their true age must remain for the moment unknown, but it is likely from their fresh and finer grained nature that they are considerably later than the picrites.

The investigations in Assynt therefore confirm O'Hara's contention that the Scourie dykes were intruded at great depth under metamorphic conditions. It is clear also that a variety of dyke types exist in the Lewisian, including possible alkali types, and that, judging from their states of alteration, not all are of the same age. The early dykes, and especially the picrites, record an extensive period of metamorphism and local metasomatism which is demonstrably earlier than the strong shearing and reconstitution of the Laxfordian event, and which is

probably pene-contemporaneous with the dykes themselves.

SIGNIFICANCE OF DIFFERENCES IN MAGNETIZATION ALONG CERTAIN DOLERITE DYKES

By Dr. D. W. POWELL
Department of Geology, University of Glasgow

SYSTEMATIC changes in magnetization have been found by measurements at localities spaced along certain dolerite dykes. The iron-oxide minerals in these dolerites have been investigated and related to a magnetic parameter. The nature of the mineralogical control on the magnetization and the distribution of iron-oxide minerals in the dykes are considered especially in relation to sills fed by the dykes.

Magnetic measurements. The natural magnetization of a dyke is generally the resultant of an induced component, KT (susceptibility × Earth's magnetic field strength) and a remanent component, J_n. Their ratio ($Q_n = J_n/KT$) is used here as a parameter of magnetization. At sixteen localities these components have been calculated from measurements on cylindrical cores cut from specimens collected at points across exposed dykes. An a.c. bridge apparatus was used to measure K and an astatic magnetometer to measure J_n. Two specimens with contrasted Q_n ratios were also a.c. demagnetized and heated to compare their J_n stabilities and the Curie points of their magnetic minerals respectively.

At the same localities and some others vertical force magnetometer profiles were surveyed across the dykes. These anomalies generally had a shape comparable with that due to a uniformly magnetized dyke. This shape is principally determined by the inclination of the magnetization, with respect to the dyke walls, in the plane normal to the dyke and to a lesser extent by the ratio of dyke width (W) to the depth of its top surface below the plane of measurement (D). Since field observations show that the dykes trend east–west, dip nearly vertically and, at exposures, have W/D ratios of 10–20, the geometric parameters are known. Since KT and the stable J_n direction (see below) lie at known inclinations in the plane normal to the dykes, their ratio, Q_n, can be expressed in terms of profile shape, in particular maximum peak/minimum peak amplitudes (R) (Fig. 1).

The results from both methods at three localities, chosen to illustrate the range of Q_n, are shown in Fig. 1. A consistent J_n direction, namely, north polarity directed horizontally towards the south, resistant to a.c. demagnetization, that is, stable, is shown by specimens with a high Q_n value. Other contemporaneous, that is, Permo-Carboniferous igneous, rocks in Britain are similarly magnetized[1–3]. Scattered J_n directions and easy a.c. demagnetization characterize specimens with low Q_n values. Specimens from the intermediate locality show varying degrees of stability[4].

Although specimen values of K and J_n vary in magnitude across these dykes they do so in the same sense tending to minimize variations in Q_n. Since the maximum Q_n range encountered between specimens from one locality is 0·3–0·7 whereas the maximum range of average values between localities is 0·1–2·0 the latter are more important. They are shown in Table 1 with profile estimates.

The tendency for profile values of Q_n to exceed specimen values could be a result of outcrop sampling since the former apply to volumes of rock extending to a depth below outcrop greater than the dyke widths where J_n may be effectively larger due to more consistent orientation[3].

The profile Q_n values along dykes in the vicinity of sills are shown in Fig. 2. Localities where profiles depart from simple dyke anomalies are indicated by a question mark or a specimen value in brackets. These localities are generally where the magnetization changes abruptly and are probably lateral discontinuities, such as en echelon offsets, in the dykes. For individual dykes Q_n varies mainly with K (Fig. 2, section along dyke C).

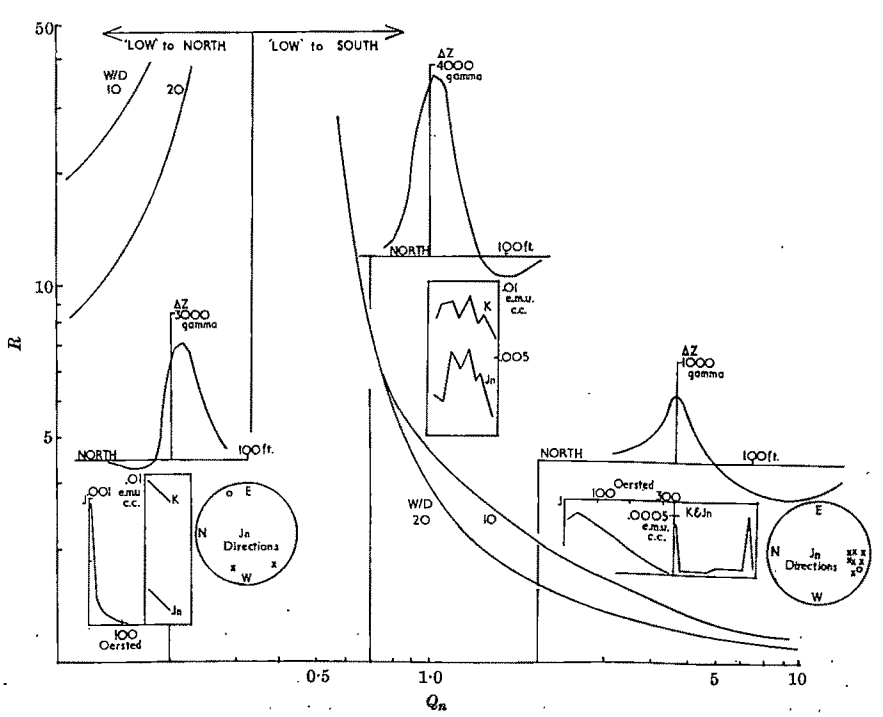

Fig. 1. Magnetometer profiles related to Q_n values and specimen measurements

TiO_2 (% wt.)	2·3	2·0	2·2	2·2	2·2	2·2

Mineralogical measurements. Observations, in reflected light, on cores from fifteen specimens show two variables in the character of their magnetite grains. Most apparent are differences in the frequency of ilmenite lamellæ within the magnetites; less obvious is a patchy alteration affecting those magnetites containing most ilmenite.

The specimens range from those with up to 80 per cent of their opaques as fresh, ilmenite-poor, magnetites with low Q_n values to those with rather altered magnetites containing many ilmenite lamellæ and up to 30 per cent of their opaques as separate ilmenite grains and having high Q_n values. Sulphides, mainly pyrite, may be more abundant in the latter specimens.

The alteration is to a mineral of lower reflectivity than the magnetite, that is, not typical maghemite. Comparable magnetites with ilmenite in a 400-ft. sill associated with the dykes are partially altered to maghemite and also have a stable remanence[3]. Petrographically similar Tertiary dolerite sheets in Japan have an unstable remanence where their magnetites are altered to maghemite but show increasing stability in proportion to the volume of ilmenite lamellæ in their magnetites[5]. The reversed magnetization of Mull Tertiary basalts is associated with ilmenite exsolution lamellæ in their magnetites[6].

For quantitative comparison with magnetic properties the strongly magnetic grains were separated from the powder (< 100 mesh) of six specimens covering a range of Q_n values (Table 2). All these contained 10–15 per cent weight opaque minerals (estimated from micrometric counts), but their magnetic fractions decreased with increasing Q_n. The proportion of ilmenite, as lamellæ, to magnetite increased with Q_n (X-ray determinations). The amounts of $TiFe_2O_4$ in solid solution in the magnetite, inferred from cell dimensions, and the amounts of FeO, Fe_2O_3 and TiO_2 in the rocks as a whole showed no systematic changes.

Mineralogical control of magnetization. It is apparent that the fresh magnetite grains, generally 0·25–0·5 mm diameter and containing only a few traces of ilmenite lamellæ, give rise to an unstable remanence. On heating, a specimen of this type showed a single Curie point at 510° C consistent with a magnetite of low $TiFe_2O_4$ content[7].

Some feature of the magnetite in the composite altered magnetite/ilmenite grains must give rise to the stable remanence. The cell dimensions and Curie point (590° C) of this magnetite show it to be similar in composition to that in the dolerites with unstable remanence.

The differences in shape and size of the magnetite in the two types of grains suggest a possible cause for their magnetic differences. Coercivity increases with decreasing grain size; the effect being significant for grains less than 0·1 mm diameter and large for grains less than 0·02 mm diameter[8]. The sub-division of the 0·5 mm composite grains by their ilmenite lamellæ may reduce the magnetite to about 0·1 mm. However, some specimens showing ilmenite lamellæ but only minor magnetite alteration are relatively unstable suggesting that the alteration is the more important factor. Although the alteration product is not typical maghemite, the stable magnetization may be comparable with the thermochemical remanence consequent on oxidation of titanomagnetite at elevated temperatures[9].

Q_n values related to dykes which fed sills. The dykes are part of an east–west trending Permo-Carboniferous swarm in the Midland Valley of Scotland[10]. Individual dykes are about 100 ft. wide, have near vertical margins and some can be traced for more than 20 miles. Petrologically similar quartz-dolerites and tholeiites occur as sills[10], up to 400 ft. thick, which have two main outcrops, more than 10 miles apart, on the flanks of the Central Coalfield Syncline. A borehole at Rashiehill[11], near the synclinal axis, proved sill *X–X′* at depth. West of the sharp Riggin Anticlinal axis (*X*-outcrop), sill *X–X′* pinches out near dyke *E* and also thins out south-westwards[12].

Since sills *X–X′* and *Y–Y′* lie at different levels and terminate against dyke *C*, it probably fed them[12]. Similarly, dyke *G* fed sill *Z* and dyke *A* may have fed the lowest sill at *X′*. Dyke *A* may have fed the sills at *X*, which it meets at their thickest point. The dyke east

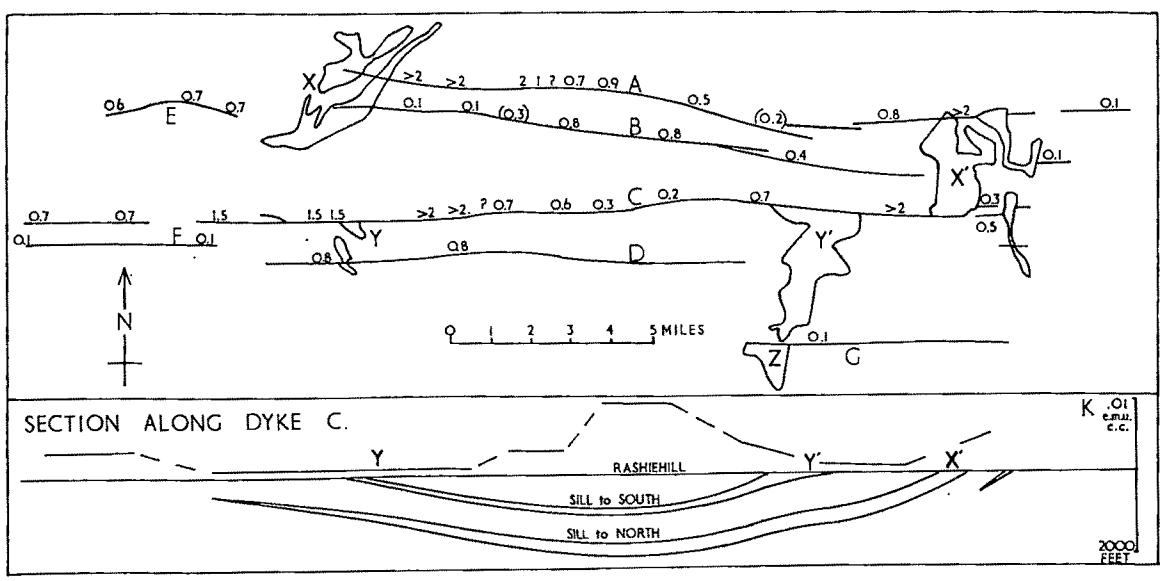

Fig. 2. Distribution of Q_n values along dykes related to sills

of X' and in line with dyke B could be a feeder from its mapped relationships. Dyke B probably intrudes sills at X (ref. 12.)

The distribution of Q_n values along the dykes which fed sills (Fig. 2) suggests that the iron-oxide minerals in these dykes vary with distances above and below the sills. Thus both dykes A and C show an increase in susceptibility, that is, low Q_n values, where they rise farthest above the sills near the centre of the Syncline. They both show high Q_n values where they are immediately above the sills. Dykes east of the sill outcrops X' and Z, that is, immediately below them, show low Q_n values. It is possible that the low Q_n values on dykes A, C, B and F indicate the former presence of now completely eroded higher sills in the areas of the Riggin and south-west of it and also in the axial region of the Syncline.

The dyke rocks immediately above the sill connexions are probably similar to the normal sill dolerite since the Rashiehill borehole core material also has a stable remanence and contains composite magnetite/ilmenite grains[3]. Comparably magnetized dolerites do, however, occur at some localities along dykes of the same swarm near Auchterader, 25 miles to the north, which intrude Lower Old Red Sandstone strata and are unlikely to be closely connected with sills. Low Q_n values along dykes are, so far, restricted to those shown in Fig. 2.

It appears then that the different modes of iron-oxide crystallization and alteration in the dykes have at least been influenced by conditions occurring during the crystallization of the magma in the sills fed by them. The magnetite/ilmenite intergrowths could be derived from a homogeneous phase by exsolution and oxidation. Such a primary phase would have crystallized at higher temperature under more reduced conditions than the magnetites carrying only traces of ilmenite[13]. The later alteration of magnetite associated with ilmenite suggests the effect of hydrothermal solutions, end-products of sill crystallization[14], affecting both the rocks in sills and overlying parts of connected dykes.

I thank Dr. C. W. F. Everitt for arranging certain laboratory facilities in the Physics Department in the Imperial College of Science and Technology, London; Dr. A. P. Millman for microscopic identification of opaque minerals; Dr. W. A. Mitchell for X-ray identification of opaque minerals; Dr. D. R. Bowes for advice on chemical analyses and Dr. W. Bullerwell for information on the Auchterader dykes.

A MATHEMATICAL MODEL OF A PERCEPTUAL MAZE TEST

By Dr. R. A. BUCKINGHAM, Dr. A. ELITHORN, D. N. LEE and W. L. B. NIXON
University of London Computer Unit, Institute of Neurology and Royal Free Hospital, London

IN the majority of intelligence tests no attempt is made to explain the difference in difficulty between test items, and few workers have tried to find any objective measure of increasing complexity to correlate with empirical tests of intelligence[1]. The essence of this problem is the development of families of test items which can be ordered theoretically in a systematic way so that this order can be related to subjective difficulty.

If the individual items in a test can be ordered logically then the relationship between these items can be given a mathematical form. This can be achieved more elegantly and almost certainly more fruitfully if the nature of the test material is such that its physical or perceptual characteristics can themselves be expressed simply in mathematical terms. Many non-verbal intelligence tests require the subject to discriminate spatial or geometric relationships. There is no inherent reason why this type of test should not be constructed systematically, but in practice this is almost never attempted. We describe here a test the perceptual characteristics of which can be rigorously defined and for which a mathematical notation can be developed to describe any parameters which might be related to the subjective difficulty of different items. This test is derived from a perceptual maze test which experimental studies have already shown to be sensitive to organic brain damage[2]. Other investigations have shown that it has a high reliability, and that scores obtained on the test correlate with those obtained on other tests of intelligence[3].

Fig. 1 shows a sample item from the test discussed in the present article. The subject is required to find a pathway from the bottom vertex to the top row which satisfies the following conditions: it must lie only along the small-dotted lines; it must be unidirectional in a general upward sense; it must pass through the greatest number of the larger black dots. Apart from the physical dimensions of the lattice and the target dots there are three variables: (*a*) the number of horizontal rows in the lattice (n) (the vertex is excluded); (*b*) the saturation (s), that is, the ratio of number of target dots to the total number of lattice points, the vertex again being omitted; (*c*) the arrangement of the dots on the lattice, a 'pattern' factor (p).

The first two parameters are clearly amenable to exact treatment and have already been made the subject of an experimental study[4]. The analysis of the 'pattern' factor (p), however, presents a formidable problem. For a lattice with 16 rows, and a variable number of dots, there are 2^{152} (more than $5{\cdot}7 \times 10^{45}$) different patterns; even with s specified, for example, at 50 per cent, there are $\binom{152}{76}$, more than $3{\cdot}6 \times 10^{44}$ patterns. Clearly the value of making an analysis of the pattern factor will depend on the practicability of developing a method of classification which can be related to psychological concepts which may explain the problem solving behaviour involved.

The psychological interest of this test material lies not in the ways in which the problem can be solved—there is no difficulty in devising a computer programme to produce a solution, and we are indebted to Mr. C. D. Alway for a particularly elegant strategy which once learnt enables most human subjects to solve fairly rapidly any pattern of any reasonable size—but in the ways in which the majority of human subjects actually solve the problems and the reasons why these fail, when the complexity of the items increases. It has been suggested that the commonest strategy is a perceptual scanning in which links are sought between areas which appear to contain

relatively high concentrations of target dots. One source of difficulty is that relationships which are irrelevant to the task, for example, horizontal groupings, may remain perceptually attractive. The topological relationships between the target dots can thus be considered from two aspects. The first of these takes account only of the rules of the problem and is 'task-orientated'. It is concerned with such questions as whether one dot is accessible from another, and how many dots may be obtained on pathways between two dots. The second aspect considers perceptual relationships between dots which are irrelevant to the task but which may, nevertheless, influence subjects in their choice of solution pathways.

What is needed, therefore, is a notation which not only permits a comprehensive description of every possible path but which also facilitates an analysis in terms of the remaining relationships between the target dots. We present here such a system and illustrate briefly how it might be developed for analysing some of the task-orientated pattern complexities which it seems possible may be related to the subjective difficulty of test items.

A system of co-ordinates (p,q) is defined, where $p = 0,1,2 \ldots n$ = the row number, numbering from the bottom vertex to the top; and $q = 0,1,2 \ldots p$ = the position of the point in the p^{th} row, numbering from left to right. Necessary and sufficient conditions for the accessibility of a point (p_j, q_j) from a point (p_i, q_i) are then:

$$p_j > p_i$$
$$p_j - p_i \geqslant q_j - q_i$$
$$q_j \geqslant q_i$$

and it may easily be shown that:

n_{ij} = No. of pathways from the point (p_i, q_i) to the point (p_j, q_j)

$$= \binom{p_j - p_i}{q_j - q_i}$$

Suppose that the maze dots are labelled 1, 2, 3 . . . r by starting at the bottom vertex and working along consecutive rows from left to right, and that the dot labelled i is situated at the point (p_i, q_i) for $i = 1, 2, 3 \ldots r$, then the number of pathways between dot i and dot j is:

$$n_{ij} = \binom{p_j - p_i}{q_j - q_i}$$

In addition we define, for $i = 1, 2 \ldots r$,

n_{oi} = number of pathways from the bottom vertex, $(p,q) = (o, o)$, up to the dot i

$$= \binom{p_i}{q_i}$$

and n_{if} = number of pathways from dot i up to the top row of the maze $= 2^{n-p_i}$.

Of course, n_{of} equals 2^n.

We may now define the matrix $N = (n_{ij})$ for $i, j = 0, 1, 2 \ldots r, f$. The matrix is square and of order $(r + 2)$. It is also clear that $n_{ij} = o$ if $i > j$, or if $i = f \neq j$: and if we further define $n_{ii} = o$ for $i = 0, 1, 2 \ldots r, f$, then N is an upper triangular matrix with zeros down the main diagonal. In this notation o and f are equivalent to dots in the sense that they are points at which paths start and end, and so they will be referred to as such in the following. But it must be remembered that o and f are never targets and hence never contribute to the score.

If m = maximum score obtainable on the maze there exists a sequence of matrices:

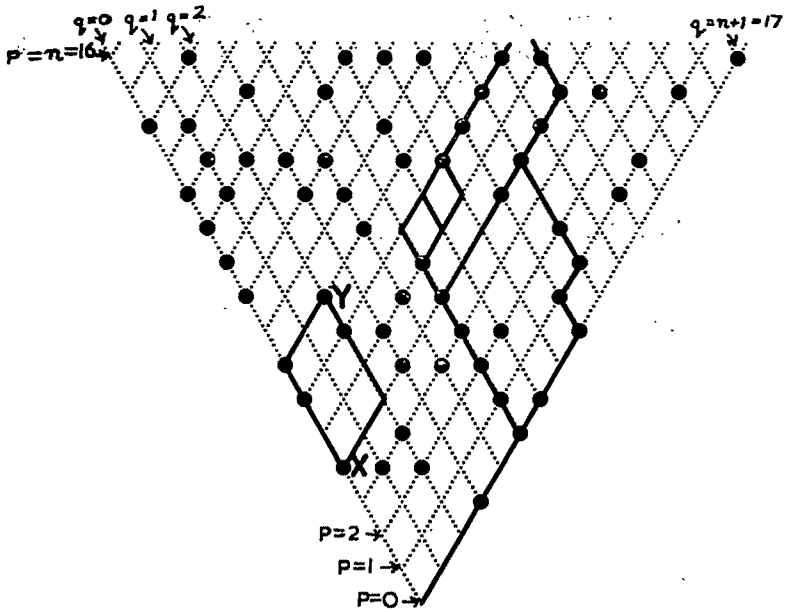

Fig. 1. An example of a test item incorporating information to illustrate some of the mathematical concepts derived in the text. Here the maximum score, m, is 11, and there are 5 solution pathways (that is, $v_{of}^{(12)} = (M^{12})_{of} = 5$), which are drawn in. However, the number of solution sets of dots = 3 (that is, $v_{of}^{(12)'} = (M'^{12})_{of} = 3$). The small parallelogram section on the left-hand side of the figure illustrates the co-ordinate system. The dot at lattice point X is designated by $i = 2$, and the lattice co-ordinates of dot j (pt. X) are $(p_i, q_i) = (4,0)$: for the dot at lattice point Y we have $j = 20$, and $(p_j, q_j) = (9, 2)$. Then the total number of pathways between dot i and dot j (that is, between X and Y) is given by:

$$n_{ij} = \binom{p_j - p_i}{q_j - q_i} = \binom{9 - 4}{2 - 0} = 10$$

The number of these pathways which pass through 0, 1 and 2 dots between dot i and dot j are given respectively by:

$$V_{ij}^{(0)} = M_{ij} = 2; \quad V_{ij}^{(1} = (M^2)_{ij} = 6; \quad V_{ij}^{(2)} = (M^3)_{ij} = 2$$

$$V^{(\alpha)} = (v_{ij}{}^{(\alpha)}), \; i, j = 0, 1, 2 \ldots r, f; \; \alpha = 0, 1, 2 \ldots m$$

where $v_{ij}{}^{(\alpha)}$ = number of pathways between dots i and j passing through α dots (excluding dots i and j) for $i, j = 1, 2 \ldots r$. $v_{oi}{}^{(\alpha)}$. $v_{if}{}^{(\alpha)}$ are similarly defined for $i = 1, 2 \ldots r$. Each of the $V^{(\alpha)}$ matrices is of the same form as N and it may be shown that $V^{(\alpha)} = M^{\alpha+1}$ where M is a matrix such that $M = N(I + N)^{-1}$ and I is the $(r + 2) \times (r + 2)$ unit matrix.

The set $v_{of}{}^{(\alpha)}$, $\alpha = 0, 1, 2 \ldots m$, is the frequency-of-scores set for the whole maze: and the sets with different suffixes give the corresponding frequency-of-scores set for different portions of the maze.

Possibly useful statistics, which may be easily derived from the foregoing are:

(1) The total score matrix $T^{(1)} = N^2$, giving the total score between two dot points (excluding these dots in totalling the score), and likewise between the vertex and a dot, the vertex and the top and a dot and the top.

(2) The sum of squares of scores matrix $T^{(2)}$
$$= N^2(I + 2N)$$

(3) The variance of scores matrix $T^{(3)}$, where:

$$t_{ij}{}^{(3)} = \frac{1}{n_{ij}} \left[t_{ij}{}^{(2)} - \frac{(t_{ij}{}^{(1)})^2}{n_{ij}} \right]$$

If the whole-maze frequency-of-scores set (that is, $v_{of}{}^{(\alpha)}$) for each member of the set of mazes of given parameters (n, r) is considered, there are $\binom{x}{r}$ members of the set, where $x = \dfrac{n(n + 3)}{2}$ = number of lattice points; then totalling these frequencies over all mazes of the set, it may be shown that the total frequency-of-scores set is given by:

$$v_T{}^{(\alpha)}(n,r) = \sum_{\substack{\text{all mazes} \\ \text{of } (n,r) \text{ set}}} v_{of}{}^{(\alpha)} = 2^n \binom{n}{\alpha} \binom{x - n}{r - \alpha}, \; \alpha = 0, 1, 2 \ldots n.$$

The expected frequency-of-scores set for a (n,r) maze is therefore:

$$\left[\nu_T^{(\alpha)}(r,n) \Big/ \binom{x}{r} \right], \ \alpha = 0, 1, 2 \ldots n.$$

These and other statistics concerning the distribution of scores may be used to define parameters for the maze which may be related to subjective difficulty.

In this notation m_{ij} equals the number of pathways between dot i and dot j with zero score ($i, j = 0, 1, 2 \ldots r, f$): and if $m_{ij} > 0$, then we may say that dot j is directly accessible from dot i. Developing this concept we may use a binary notation in the form of matrix $M' = (m'_{ij})$ $(i, j = 0, 1, 2 \ldots r, f)$ where $m'_{ij} = 1$ if $m_{ij} > 0$ (that is, if j is directly accessible from i) and $= 0$ otherwise. Matrices $V^{(\alpha)\prime}$, $T^{(1)\prime}$, $T^{(2)\prime}$, $T^{(3)\prime}$ may also be derived corresponding to the unprimed matrices given here. The basic difference between the two sets of matrices is that in the first set the number of different pathways with score α between dots i and j is considered, whereas in the second series the number of different sets of α dots lying on pathways between dots i and j is the underlying concept. Thus, for example, $\nu_{of}{}^{(m)\prime}$ gives the number of different solution sets of dots.

Further, the dots (not including o and f) may be divided into n groups corresponding to the n horizontal maze rows, and the vector (d_p) may be defined, where $d_p =$ number of dots on the p^{th} horizontal maze row $(p = 1, 2 \ldots n)$.

The matrix M' may now be partitioned into sub-matrices $R_{\alpha\beta}$ where α, β refer to maze rows; here 'maze rows' are taken to include a zero row and an f row and so $\alpha, \beta = 0, 1, 2 \ldots n, f$. $R_{\alpha\beta}$ is a $d_\alpha \times d_\beta$ matrix which gives direct accessibility relationships between dots on the α^{th} row and the β^{th} row. Again, $R_{\alpha\beta} = O$ if $\alpha \geqslant \beta$.

Since one theory describing maze problem-solving activity postulates that individuals differ in the size of the perceptual unit which they use, it seems relevant to illustrate one way in which the present approach could be used to analyse this aspect of the problem. To do this we have defined as a Δ any maze-linked set of dots. A Δ is designated by $\delta(\nu,\gamma)$ where ν is the number of dots in the Δ and γ is the number of gaps, or vacant sites, interspersed between the dots. Now considering M' in the partitioned form $R_{\alpha\beta}$ $(\alpha, \beta = 0, 1, 2 \ldots n, f)$ which is an upper triangular matrix with zero sub-matrices $R_{\alpha\alpha}$ in the main diagonal, then it will be seen that the $\delta(\nu,\gamma)$'s are given by the $(\nu - 1 + \gamma)$th parallel of sub-matrices of $M'^{\nu-1}$. If the partitioned matrix $M'_{(\rho)}$ is defined so that $M'_{(\rho)}$ has the same first ρ parallels of sub-matrices as M' but all other parallels consist of zero sub-matrices, then it will be seen that the $\delta(\nu,\gamma)$'s are given by the $(\nu - 1 + \gamma)$th parallel of sub-matrices of $M'^{\nu-1}_{(\gamma+1)}$. In the particular case of the complete solution Δ's, that is, the $\delta(m + 2, n-m)$'s these are given by the $(n + 1)$th parallel of sub-matrices of $M'^{m+1}_{(n-m+1)}$. In other words, $M'_{(n-m+1)}$ and not M' need be considered for the solution. Thus for a maze with $n = 16$, $m = 12$ (that is, $n - m + 1 = 5$), the subject need only consider direct accessibility relationships between dots which are separated by not more than five maze rows.

The foregoing mathematical analysis is one of several which might be equally or more valuable. It is presented in this form because it deals primarily with the target dot relationships and so lends itself to a study of the problem-solving activity involved. It has, we hope, been developed sufficiently to show that a systematic analysis of this test material is both practical and potentially fruitful.

We thank Dr. A. M. Uttley, Mr. C. D. Alway, Mr. E. F. Davis and other members of the Autonomics and Mathematics Divisions of the National Physical Laboratory, and also Mrs. M. Kerr, for advice. Two of us (A. E. and D. N. L.) are receiving support from the Medical Research Council.

DISTORTION OF VISUAL SPACE AS INAPPROPRIATE CONSTANCY SCALING

By R. L. GREGORY
Psychological Laboratory, University of Cambridge

DISTORTIONS of visual space associated with certain simple patterns have been investigated since the beginning of experimental psychology[1], and many theories have been proposed[2], but so far none, in my opinion, has been satisfactory in explaining these so-called 'geometrical' illusions. Figs. 1, 2 and 3 show representative illusions of the kind we are considering.

The traditional theories fall into three classes: (1) That certain shapes produce, or tend to produce, abnormal eye movements. (2) That some kind of central 'confusion' is produced by certain shapes, particularly non-parallel lines and corners. (3) That the figures suggest depth by perspective, and that this 'suggestion' in some way distorts visual space.

The eye movement theories are difficult to support because the illusions occur undiminished when the retinal image is optically stabilized on the retina[3], or when the figures are viewed as after-images following illumination by a bright flash of light. Further, since distortions can occur in opposed directions at the same time (as with the Müller–Lyer figure[4] (Fig. 1*a*) it is difficult to see how either overt or incipient eye movements could be involved. The various 'confusion' theories all suffer from vagueness, and they give us no idea as to why the distortions should occur in the observed directions, or only in certain kinds of figures. The perspective theory[2] is inadequate because it does not suggest why or how perspective should produce distortions in flat figures, but it does imply a generalization which seems to hold true of all the known illusion figures, and this gives a clue vital to understanding the origin of the illusions.

The illusion figures may be thought of as flat projections of typical views of objects lying in three-dimensional space. For example, the outward-going Müller–Lyer arrow figure is a typical projection of, say, the corner of a room—the fins representing the intersections of the walls with the ceiling and floor—while the in-going arrow is a typical projection of an outside corner of a house or a box, the converging lines receding into the distance. The following generalization seems to hold for all the illusion figures thought of in this way: The parts of the figures corresponding to distant objects are expanded and the parts corresponding to nearer objects are reduced. Thus in the Müller–Lyer figure the vertical line would be further away in the diverging case, and is expanded in the illusion, and vice versa, while in the Ponzo figure

the upper horizontal line would be farther away and it also is expanded in the flat illusion figure.

Given that this generalization holds for all the illusions, why should these distortions occur ?

Do we know of any other perceptual phenomena involving systematic perceptual modification of the retinal image ? There is a well-known set of phenomena which certainly does involve perceptual modification of retinal images—size constancy[5,6]. This is the tendency for objects to appear much the same size over a wide range of distance

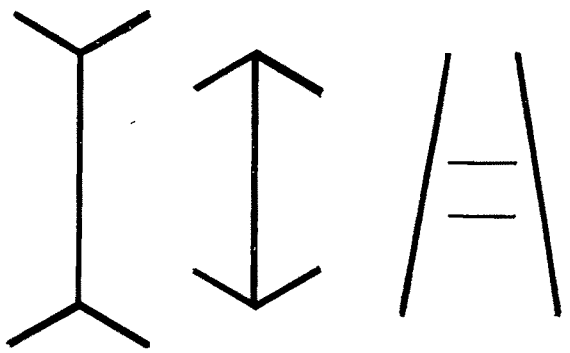

Fig. 1. (*a*) The Müller-Lyer; (*b*) the Ponzo illusion

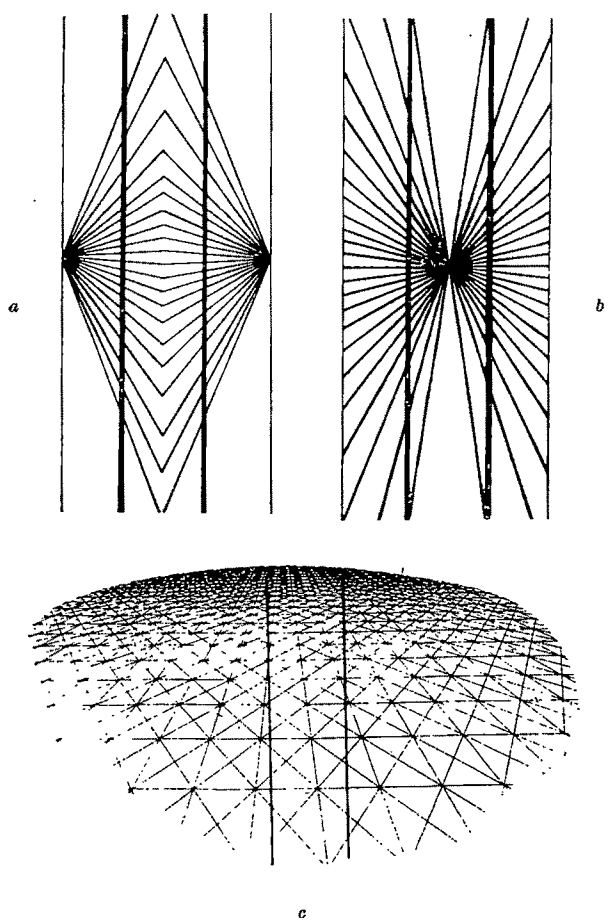

Fig. 2. (*a*) and (*b*) Alternative forms of the Hering illusion. The vertical lines are bowed inwards and outwards, respectively. (*c*) An illusion showing how parallel lines indicating distance seem to diverge when presented on a texture gradient. (The texture taken from Gibson, *The Perception of the Visual World*. 1951)

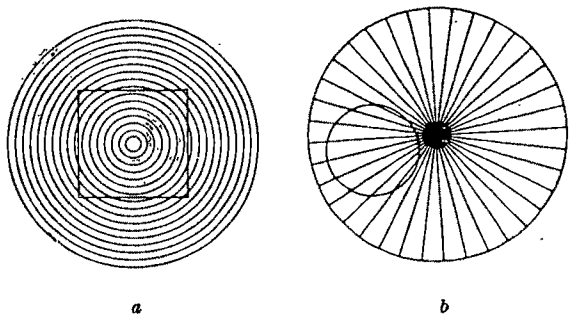

Fig. 3. Further distortions to be expected on the distance hypothesis; the concentric circles and spokes set the constancy scaling by indicating depth. (Figures, though not interpretation, from Orbison, *Amer. J. Psychol.*, 52, 39; 1939)

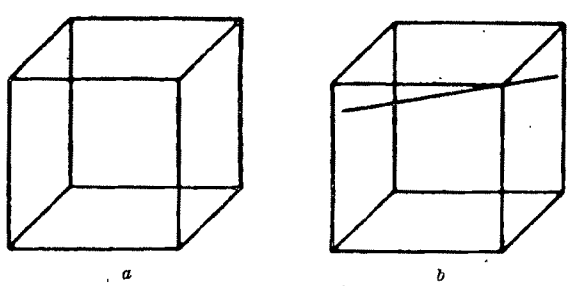
in spite of the changes of the retinal images associated with distance of the object. We may refer to the processes involved as constancy scaling. Now in constancy scaling we find known processes which not only could but also must produce distortion of visual space if the scaling were set inappropriately to the distance of an observed object. It is strange that apparently only one writer, Tausch, has considered constancy in connexion with the geometrical illusions[7].

We can see our own scaling system at work in the following demonstration of Emmert's law[8]. The after-image of a bright light is 'projected' on to a series of screens lying at various distances, or a single screen moved away or towards the observer. Although the effective retinal image is constant, the after-image perceived as lying on a screen looks larger the farther the screen is from the observer. Complete constancy would give a doubling in size for each doubling of distance, and the amount of scaling can be quantified under various conditions for stationary or moving screens[9,10].

Clearly inappropriate constancy scaling would produce distortion of visual space, but why should this occur with the illusion figures which are in fact flat and are generally seen to be flat ? It is generally assumed that constancy scaling depends simply on apparent distance (as Emmert's law might suggest); but if we are to suppose that constancy scaling can operate for figures clearly lying on a flat surface we must challenge this assumption, and suggest that visual features associated with distance can modify constancy scaling even when no depth is seen. If we are to suppose that the illusions are due to misplaced constancy scaling, we must suppose that the scaling can be set directly by depth features of flat figures, and that the scaling is not set simply as a function of apparent distance as is generally thought to be the case.



Perspective drawings and photographs are seen to depict objects as if they lay in three dimensions, and yet at the same time they appear flat, lying on the plane of the paper, and so they are perceptually paradoxical. The surface texture of the paper evidently prevents the perspective from making the objects appear truly three dimensional, for if we remove all texture and view with one eye, then perspective drawings can look as impressively in depth as the real world viewed with one eye.

We have presented the well-known illusion figures with no background texture—by making wire models coated in luminous paint so that they glow in the dark, or using back illuminated transparencies—and we find that, viewed with one eye, they look three dimensional, provided the angles are not marked exaggerations of perspective. The Müller–Lyer arrows, for example, look like corners and not like flat projections when presented as luminous figures in the dark, and those parts which appear most distant are the parts which are expanded in the illusions as normally presented on textured paper. What happens to the distortions when we remove the background texture

is complex, and will be discussed more fully elsewhere; but, in general, distortions are reduced or disappear.

Emmert's law may suggest that constancy scaling arises directly from apparent distance; but there is retinal information indicating the distance of each position of the screen, and possibly this might serve directly to set the scaling. However, the following demonstration shows conclusively that scaling can occur simply as a function of apparent depth and independently of retinal or other sensory information.

Fig. 4*a* shows the well-known Necker cube figure—a skeleton cube which reverses spontaneously in depth so that sometimes one face, sometimes another, appears the nearer. As shown on textured paper, it is paradoxical in the manner described here—it looks as if it were in depth and yet it is seen to be flat on the paper. By making a luminous model of this figure, and viewing it in the dark, we find that it still reverses but now it looks like a true three-dimensional figure, and it undergoes size changes—the apparently farther face looking somewhat larger than the nearer, showing that constancy scaling is now operating. Since the retinal image remains unchanged it follows that the scaling is set under these conditions as a simple function of apparent distance. This is shown most dramatically with a three-dimensional luminous cube. This looks like a true cube when seen correctly, but when perceptually reversed in depth it looks like a truncated pyramid, the apparently front face being the smaller[11].

a *b*

Fig. 4. (*a*) The Necker cube. This reverses in depth. When viewed as a self-luminous figure, the apparent front looks smaller, the back larger. (*b*) Humphrey's figure. The oblique line is seen as slightly bent; the direction of bending being determined by the angle against which it is placed, and not by the way the cube appears to lie in depth

It thus appears that there are two ways in which constancy scaling can be set. We may name these:

(1) *Primary constancy scaling.* This is set by perspective or other features normally associated with distance. These features can be at variance with apparent distance in special cases, such as the illusion figures. (We call it 'primary' because it seems to be primitive, and to be mediated by neural systems situated early in the perceptual system.)

(2) *Secondary constancy scaling* is set simply by apparent distance, and this may be a function of previous knowledge and is not necessarily tied directly to visual information. Its existence is suggested but not proved by Emmert's law; but it is conclusively demonstrated with the ambiguous self-luminous objects which change their shape systematically according to which faces appear nearer or farther though there is no change in the retinal image. Errors in apparent distance should produce distortion of visual space via this secondary scaling system, and the well-known moon illusion may be an example.

Although the self-luminous figures do clearly demonstrate what we have called the secondary constancy scaling system, what clear evidence have we for the primary system, supposed to be set by typical depth cues even in the absence of depth perception? For our present purpose it is much more important to demonstrate the existence of primary than secondary scaling. To get evidence for primary scaling entirely independent of the illusions is very difficult, but the following is at least suggestive.

(1) It has been noticed by Humphrey[12] that a straight line drawn across a corner of a Necker cube (Fig. 4*b*) appears bent. Now this is particularly interesting because the direction of bending is the same which ever way the cube appears to lie in depth. It is bent in the direction to be expected if constancy scaling is operating from the typical perspective interpretation of the angle against which the line lies.

(2) In primitive races living in houses without corners the geometrical illusions are reduced[13,14]. If learning is important, this would be expected.

(3) In a case of a man blind from the first few months of life, but gaining his sight after operation fifty years later, we have found that the illusions were largely absent, and his constancy appeared abnormal or absent although he could at that time, some weeks after the corneal graft operation, recognize common objects[15]. This has been noted in other cases. (In fact, it was this observation which suggested to me this kind of theory of the illusions.)

We should expect the different scaling systems to have somewhat different time-constants, and we are attempting to measure these to establish their separate existence quite apart from considerations of distortions of visual space.

It further may be suggested that figural after-effects —distortions similar to the geometrical illusions, but produced as a result of prolonged viewing of a suitable stimulus pattern and transferring to a second test pattern—may be due to the primary scaling being set by depth features present in the stimulus pattern, this scaling taking some time after lengthy fixation to become appropriate to the second test pattern, so the second pattern is distorted by scaling carried over from the earlier pattern. Preliminary experiments are providing strong evidence that figural after-effects can be thought of in this way, and such a theory would have advantages over present theories of the figural after-effects which are *ad hoc*, involve dubious physiological speculation and fail to make useful predictions[16,17].

In attempting to give a general account of all illusions involving systematic distortions of visual space, either while viewing a figure or following on prolonged viewing, and relating the distortions to a known perceptual phenomenon—size constancy—we have not attempted to specify the neural processes involved, and we believe this to be impossible at this time. Recent work on recording from the visual regions of the cat's brain while presenting the eyes with moving or fixed patterns[18] gives promise that the underlying neural mechanisms may soon be revealed.

This work was supported by the U.S. Air Force under grant No. *AF–EOAR* 63–93 and monitored by the European Office, Office of Aerospace Research and also by the Medical Research Council.

ASTRONOMY

A Supernova Remnant in the Large Magellanic Cloud

THE proximity of the Large Magellanic Cloud offers an unparalleled opportunity for the detailed comparison of an external galaxy at optical and radio wave-lengths. Recently the 210-ft. steerable reflector at the Australian National Radio Astronomy Observatory has been used to survey the Large Cloud at a number of wave-lengths between 11 cm and 220 cm. The results of this work have been presented at the recent International Astronomical Union/International Scientific Radio Union Symposium No. 20 (ref. 1).

Fig. 1. $H\alpha$ photograph of *N49* taken with the Uppsala Schmidt telescope

The high resolving power and sensitivity of the 210-ft. reflector at short wave-lengths enabled the radio emissivities of about 40 emission nebulæ in the main body of the Large Cloud to be determined. Observations of these *H*II regions were carried out at 21 cm and 11 cm where the aerial beam-widths at half-intensity points are 14′ of arc and 7·5′ of arc respectively and the receiving systems allow temperature differences of 0·1° K to be measured. For each *H*II region, the expected flux density at 11 cm was calculated from the $H\beta$ flux densities of Dickel, Aller and Faulkner[2] and the $H\alpha$ flux densities of Doherty, Henize and Aller[3] and compared with the observed flux density. In most cases reasonable agreement was obtained between the radio and optical observations which was consistent with a thermal origin of the radio emission.

However, in the case of one small emission nebula listed as N49 in the catalogue of Henize[4], the flux density at 11 cm ($1{\cdot}3 \times 10^{-26}$ W m^{-2}(c/s)$^{-1}$) is some 15 times greater than that calculated from the $H\alpha$ intensity. This suggests that a considerable proportion of the radio emission could be of non-thermal origin. Our measured position at 11 cm of (1950·0) R.A. $05^h\ 26^m{\cdot}0$, Dec. $-66°\ 08'$, is within 0·5′ of arc (our experimental accuracy) of the optical position. Combining our intensity measurements of *N49* at 11·21 and 75 cm and that of the Mills, Slee and Hill[5] source (05–64) at 85·5 Mc/s, the spectrum has an index of -1 which clearly indicates a non-thermal origin of the radiation. Mills, Slee and Hill give an estimate of the east–west diameter of 0·5′ of arc which is in fair agreement with the overall optical size of 1′ of arc.

Fig. 1 shows the region of *N49*. The photograph is from a 7-min exposure in $H\alpha$ light with the 20/26-in. Schmidt telescope of the Uppsala Southern Station. It may be noted that no exciting star can be seen in the nebula either in Fig. 1 or on longer exposures. On a 1-h exposure in ultra-violet light with the Uppsala Schmidt telescope the central part of *N49* is filled by weak emission but no stellar object appears. The nebula shows a looped filamentary structure characteristic of remnants of galactic supernovæ. Henize[4] also reported strong OI emission from *N49* which is another characteristic feature of these objects[6].

It therefore appears reasonable to assume on the basis of these radio and optical observations that *N49* is a supernova remnant in the Large Magellanic Cloud and is the first such remnant to be discovered in an external galaxy. The outer diameter of the looped structure of *N49* is 16 parsecs and the inner diameter is 6 parsecs, using 55 kiloparsecs as the distance to the Large Cloud. If we assume an expansion rate of 5,000 km/sec for the supernova shell with no deceleration due to collision with interstellar matter then the minimum age is 1,500 years. The intrinsic radio luminosity of *N49* is only 5 times less than Cassiopeia *A*, the most intense of the known galactic supernovæ. It is of interest to note that the spectral indices of the radio emission from Cassiopeia *A* and *N49* are very similar and much 'steeper' than that of other galactic supernovæ.

If Shklovsky's[7] formula for the variation of flux density with radius of supernova remnants is applied, it is found that *N49* would be intrinsically 1,000 times more intense than Cassiopeia *A* at comparable ages. Such supernovæ in the first few years of their existence would be readily observable with existing radio telescopes in galaxies many megaparsecs distant.

RADIO ASTRONOMY

Angular Size of Radio Stars

The existence of a number of radio sources with an angular extension less than 1″ is well known[1]. Some of them were identified with star-like objects and therefore they are referred to as radio stars. Among these are 3*C*-48, 3*C*-119, 3*C*-147, 3*C*-273, 3*C*-286. Their non-thermal spectra and the evidence of a rather strong linear polarization suggest the synchrotron mechanism of radio emission. Twiss[2], Razin[3], and Le Roux[4] have shown that a self-absorption of synchrotron radiation by relativistic electrons must occur at frequencies $f < f_1$, f_1 depending on relativistic electrons concentration, normal component of magnetic field $H_\perp$, spectral index of radio emission α (the spectrum being of the form $S(f) \propto f^{-\alpha}$), and on linear dimension of radio-emitting region. At frequencies below f_1 the spectrum of radio emission is $S(f) \propto f^{2.5}$ whatever α is, thus f_1 is a frequency where maximum flux density of a radio source occurs.

Using well-known formulæ for synchrotron radiation, it is possible to derive f_1 as a function of the observational values of flux density $S(f)$, apparent angular diameter θ and spectral index α:

$$f_1 = K(\alpha)\,[S(f_2)\,.\,\theta^{-2}\,.\,f_2^{\alpha}\,.\,10^{33}]^{\frac{1}{2.5+\alpha}}\,H_\perp^{\frac{1}{5+2\alpha}} \quad (1)$$

where $K(\alpha)$ is the slowly varying function of spectral index α of order of unity, $S(f_2)$—flux density in M.K.S. units at a frequency $f_2 > f_1$, not affected by self-absorption.

$H_\perp$ is the only term in equation (1) which cannot be obtained through direct radio astronomy measurements, but there is a good chance for a reasonable use of equation (1), since f_1 appears to be quite insensitive of $H_\perp$ ($f_1 \propto H_\perp^{1/7}$). In this communication $H_\perp$ is equal to 10^{-4} gauss.

Considerations of possible red shift effects show that f_1 in equation (1) must be increased by a factor $(1 + Z)^{\frac{1}{5+2\alpha}}$, where $Z = \frac{\Delta\lambda}{\lambda_0}$; for $Z < 10$ the red shift factor is less than 1·4. Therefore, equation (1) is also insensitive to red shift.

Inspection of equation (1) reveals dependence of self-absorption on the surface brightness temperature of a radio source. The sources with very high brightness temperature due to self-absorption must show a sharp 'fall-off' of the flux density at metre wave-lengths, while in sources with relatively low-brightness temperature the 'fall-off' occurs at decametre wave-lengths and is due mainly to absorption by ionized hydrogen. For example, the critical frequency f_1 for self-absorption in *M*31 (Andromeda nebula) is 0·1 Mc/s, in Cygnus-*A*, 10 Mc/s, in 'radio-stars' more than 20 Mc/s, depending on their angular size.

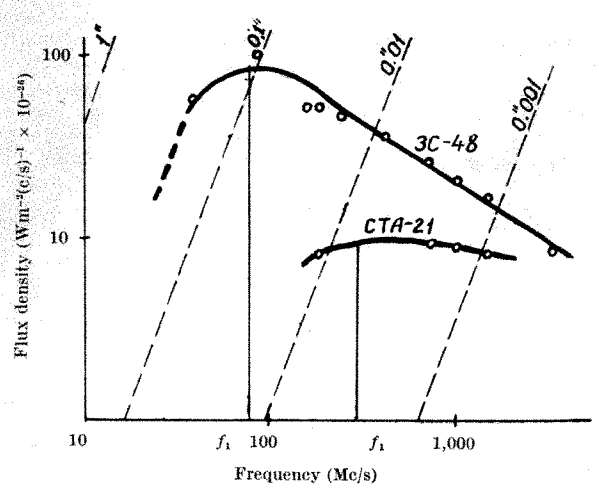

Fig. 1. Spectra of radio sources 3*C*-48 and *CTA*-21. Dashed lines represent equation $\log S = 2{\cdot}5 \log f + \log 0{\cdot}14\,\theta^2$ (S in 10^{-26} W per m² per hertz, f in Mc/s, θ in sec of arc)

The spectrum of 3*C*-48 is shown in Fig. 1, all data except for 81·5 Mc/s are taken from ref. 5 and flux density at 81·5 Mc/s is taken from 2*C* catalogue. The spectrum shows a distinct maximum near 70 Mc/s, which may be due to self-absorption. Apparently the self-absorption of synchrotron radiation may account for observed correlation of spectrum curvature and high brightness temperature[6].

It is possible from equation (1) to derive an expression for the apparent angular diameter in terms of maximum flux density and critical frequency f_1 (including the red shift correction):

$$\theta = 4{\cdot}3 \times 10^{16}\,[S(f_1)]^{0.5}\,f_1^{-1.25}\,H_\perp^{0.25}\,(1 + Z)^{0.25} \quad (2)$$

The radio source 3*C*-48 then turns out to be 0·14″ in diameter. Fig. 1 also shows a spectrum of radio source *CTA*-21 with a maximum near 300 Mc/s, which corresponds to an angular diameter 0·01″. Dashed lines in Fig. 1 represent possible positions of maxima of spectra for radio sources with angular diameters of 1″; 0·1″, 0·01″ and 0·001″.

Comparison of Fig. 1 with spectra of all 160 discrete sources given in ref. 5 shows that there are no sources with apparent angular diameters less than 0·02″, except for *CTA*-21 and *CTA*-102 which may be of the order of 0·01″. The same conclusion holds for all sources of revised 3*C* catalogue. This means that angular diameters of all non-thermal sources known greatly exceed angular diameter of stars and therefore so-called radio stars identified with star-like objects in fact are not stars and there are no stars among the radio sources known at the present time.

This conclusion may be of interest to cosmology regarding the minimum angular size of radio sources predicted by cosmological models.

I thank Prof. J. S. Shklovsky and Dr. N. S. Kardashev for helpful discussions.

A Radio Source with a Very Unusual Spectrum

Conway, Kellerman and Long[1] have recently determined the spectra of 160 radio sources in the wave-length range of 10 cm–26 m. Their results were obtained by combining measurements at nine wave-lengths made at the California Institute of Technology, Mullard and Nuffield Radio Observatories. At wave-lengths longer than 20 cm they found that most of the spectra could be represented by power laws and that the median spectral slope was 0·7. Two notable exceptions are the sources *CTA* 21 and *CTA* 102 (ref. 2) which have curved spectra with maxima in the region of 30–50 cm. These two objects were originally found from observations at 30 cm whereas all the others were selected from the 3*C* (ref. 3) and the Mills, Slee and Hill (MSH) (ref. 4) catalogues. As these surveys were made at wave-lengths of 2 and 3·5 m respectively, selection from them would tend to discriminate against objects of the type of *CTA* 21 and *CTA* 102. Kellerman (private communication) has pointed out that it is important to know the relative population of such sources because of their possible influence on source counts at different wave-lengths.

We have recently made a survey of the sky south of −20° declination at a wave-length of 75 cm with the

210-ft. telescope. Sources of flux density greater than 4×10^{-26} W m^{-2} (c/s)$^{-1}$ were afterwards observed at 22 and 11 cm. The catalogue comprises 300 objects with galactic latitude greater than $\pm 10°$ and of these 230 occur in the MSH catalogue. On linear extrapolation of the spectra defined by the 22 and 75 cm measurements, some 50 would be below 15×10^{-26} W m^{-2} (c/s)$^{-1}$ at 3·5 m and thus might not be expected in the MSH catalogue. On the same basis, the other 20 would be well above the lower limit of the MSH survey. The absence of a few of these could be due to their proximity to side-lobe regions of the cross-aerial associated with strong sources. However, the remainder could be explained in terms of strong curvature in their spectra between 75 cm and 3·5 m. For 3 out of the 230 sources common to both surveys there is reasonably direct evidence of maxima in the spectra in the decimetre wave-length range. It seems, therefore, that the frequency of occurrence of objects such as *CTA* 21 and *CTA* 102 lies somewhere between 1 and 6 per cent and thus they should not have a significant effect on source counts.

The most unusual case we have of a curved spectrum (Fig. 1) is that of the source which we have designated 1934–63. Its co-ordinates are:

R.A. 19h 34m 46s ± 4s (1950)
δ −63° 49·4′ ± 0·5′

Between 10 and 50 cm the flux densities were measured relative to Hercules-*A* as the two were comparable in this range; above 70 cm they were measured relative to a nearby source, MSH 19–56, which has about the same flux density at 75 cm and has a well-defined power-law spectrum. The angular size of the source is not known, but as it does not noticeably broaden the aerial beam at 11 cm it must be less than 2′ of arc. Linear polarization is less than 2 per cent at 11 cm and less than 1 per cent at 22 cm. A 74-in. plate taken by Dr. Bengt Westerlund at Mount Stromlo Observatory shows no prominent visible counterpart for the source although there are several galaxies of about eighteenth magnitude in or near the error area.

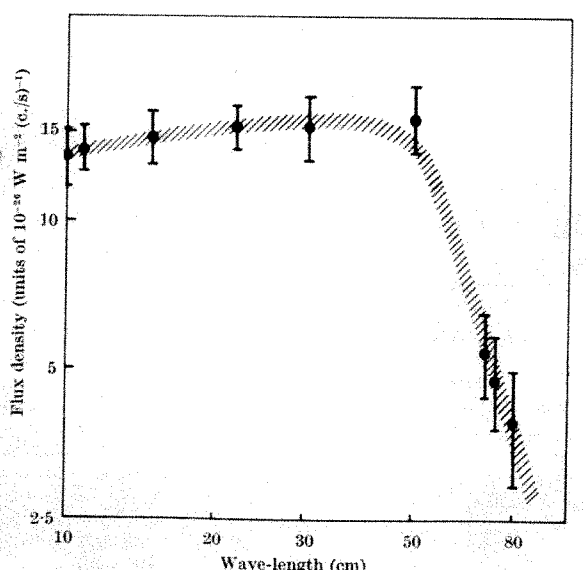

Fig. 1. Radio spectrum of the source 1934–63. Both scales are logarithmic

The marked difference between the spectra of *CTA* 21 and *CTA* 102 and this new object lies in its extremely sharp long-wave-length cut-off. The gradual slopes of *CTA* 21 and *CTA* 102 are just consistent with the assumption of radiation from an almost mono-energetic electron spectrum. With 1934–63 the sharp cut-off appears to rule out an origin solely in an emission process and suggests the presence of an absorbing or reflecting medium in front of a normal non-thermal source. Even in this case extremely high values of optical depth or plasma critical frequency are required. A knowledge of the angular size and thus surface brightness temperature is required before possible models can be profitably investigated.

PHYSICS

Stimulated Compton Scattering of Electrons by Standing Waves of Light

The production of very intense visible radiation by lasers has facilitated investigations of the interactions between photons and electrons. A recent communication shows that for the case of a beam of multi-GeV electrons incident head-on upon a ruby-laser beam, Compton scattering produces an appreciable quantity of high-energy scattered photons, which largely preserve their initial polarization[1]. Thomson scattering of a laser beam by a beam of 2-KeV electrons has been observed experimentally[2].

It is interesting that, thirty years ago, Kapitza and Dirac calculated the probability of reflexion of very-low-energy electrons from standing waves of light[3]. Because the standing wave-train gives rise to stimulated Compton transitions, Bragg's law is obeyed, one-half the light wave-length being equivalent to the lattice spacing. This, of course, is a non-linear effect distinct from that cited in the previous paragraph. Using Thomson's formula, the probability of an electron being deflected is shown to be:

$$\frac{e^4 L}{2m^2c^2h^2\nu^4 v}\int I_\nu I'_\nu d\nu$$

L is the length of the electron path through the light beam and v is the electron velocity. I'_ν is the energy of the stimulating beam per unit area per unit time per unit frequency-range. I_ν is the corresponding quantity for an element of the incident beam, the total energy per unit area per unit time of which is $I_0 = \int I_\nu d\nu$.

It was concluded by the authors that the experiment could not be made with the apparatus then available. For example, the probability of deflexion of 25-eV electrons from standing waves produced by a mercury arc delivering 1 W at 5461 Å with a band-width of 0·1 Å is about 10^{-14}.

The probability depends on the square of the intensities, however, and the advent of lasers would seem to bring the experiment within range of possibility. Using values characteristic of ruby lasers produced commercially—power output 10 kW and line-width of 0·04 Å—the probability of electron deflexion is increased to the order of 10^{-7}. Experimental problems, while far from trivial, appear to be surmountable. The primary and deflected beams lie very close together, and separating them may be somewhat difficult.

I thank the Socony Mobil Oil Co., Inc., for permission to publish this communication, and Prof. Richard H. Milburn for criticisms and suggestions.

Basic Concepts of Measurement and the Michelson–Morley Experiment

One of the reasons for the success of the scientific method is the rigorous control of the conditions of measurement. The effect of varying one parameter is examined while the other conditions are maintained constant. It must not be overlooked, however, that some of the conditions cannot be varied, and their effects cannot therefore be examined in this way. All measurements which have been made so far have been carried out on the Earth's surface where there is a strong gravitational field due to the Earth, a rotational velocity, and a centrifugal force balancing the Sun's gravitational field.

The effect of this permanent environment is usually ignored. It is ignored, for example, in the definition of the units of measurement. Although the units of mass length and time are regarded as independent this is not quite true since their experimental realization must be effected in the gravitational field having dimensions involving both length and time. Moreover, since the Earth's gravitational field cannot be varied and indirect effects produced by the field cannot be examined, no allowance can be made for them. Possible effects of the field are ignored in experiments concerned with electricity and magnetism and in the formulation of the laws of electromagnetism including the velocity of propagation of electromagnetic waves.

In view of these unavoidable difficulties care must be taken in the interpretation of experimental results and theoretical predictions. The laws of physics developed in this particular environment might be expected to hold within this environment but not necessarily outside it. Consider the Earth revolving around the Sun. Its gravitational field moves with it, the gravitational field of the Sun is always balanced by the centrifugal force and the rotation of the Earth on its axis remains the same. The environment is unaltered and the laws might be expected to remain valid. In particular there is no reason to expect a change in the speed of light in consequence of the Earth's movement around the Sun and a null result would be expected for the Michelson–Morley experiment.

If, however, we assume that the particular environment can be ignored and that the speed given by Maxwell's theory is the 'free-space' speed, as is usually done, then a positive result would be expected. The simplest interpretation of the null result is that this extrapolation to 'free-space' propagation cannot be made. There is nothing to indicate whether the environment affects the propagation of light or the units of length and time; but if, as in the special theory of relativity, the velocity of light is made constant by definition, then it is the units of length and time which must be affected.

The contraction of length and time. The null result of the Michelson–Morley experiment can be brought into accord with the conception of free space velocity if the unit of length is changed so that the arm of the instrument in the direction of the movement around the Sun is reduced in length in the ratio $(1-v^2/c^2)^{1/2}$. Then, in order to preserve the constancy of the velocity of light, the unit of time must be modified in the same way. This purely empirical adjustment of the units is to be regarded as a first attempt to free the units of measurement from the restriction placed by the Earth's environment.

If one seeks a physical cause for the necessity of these adjustments it seems reasonable to look for it in the Earth's environment which is known to differ from the ideal 'free-space' condition.

Einstein's special theory of relativity. It seems to me that the derivation of the time and space contraction in Einstein's special theory is equally empirical. It is true that Einstein's paper[1] contains an important section on the synchronization of clocks in which it is pointed out that distant clocks cannot be synchronized unless some assumptions are made about the velocity of light. This section is particularly relevant to experiments that may be made in the future with atomic clocks in artificial satellites, but it is not relevant to any measurements that have been made in the past. Nor do these ideas play an important part in the derivation of the Lorentz transformations in Einstein's paper. He uses them to define time in such a way as to eliminate the ordinary pre-relativity Doppler effect, but this is a convenience rather than a necessity. It has been shown that the well-known clock paradox is predicted by the theory only by changing the meaning of the symbols during the course of the argument[2–4]; but there seems to be a more serious contradiction which has not yet been explained or indeed aroused any comment. This is, that although the theory is in accord with experimental results obtained in the Earth's environment, and was indeed inspired by the difficulty in explaining the Michelson–Morley result, the theory itself is deliberately restricted to another environment in which there is no gravitational field.

An experimental approach to gravitation. The main purpose of this communication is to direct attention to the fact that the restrictions in the environment placed by the gravitational field have at last been removed. Satellites have so far been used mainly to overcome the effects of the Earth's atmosphere on the absorption of electromagnetic and other radiations and to investigate the magnetic field and ionization at greater distances from the Earth than is possible by older methods. But the balancing of the Earth's gravitational pull by a centrifugal force may be a more important advantage. It may be possible to investigate gravitational and inertial effects by controlled experiment. Even simple experiments like Newton's rotating bucket might yield interesting results; and techniques now exist for measuring the precise frequency of atomic oscillators travelling in satellites both by means of recording instruments in the satellite and radio transmissions to Earth.

Thermal Resistivity of Irradiated Graphite

Mason and Knibbs[1] have recently measured the thermal resistivity of polycrystalline graphite of various crystallite sizes irradiated for various doses at 250°–275° C. They explain the extra phonon scattering arising from the irradiation by attributing it to interstitial clusters, one cluster per crystallite-plane, and they reckon that vacancies make only a small contribution. This explanation is not entirely satisfying. For, at all crystallite sizes studied[1], the increase of thermal resistivity on irradiation was found experimentally to be comparable with the thermal resistivity before irradiation, implying that the mean free path of scattering from irradiation-induced defects, L_i, is comparable with the mean free path for crystallite-boundary scattering, L_a, which is taken as equal to the mean crystallite diameter. This means that if there is only one scattering defect per crystallite-plane, then the diameter of this defect is a substantial fraction of the crystallite diameter, and therefore the concentration of surviving interstitials is large, say at least 10 per cent. With a dose of only 177 MWD/Ate, however, the number of displaced atoms calculated by the Kinchin–Pease method[2] is only about 2 per cent and at 250° C a large proportion of these are lost by recombination with vacancies; this is confirmed by electron microscopy of single crystals[3] and by stored energy results[4]. There cannot,

therefore, be enough interstitials to construct the defects postulated.

As an alternative approach, we regard the grain boundary as a sink or gutter for interstitials, and we assume that free clusters do not occur in fine-grained material of the type studied. If the vacancies are dispersed throughout the lattice as immobile singles and their concentration is n_0 per lattice atom, and if we assume that the rates of reaction between the mobile interstitials and (*a*) the vacancies and (*b*) the crystallite boundary are proportional to the perimeter of the vacancies and of the boundary respectively[5], we deduce that:

$$dn_0/dt = cL_a/n_0L_a^2$$

where c is a constant of order unity, L_a is the crystallite size measured in units of 1·62 Å (the mean diameter of a graphite atom), and where t represents dose in units of 10^4 MWD/Ate, this being the dose in which all lattice atoms are displaced on the average once by the irradiation. Integrating, we obtain $n_0 = (2ct/L_a)^{1/2}$. The phonon-scattering cross-section of a vacancy is of the order of its geometrical cross-section[6], so the corresponding mean free path, L_v, is of the order of $1/n_0$ atoms. The thermal resistivity is therefore represented theoretically by:

$$\frac{1}{K} = \text{const.}\left(\frac{1}{L_a} + \frac{1}{L_v}\right) = \text{const.}\left(\frac{1}{L_a} + (2c)^{1/2}\frac{t^{1/2}}{L_a^{1/2}}\right)$$

The experimental results of Mason and Knibbs[1] can be represented well enough by:

$$\frac{1}{K} = 1{,}040\left(\frac{1}{L_a} + \frac{t^{1/2}}{L_a^{1/2}}\right) \quad (K \text{ in c.g.s.u.})$$

which is of the required form. By comparison, $c = 0{\cdot}5$. This value is satisfactorily near unity; I shall not discuss it further here, as it includes various factors the theoretical value of which it is difficult to estimate accurately.

GEOLOGY

New Isotopic Age Measurements from the McMurdo Sound Area, Antarctica

Subsequent to the publication[1,2] of potassium/argon dates from basement rocks of the McMurdo Sound area, a few additional dates have been obtained. As shown in Table 1, the potassium/argon dates now available represent a variety of igneous and metamorphic rock types. Each reported date is based on an average of two or three determinations of radiogenic argon content.

Table 1. Potassium/Argon Ages from the McMurdo Sound Area*

Sample No.	Rock type	Mineral dated	Age ($\times 10^6$)	Reference	Location
ATZ-1	Monzonite gneiss	Biotite	425 ± 15	1	77° 40′ S., 162° 45′ E.
ATZ-2	Lamprophyric dyke	Biotite	458 ± 20	1	77° 40′ S., 162° 45′ E.
ATZ-3	Marble	Biotite	500 ± 20	1	77° 26′ S., 163° 48′ E.
GD-1	Paragneiss	Biotite	500 ± ?	2	77° 24′ S., 163° 40′ E.
P-1	Diorite	Biotite	496 ± 15		77° 25′ S., 163° 50′ E.
P-2	Basic dyke	Biotite	524 ± 15		77° 25′ S., 163° 50′ E.
AS-1	Lamprophyric dyke	Biotite	520 ± 30		77° 43′ S., 162° 40′ E.

* Except for *GD*-1, determinations were carried out by Geochron Laboratories, Inc., Cambridge, Mass., and constants used were: $\lambda\beta = 4{\cdot}72 \times 10^{-10}$/year and $\lambda_e = 0{\cdot}585 \times 10^{-10}$/year and $^{40}K/K = 1{\cdot}22 \times 10^{-4}$ g/g.

A comparison of samples *ATZ*-3 and *P*-2 emphasizes the importance of realizing that the potassium/argon ages are interval estimates. The central figure for *ATZ*-3, a marble sample, is 500 m.y. The corresponding figure for *P*-2 is 524 m.y. In this case, field observation reveals that the basic dyke cuts the marble, shows no sign of post-intrusion metamorphism, consequently is younger than the marble. Consideration of the reported intervals reveals that the dyke may be as much as 11 m.y. younger than the marble without contradicting the potassium/argon determinations.

The reported ages suggest that there may actually have been two distinct periods of activity: (1) Late Cambrian–Early Ordovician (510 ± 25 m.y.) metamorphism of previously existing sediments, accompanied by the intrusion of certain igneous systems; (2) Late Ordovician–Early Silurian (440 ± 25 m.y.) intrusion of later systems. Observations by McKelvey and Webb[3] and Allen and Gibson[4] in Wright Valley and Victoria Valley respectively also suggest that the basement intrusives of the McMurdo Sound area may be divided into two groups of slightly different ages (Table 2). Present results tend to strengthen this hypothesis.

Table 2. Tentative Correlation of Marble Point with Wright Valley Intrusives

	Pearn (1963)	McKelvey and Webb (1962)
		Wright intrusives
Late Cambrian	Brewer Hill granite	Dais granite
	Bill Hill granodiorite	Theseus granodiorite
(*P*-2)	Bill Hill 'trap'	Loke microdiorite
(*P*-1)	Surko Creek diorite	(No apparent equivalent)
		Victoria intrusives
Ordovician	Surko Creek granite	Vida granite
	Surko Creek and Air Strip 'trap' dykes	Vanda lamprophyres

The Marble Point locality has recently been examined in some detail[5], and the intrusive units recognized by McKelvey and Webb in the Wright Valley area have been tentatively identified. It is likely that some of the intrusives of Taylor Valley also are referable to the two groups of McKelvey and Webb.

From Antarctica in general there have been more than 65 isotopic dates reported in the 450–550 m.y. range[6]. An extensive period of metamorphism–plutonism occurred during early Palæozoic time with a peak of activity indicated in lower Ordovician. The geographical distribution of 400–550 m.y. dates extends over the entire peripheral area of eastern Antarctica from the Conrad Mountains (72° 00′ S., 9° 30′ E.) to Cape North (70° 40′ S., 165° E.) and south to McMurdo Sound Region, Victoria Land. Such distributions suggest that a widespread period of severe orogenic activity affected the whole eastern Antarctic region about 450–550 m.y. ago.

Norwegian Minerals and Rocks of Possible Caledonian Origin

In a recent communication[1] an outline is given of the sequence of metamorphic and structural events which affected the Lewisian rocks of the Glenelg inlier. In this outline a period of folding, about 740 million years old, and certainly older than 560 million years, is considered to form part of the Caledonian orogeny. Further can be mentioned the intrusion of the Ben Vuroch granite into Dalradian sediments between 700 and 500 million years ago[2].

These results are of importance for the discussion of the Norwegian part of the Caledonian chain. Age determinations[3] of minerals and rocks from three districts are referred to here. They may all be of Caledonian origin:

(1) The Rødsand mine is situated in the Molde–Kristiansund district, central Norway. A molybdenite from the mine gave the rhenium/osmium age 540 (± 10%) million years.

(2) Two micas from pegmatites in the county of Sogn and Fjordane, Southern Norway, gave the potassium/argon ages 582 and 590 million years.

(3) Potassium/argon determinations of micas in the carbonatite in the Fen area, 119 km south-west of Oslo, gave the ages 565, 590 and 603 million years.

According to my investigations in the Molde–Kristiansund district, we here have a Precambrian–post-Precambrian Caledonian stratigraphic sequence. The Precambrian part of this sequence is quite as important as the post-Precambrian part. A Precambrian basement is not found.

The two pegmatites in the county of Sogn and Fjordane are both situated in gneisses. These gneisses may belong to a Caledonian stratigraphic sequence, but are probably parts of the Precambrian basement. In both cases the rocks may have undergone an early Caledonian metamorphism.

According to Prof. J. Tuzo Wilson[4], the graben in the South Norwegian sparagmite region can be considered to belong to the Caledonian orogeny. The Fen area may have originated in connexion with these faults.

The age determinations given here indicate that the Precambrian–Cambrian part of the Norwegian Caledonian history is more important than is generally assumed.

A Beacon Sandstone: its Petrology and Hydrocarbon Content

After the ill-fated Scott expedition of 1910–13 a valuable suite of Antarctic rocks, collected by Sir Raymond Priestley, was donated to the University of Nottingham. In it was a specimen from the Beacon Sandstone series collected from Cape Royds. This we have investigated to see whether such a series might conceivably possess the properties of reservoir or source rocks for oil.

The Beacon Sandstones extend throughout eastern Antarctica in the region of the Great Fault Scarp. The succession, consisting of nearly horizontal strata interleaved with dolerite sills, characterize the tabular mountains for more than a thousand miles[1]. In some places, such as north of the Mackay Glacier, the series is more than 3,500 ft. thick and has been subdivided into three main lithological divisions[2]. Unfortunately, we do not know to which of these subdivisions the Priestley specimen belongs.

In hand specimen it is a light-coloured, very coarse-grained, hard quartzite with numerous small pebbles. The sorting is rather poor and the grain size varies from 10 mm down to silt grade interstitial sediment. The majority of the pebbles are of unstrained quartz, the rest are of granite, gneiss, schist and quartzite. Very little cement has been introduced, and while a small proportion of the grains have a fringe of secondary quartz most of them are welded along common margins. Sporadically distributed throughout are small chalky patches and also small holes often lined with chalky material. On X-ray analysis this chalky substance has proved to be albite-rich alkali felspar. It is not known why the felspar is in this condition, and further investigation is required. Of interest and significance to the present study are euhedra and granular aggregates of sphene. While no metamorphic significance is normally attached to this mineral, in some instances elsewhere, it is clear that it has begun to crystallize at higher temperatures than associated epidote. The minimum temperature of formation of epidote is 160° C, so that of sphene must be higher. If the recrystallization of the sphene and the quartz were at the same time, then the formation of the quartzite must have occurred above 160° C.

In essence, therefore, this is a quartzite of low porosity of which the induration and association with dolerite intrusions would, at first sight, appear to rule out the possibility of the survival of hydrocarbons. Moreover, the rock was digested with hydrofluoric acid in order to

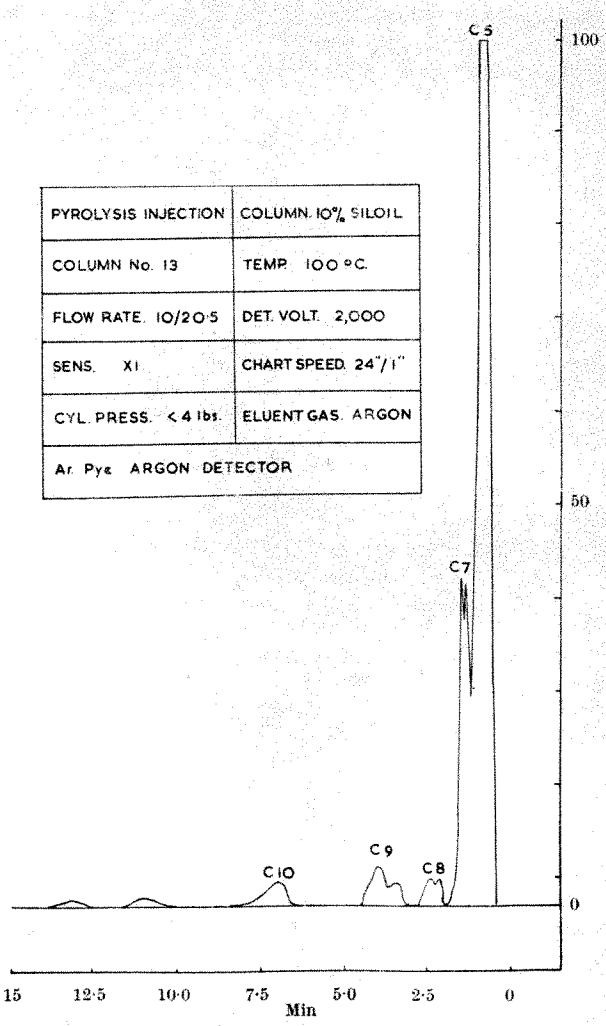

Fig. 1

scan the sediment for micro-organisms such as dinoflagellates. No trace of these or other organic matter was found. Nevertheless, seven powdered specimens were subjected to the version of gas chromatography known as 'pyrochromatography'[3].

All seven samples yielded identical chromatograms and Fig. 1 is a typical example. Of the ten compounds extracted from the specimen five consist of paraffins ranging from C_5 to C_{10}; the remainder have not yet been identified. These oils differ from the indigenous oils of normal sediments not only in containing no light fraction but also in the narrow range of their boiling points, and from those of metamorphosed oil-bearing strata in containing no naphthenic or phenolic compounds. In other words, they are neither original nor residual but are probably migrants which have been fixed by condensation.

It would be imprudent to speculate too far from one sample but the following conditions might be envisaged. The presence of sphene suggests that during metamorphism, presumably by the dolerites, the Beacon Sandstone was subjected to a temperature in excess of 160° C. Adjacent to the intrusions higher temperatures would develop accompanied by hydrothermal activity derived from the inherent water content of the invaded sediments. Consequently, by a process akin to steam distillation, the volatile constituents of the sediments would migrate laterally and upwards throughout the thermal aureole and would condense as soon as they found themselves in a rock with a temperature lower than their own boiling point. Such a thermo-dynamic process would account for the narrow range of saturated hydrocarbons found in this specimen. The fact that the boiling point of the highest recorded C_{10} paraffin is 174° C, which is very little above the minimum temperature indicated by the sphene, would support such a hypothesis. Moreover, such an explanation seems to indicate that this considerable column of upper Palæozoic and Mesozoic sediments might well contain source rocks capable of producing oil. Unfortunately, so far as we know, there are no structures capable of concentrating such oil into an oilfield, but from the nature of these deposits there might conceivably be stratigraphic traps.

CHEMISTRY

Decontamination of Synthetic Effluent by Flotation

Interested by the communication of Sebba[1], some scanning tests were undertaken in order to ascertain whether the flotation of ions could be used for the decontamination of radioactive effluent. The results obtained may be considered as being indicative and of limited value only, owing to the fact that no special efforts have been made to achieve optimal conditions, to use foam stabilizers, etc.

The glass flotation cell used is illustrated in Fig. 1. Encouraging results have been obtained by use of a foam column of 60 cm and by introducing the surfactant, that is, sodium lauryl sulphate, 25 cm underneath the liquid inlet. The foam column proved to be very stable at $pH = 2$ if distilled water was used for effluent make-up. When tap water, containing about 40 p.p.m. Ca^{2+}, was used, less-stable columns were obtained. In this case, a foam stabilizer should be used. Each run lasted at least 2 h; equilibrium was attained after 1 h.

Table 1

No.	Tracer	Carrier (p.p.m.)	Chemicals added		Decontamination factor*	
			Cu^{2+} (p.p.m.)	$Fe(CN)_6^{4-}$ (p.p.m.)	Flotation	Flocculation
1	^{134}Cs	—	—	—	1·4 ± 0·2	—
2	^{134}Cs	1	—	—	1·1 ± 0·0	—
3	^{134}Cs	—	15·1	11·5	375 ± 125	150 ± 50
4	^{134}Cs	1	15·1	11·5	90 ± 30	45 ± 20
5	^{134}Cs	—	15·1	11·5	25 ± 6	32 ± 6
6	^{89}Sr	—	—	—	2·5 ± 0·5	—
7	^{89}Sr	—	—	—	2·4 ± 0·1	—
8	^{89}Sr	—	15·1	11·5	1·7 ± 0·3	1·3 ± 0·1
9	^{89}Sr	1	15·1	11·5	1·3 ± 0·2	1·1 ± 0·1
10	^{152}Eu	—	—	—	330 ± 150	—
11	^{152}Eu	1	—	—	400 ± 90	—
12	^{152}Eu	—	15·1	11·5	200 ± 60	1·6 ± 0·2
13	^{152}Eu	1	15·1	11·5	750 ± 250	1·1 ± 0·0

Flotation runs, $pH = 2$; 25 p.p.m. sodium lauryl sulphate; distilled water, except No. 5, where tap water was used; liquid flow-rate, 0·7 m/h; air flow-rate, 1 m/h, except No. 5, 1·55 m/h. Flocculation runs, in beakers under slow stirring during 0·5 h; distilled water; phase separation by centrifugation directly after stirring; $pH = 2$.
All decontamination factors are average values from two or more runs; during each run three or more samples were taken after 1 h of operation when equilibrium was attained.
* Concentration column influent over effluent.

Some results are given in Table 1. It appears that decontamination by straight ion flotation is high for Eu^{3+} and relatively low for Sr^{2+} and Cs^+. In order to improve the Cs^+ decontamination, a copper ferrocyanide floccule was formed in the solution. It appeared that the ion flotation of Eu^{3+} is not affected but that the Cs^+ decontamination improved markedly. Sr^{2+} decontamination remains almost unchanged, which becomes understandable after comparing the flotation results with the reference flocculation runs that were executed simultaneously under comparable conditions. In every case the effluent from the cell was completely clear and contained no floccules. On the whole, flotation gives equal or better results than does flocculation. It is noted that the flocculation, especially of Sr^{2+} and Eu^{3+} for which other chemical treatments give better results, was done under relatively unfavourable conditions, since at $pH = 2$ only copper ferrocyanide could be formed as precipitate, and this is a specific scavenger for Cs^+ only. It is, however, very likely that if favourable conditions can be found, the same conclusion will be arrived at, although the influence

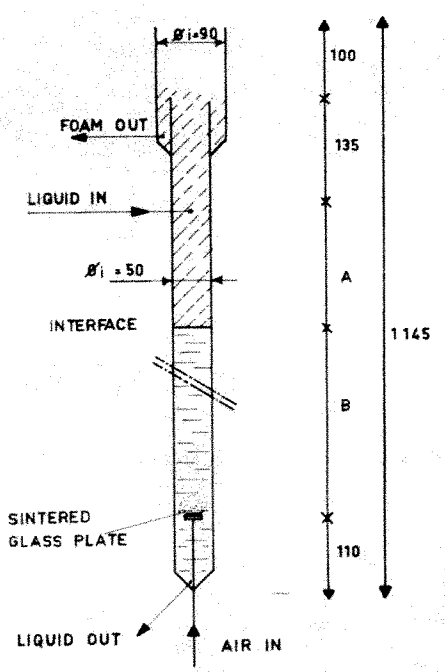

Fig. 1. Flotation cell (× 0·1). *A*, Distance from liquid inlet; *B*, distance from air inlet

of other contaminants present in waste effluent, such as organic materials, is unknown.

An interesting result of the flotation runs was that the separated foam volume represented a very small part of the volume of effluent treated. The average value obtained for more than 30 runs was 0·01 vol. per cent. This is of great importance for the treatment of radioactive effluent since the concentrated radioactive phase, foam + floccule, can possibly be stored insolubilized or contained without any further volume reduction.

Analysis of Reversibly Interacting Systems by Differential Boundaries in Electrophoretic and Sedimentation Experiments

Differential boundaries, which can be formed in Tiselius electrophoresis cells or in special ultracentrifuge cells[1,2] between solutions differing slightly in composition, may prove to have distinct advantages over ordinary boundaries for the study of rapidly reversible interacting systems. This possibility is being explored theoretically by considering model systems in which it is assumed that the transport of species occurs in rectangular cells under a uniform force field, that the mobilities or sedimentation coefficients of reacting species are independent of concentration[3] and that reaction is governed by the simple form of the law of mass action.

To illustrate this approach we consider a model in which reactants A_1 and A_2 form complexes C_1 and C_2 reversibly in solution, according to the equations $A_1+A_2=C_1$ and $A_1+C_1=C_2$. Suppose an experiment is performed in which a solution is made up with A_1 and A_2 at constituent molar concentrations $\overline{m}_1$ and $\overline{m}_2$, and that a differential boundary is formed in a suitable cell between this solution and another with A_1 and A_2 at the slightly different constituent molar concentrations $\overline{m}_1+\Delta\overline{m}_1$ and $\overline{m}_2+\Delta\overline{m}_2$: then it can be shown[4] that the initial differential boundary must split into as many boundaries as there are basic constituents present. These boundaries should possess little structure, and will appear in the schlieren pattern simply as 'blips' drawn out by diffusion. The information required from the experiment is the velocities and areas of these blips.

In the present case two boundaries will form. Let their velocities be V_1 and V_2 and the changes in total concentration (wt./vol.) across each boundary, as deduced from the areas of the blips, be ΔW_1 and ΔW_2. Then since ΔW_1 and ΔW_2 are linearly related to $\Delta\overline{m}_1$ and $\Delta\overline{m}_2$, provided the latter are sufficiently small[4], we may write:

$$\begin{aligned}\Delta\overline{m}_1&=\sigma_{11}\,\Delta W_1+\sigma_{12}\,\Delta W_2\\ \Delta\overline{m}_2&=\sigma_{21}\,\Delta W_1+\sigma_{22}\,\Delta W_2\end{aligned}\qquad(1)$$

where σ_{11}, σ_{12}, σ_{21} and σ_{22} are appropriately valued coefficients. By repeating the experiment for different values of $\Delta\overline{m}_1$ and $\Delta\overline{m}_2$, the values of these four unknown coefficients can be determined.

Let v_1 and v_2 be the sedimentation velocities of A_1 and A_2 and assume that these are known since they are properties of the pure constituents. Also let the sedimentation velocities of the complexes C_1 and C_2 be u_1 and u_2 and consider these as unknown. Further, let the unknown free molar concentrations of A_1, A_2, C_1 and C_2 in the solution be a_1, a_2, c_1 and c_2 respectively. Then having determined V_1, V_2 and σ_{11}, σ_{12}, σ_{21}, σ_{22} experimentally, these six unknown quantities, together with two, necessarily positive, unknown multipliers λ_1 and λ_2, can be found[4] from the eight equations:

$$a_1+c_1+2c_2=\overline{m}_1 \qquad(2)$$

$$a_2+c_1+c_2=\overline{m}_2 \qquad(3)$$

$$a_1+c_1+4c_2=\sigma_{11}^2\lambda_1+\sigma_{12}^2\lambda_2 \qquad(4)$$

$$a_2+c_1+c_2=\sigma_{21}^2\lambda_1+\sigma_{22}^2\lambda_2 \qquad(5)$$

$$c_1+2c_2=\sigma_{11}\sigma_{21}\lambda_1+\sigma_{12}\sigma_{22}\lambda_2 \qquad(6)$$

$$v_1a_1+u_1c_1+4u_2c_2=\sigma_{11}^2V_1\lambda_1+\sigma_{12}^2V_2\lambda_2 \qquad(7)$$

$$v_2a_2+u_1c_1+u_2c_2=\sigma_{21}^2V_1\lambda_1+\sigma_{22}^2V_2\lambda_2 \qquad(8)$$

$$u_1c_1+2u_2c_2=\sigma_{11}\sigma_{21}V_1\lambda_1+\sigma_{12}\sigma_{22}V_2\lambda_2 \qquad(9)$$

These equations are linear in a_1, a_2, c_1, c_2, u_1c_1, u_2c_2 and λ_1, λ_2, and their solution is therefore unique. After these equations have been solved, the equilibrium constants k_1 and k_2 for the two reactions $A_1+A_2\rightleftharpoons C_1$ and $A_1+C_1\rightleftharpoons C_2$ are immediately obtained from the mass action equations $k_1=(a_1a_2)/c_1$ and $k_2=(a_1c_1)/c_2$.

Equations (2) and (3) merely define the constituent molar concentrations of A_1 and A_2. The remaining six equations are obtained by considering the flux of A_1 and A_2 in their free and combined state through the two differential boundaries, assuming that A_1 and A_2 are in chemical equilibrium with the complexes C_1 and C_2 at all times.

This method of analysing a differential boundary experiment can be generalized to deal with more complicated systems. The advantage of differential boundaries over ordinary boundaries lies in the fact that the parameters of an interacting system can be found by solving linear equations instead of non-linear differential equations. It remains to be seen what limitations are implied by the simplifying assumptions mentioned here, or are inherent in the experimental measurement of differential boundaries.

Fibres of Guanine Nucleosides and Nucleotides

It has been shown by Gellert, Lipsett and Davies[1] that guanylic acid will form a gel under certain *p*H conditions and they were able to draw fibres from gels of the disodium salt of 3′-guanylic acid and of the free acid, 5′-guanosine monophosphate. From X-ray diffraction studies of these fibres the foregoing workers concluded that they consisted of a helical arrangement of the ribose nucleotides.

We have been studying corresponding deoxyribose compounds and we have observed gel formation in deoxyguanosine, deoxyguanosine-5′-monophosphate and the ammonium salt of deoxyguanylic acid. In addition we studied gels of the mixed 2′-, 3′-guanosine monophosphate disodium salts. (Gellert *et al.* separated these isomers before forming fibres.)

Deoxyguanosine. Solutions were prepared in the *p*H range 4–7 by dissolving 25 mg/ml. in a warm buffer solution (disodium hydrogen phosphate and citric acid), and on cooling a gel formed in the solution. From this gel it was possible to draw fibres suitable for X-ray diffraction studies which showed that the material was oriented.

Fig. 1. X-ray diffraction patterns. *a*, Fibres of deoxyguanosine; *b*, oriented crystals of deoxyguanosine; *c*, fibres of mixed disodium salts of 2′- and 3′-guanosine monophosphates

Occasionally, however, the substance crystallized and no gel was observed. If the gel is stirred it crystallizes and then it is not possible to draw fibres. Gel formation was observed at *p*H 4, 5 and 6, but not at *p*H 7. Attempts to form gels with guanosine were unsuccessful.

Fig. 1*a* is the X-ray diffraction pattern from deoxyguanosine fibres. There is a strong meridional reflexion at 3·4 Å on the second layer line and a strong equatorial reflexion at 20·5 Å. Six additional equatorial reflexions were observed, and they can all be indexed satisfactorily on the basis of a hexagonal lattice with $a = 23{\cdot}9$ Å. The 3·4 Å spacing along the fibre axis suggests that the molecules are packed so that the guanine bases are perpendicular to the axis with two units, possibly related by a 2-fold screw axis, forming the repeat distance along the axis. The number of molecules forming a co-planar set may be three as in some synthetic polynucleotides[2] or it might be four as suggested for guanylic acid gels[1]. The deoxyguanosine as supplied is in the form of extremely fine needles which tend to form a 'mat' with the needles lying parallel to one another and from this material it is possible to choose an oriented powder specimen. The X-ray diffraction pattern of such a specimen, kept stationary, is shown in Fig. 1*b*. Again there is a strong reflexion on the meridian on the second layer line at approximately the same spacing (3·58 Å) as for the gel fibres but the equatorial reflexions are different. X-ray Weissenberg photographs of a single needle recrystallized from water indicated that the lattice was orthorhombic with $a = 11{\cdot}0$ Å, $b = 59{\cdot}7$ Å, $c = 7{\cdot}16$ Å. The density determined by flotation in a calibrated gradient column of carbon tetrachloride and *n*-hexane was 1·535 g/cm³, which indicated 16 molecules per unit cell. From these measurements it would seem that there is no water of crystallization in the cell. If larger crystals can be grown it is hoped to examine the structure of deoxyguanosine in the same detail as that of guanine[3], but so far it has not been possible to get sufficiently large crystals.

Deoxyguanosine-5′-monophosphate and deoxyguanylate, ammonium salt. Both these substances formed gels at *p*H 5 and *p*H 6 but it was difficult to draw satisfactory fibres for X-ray diffraction examination. In each case the photographs which were obtained showed a strong meridional reflexion at 3·35 Å. This indicates, as for deoxyguanosine, that the bases are stacked in planes perpendicular to the fibre axis.

Mixed isomers 2′-, 3′-guanosine monophosphate, disodium salts. When a solution (*p*H 6) of these mixed isomers was allowed to stand for over a week at room temperature a whitish gel formed which could be drawn quite easily into fibres several inches long. The X-ray diffraction diagram (Fig. 1*c*) is different from the above deoxyguanosine diagrams and from the diagrams obtained by Gellert *et al.*[1] with the separated isomers. The layer line spacing is approximately 16·0 Å with a strong reflexion on the meridian at 3·25 Å (5th layer). This could indicate that the molecular units are arranged on a helix with five units per turn of the helix. There are six reflexions on the equatorial layer line and these can be indexed on the basis of a hexagonal lattice with $a = 27{\cdot}1$ Å. A molecular unit could be a tetramer as suggested by Gellert *et al.* but we do not find in any of our patterns the strong meridional reflexion at 6·75 Å which is a feature of their 3′-isomer patterns.

We thank Dr. P. Brooks of the Chester Beatty Research Institute for a supply of the mixed 2′-, 3′-isomers. We also thank the British Empire Cancer Campaign for grants in support of this work.

Formation of Electrons and of Atomic Hydrogen in γ-irradiated Ice

In ice at 77° K containing acids such as sulphuric, perchloric and orthophosphoric, irradiated with γ-rays, hydrogen atoms were first detected by electron spin resonance by Livingston, Zeldes and Taylor[1]. In neutral ice, however, no hydrogen atoms were observed at 77° K although some were detected at 4° K[2]. It has been suggested[3] that radiation-produced electrons, $(H_2O)^-$, which have been shown[4] to occur in the radiolysis of aqueous solutions, may react with a hydrogen ion in the acidic ice to produce a (stable) hydrogen atom:

$$(H_2O)^- + H^+ \rightarrow H + H_2O \qquad (1)$$

In an analogous manner we may expect that a Brønsted acid such as $H_2PO_4^-$ may react to form a hydrogen atom, by a proton transfer, according to the equation:

$$(H_2O)^- + H_2PO_4^- \rightarrow H + HPO_4^{2-} \qquad (2)$$

Such reactions have been suggested to occur in aqueous solution[5]. In the case of bisulphate, one would have the analogous reaction:

$$(H_2O)^- + HSO_4^- \rightarrow H + SO_4^{2-} \quad (3)$$

although there are reasons to suggest that here, as in the other cases, the reaction goes to a greater or lesser extent through an unstable intermediate, namely $(HSO_4)^{2-}$, which may break up according to:

$$(HSO_4)^{2-} \rightarrow H + SO_4^{2-} \quad (4)$$

and possibly also to some extent:

$$(HSO_4)^{2-} \rightarrow OH^- + SO_3^- \quad (5)$$

To ascertain whether or not hydrogen atoms are formed under these conditions, experiments were carried out with ice containing different solutes. Cylinders of crystalline ice weighing about 0·03 g were formed by rapidly freezing the appropriate solution to 77° K in 0·15-cm diameter tubes. These cylinders were then removed from the glass tubes and irradiated directly in contact with liquid nitrogen with cobalt-60 γ-rays at a dose rate of 0·17 megarads/h. Tests with degassed and non-degassed solutions showed no difference and the results reported are for non-degassed solutions. After a total dose of 2·5–8 megarads, the ice cylinders were transferred to a standard quartz-tipped electron spin resonance Dewar, thus avoiding any possible electron spin resonance signals from the irradiated sample tube, and were examined with a 'Microspin' electron spin resonance spectrometer operating at 9,200 Mc/s.

The appearance of hydrogen atoms was found to be of quite general occurrence in the systems containing certain oxyanions. Hydrogen atoms were recognized by their characteristic hyperfine doublet split by 505 gauss. The yields of hydrogen atoms per 100 eV, $G(H)$, for the various solutes are shown in Table 1. The yield, for example, in solutions containing $H_2PO_4^-$, was determined by direct comparison, under identical experimental conditions, with the hydrogen atom yield in glassy 0·20 mole fraction sulphuric acid, for which $G(H) = 1·66$ has been reported[6]. This comparison was made in high-purity quartz tubes in which the background hydrogen atom signal from the quartz itself was negligible. The other yields were obtained by comparison with a standard sample containing $H_2PO_4^-$ as solute. The relative values were reproducible to within less than 15 per cent. These represent initial yields since the hydrogen atom yields were found to be linear with dose up to 10 megarads.

Fig. 1 shows that the hydrogen atom yields are linear with concentration of the solute. It is significant that hydrogen atoms are formed even in irradiated ices containing neutral salts as solutes. The linearity shown in Fig. 1 as well as the consistent reproducibility of the results indicate that homogeneity of the solute was retained on rapid freezing.

It was also found that the observed hydrogen atom electron spin resonance signals in ices containing $H_2PO_4^-$ or HSO_4^- could be decreased by the addition of various second solutes which are known to be good electron scavengers in aqueous solutions. This is as predicted if the hydrogen atoms do originate by equations (2)–(4). Such

Table 1. Hydrogen Atom Yields per 100 eV ($G(H)$) in Irradiated Ice containing Various Solutes at 77° K

Solute	pH	$G(H)$ (for 1·0 M solute)
NaH_2PO_4 (1·0 M)	4·3	0·27
KH_2PO_4 (1·0 M)	4·3	0·27
Na_2HPO_4 (0·2 M)	9·2	0·07*
Na_3PO_4 (0·6 M)	12·6	0·03*
$NaHSO_4$ (1·0 M)	1·2	0·14
Na_2SO_4 (1·0 M)	6·0	0·04
$NaHCO_3$ (1·0 M)	8·2	0·01
K_2CO_3 (1·0 M)	11·3	0·006

* Extrapolated linearly to 1·0 M concentration.

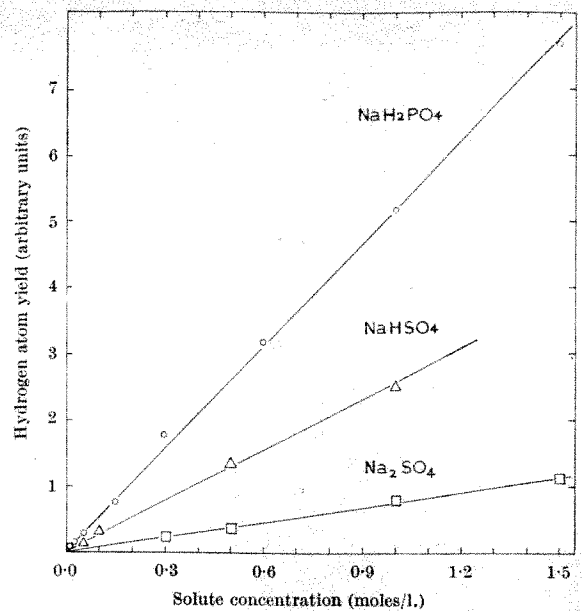

Fig. 1. Dependence of hydrogen atom yields on concentration of solutes in irradiated ice at 77° K. ○, NaH_2PO_4; △, $NaHSO_4$; □, Na_2SO_4

solutes include nitrous oxide, nitrate, nitrite and acetone, which latter would react according to:

$$(H_2O)^- + CH_3.CO.CH_3 \rightarrow [CH_3.CO.CH_3]^- + H_2O \quad (6)$$

In this case a seven-line electron spin resonance spectrum is observed which one has reason to attribute to the acetone negative ion-radical. The kinetics of such competition reactions in the solid and the paramagnetic species produced are at present being studied. In the case of SO_4^{2-} as solute anion these scavengers were found to have no effect on the hydrogen atom electron spin resonance signal.

While a mechanism represented by equations (2)–(4) may account for all or part of the hydrogen atoms observed in the cases of the Brønsted acid solutes: $H_2PO_4^-$, HPO_4^{2-}, HSO_4^- and HCO_3^-, the hydrogen atoms found in the SO_4^{2-}, PO_4^{3-} and CO_3^{2-} systems should arise from the water molecules by a different mechanism. It would appear that the solute anion is necessary for the 'stabilization' of the hydrogen atoms at 77° K (since at this temperature hydrogen atoms are not observed in irradiated pure ice) and that the hydrogen atoms observed in ices containing these latter solutes, which do not contain hydrogen, are directly produced only from water molecules which are in the solvation shell of these solute anions. This may explain the fact that these hydrogen atoms are not affected by the presence of scavenging solutes.

One of us (L. K.) thanks the U.S. National Science Foundation for a fellowship. Another (P. N. M.) thanks the Colombo Plan authorities for a fellowship and the Atomic Energy Establishment, Trombay (India), for their support.

Stimulated Singlet–Triplet Transitions in Organic Phosphors

Morantz *et al.*[1] have reported that stimulated emission may be observed from the triplet states of organic phosphors. The emission was characterized by a regular series of spikes of intensity implying an oscillatory condition due to the amplification of the stimulated emission as in similar experiments on ruby. Workers in other laboratories, including our own, have failed to detect this effect. We have, however, succeeded in producing the triplet state of such a compound by the reverse process of direct singlet–triplet absorption using a typical flash photolysis apparatus. This is interesting in its own right as it paves the way for studies of triplet states in the absence of excited singlet states, something which hitherto had not been thought possible. Furthermore, the small fraction of molecules excited in this way is in agreement with calculations which suggest that a prohibitively high inversion population density is required to obtain oscillation in a resonant cavity with such compounds using flashes of energy less than 1,000 joules. Experience suggests that even with a 100-fold increase in flash intensity, such concentrations would be difficult to realize.

The phosphors used were naphthalene and 1-bromonaphthalene which have similar singlet–singlet absorption spectra both in position and intensity whereas the singlet–triplet absorption, although in the same spectral region, is much more intense for 1-bromonaphthalene. In the apparatus used the quantum output of a 640-joule flash was found, by potassium ferrioxalate actinometry[2], to be $1{\cdot}8 \times 10^{19}$ quanta. These were detected in a cylindrical reaction vessel (20 cm long, 2 cm internal diameter) which was placed between two photolysis lamps within a highly reflecting enclosure. To prevent the production of triplet phosphor by singlet–singlet excitation followed by intersystem crossing, the mechanism usually responsible for triplet states observed in flash experiments[3], filter solutions were placed in an outer jacket surrounding the reaction vessel. The spectra of the filter solutions, together with the spectra of solutions of naphthalene and 1-bromonaphthalene in liquid paraffin, the solvent chosen for this work, are illustrated in Fig. 1.

Any transient spectra formed in the degassed solutions were recorded on photographic plates ~50 μsec after the photolysis flash using a second spectroscopic flash. The results, summarized in Table 1, show that absorption in the region of the singlet–triplet transitions gives rise to the triplet state of 1-bromonaphthalene but not that of naphthalene. The negative result obtained in this wavelength region for naphthalene confirms the adequacy of

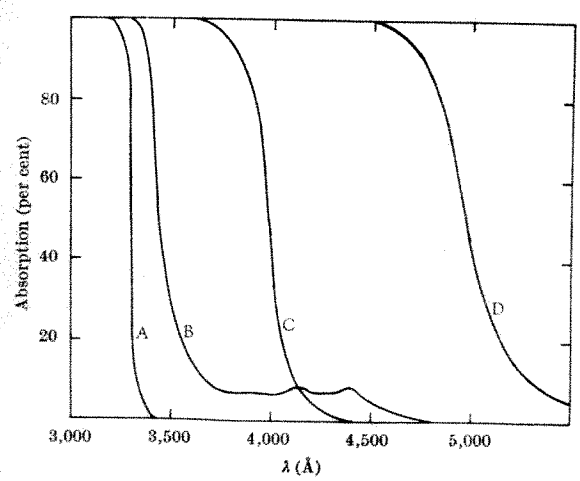

Fig. 1. Absorption spectra of phosphor and filter solutions (path-length, 1 cm). *A*, Naphthalene in liquid paraffin (0·43 mole/l.); *B*, 1 bromonaphthalene in liquid paraffin (1·1 mole/l.); *C*, filter 1 (400 g/l. $NaNO_2$, 10 g/l. $NaNO_3$ in water); *D*, filter 2 (40 g/l. K_2CrO_4, 120 g/l. $NaNO_2$ in water)

Table 1. Transients detected in flash photolysis experiments using degassed liquid paraffin solution within a 'Pyrex' reaction vessel

Filter	Transients: Naphthalene (0·43 mole/l.)	Transients: 1-Bromonaphthalene (1·1 mole/l.)
None	Triplet naphthalene	Triplet 1-bromonaphthalene
Filter 1 Transmission above 3700 Å	None	Triplet 1-bromonaphthalene ($\sim 10^{-5}$ mole/l.)*
Filter 2 Transmission above 4500 Å	None	None

* Assuming the triplet–triplet extinction coefficient to be 10^4 (cf. ref. 4).

filter 1 in preventing singlet–singlet absorption. In fact filter 1 also cuts out part of the singlet–triplet absorption region.

Since the energy output of gas-filled flash lamps is almost independent of wave-length[5], the fraction of molecules raised to the triplet state by direct absorption may be calculated from the relation:

$$\frac{\Delta n}{n} = B\rho(\nu) = \frac{Qh\nu}{\Delta\nu c}\,\frac{c^3}{8\pi h\nu^3}\,A$$

where A and B are Einstein coefficients for spontaneous and stimulated emission, n is the number of molecules in the ground state, $\rho(\nu)$ is the radiation density at any frequency ν, Q is the quantum output of the photolysis flash in the frequency range $\Delta\nu$. For organic phosphors A may be put equal to $\frac{\gamma_p}{(1-\gamma_F)}\tau_p$, where γ_p, γ_F are the quantum yield of phosphorescence and fluorescence and τ_p is the measured phosphorescence lifetime. The calculated values of $\Delta n/n$ are given in Table 2. These values are in good agreement with the amount of triplet 1-bromonaphthalene formed by direct absorption detected by experiments (Table 1) provided allowance is made for absorption by filter 1 in the singlet–triplet absorption region. The negative result in the case of naphthalene is also to be expected.

Table 2. Calculated values for the fraction of molecules expected to be excited to the triplet state by direct absorption $\Delta n/n$ and the critical inversion concentration (Mc) necessary for oscillation in a resonance cavity under the conditions specified in the text

Compound	First triplet level (cm^{-1})	τ_p (sec)	γ_p	γ_F	$\Delta n/n$	Mc
Acetophenone	26,000 (ref. 6)	$8{\cdot}0 \times 10^{-3}$ (ref. 8)	0·63 (ref. 8)	—	9×10^{-5}	3×10^{-1}
Benzophenone	24,400 (ref. 6)	$6{\cdot}0 \times 10^{-3}$ (ref. 8)	0·84 (ref. 8)	—	2×10^{-4}	2×10^{-1}
Pyrazine	26,000 (ref. 7)	$2{\cdot}0 \times 10^{-2}$ (ref. 9)	1·00 (ref. 7)	—	6×10^{-5}	2×10^{-1}
Naphthalene	21,300 (ref. 6)	2·6 (ref. 9)	0·09 (ref. 8)	0·37 (ref. 8)	9×10^{-8}	3×10^{3}
1-Bromonaphthalene	20,700 (ref. 6)	$1{\cdot}8 \times 10^{-2}$ (ref. 9)	0·55 (ref. 10)	—	5×10^{-5}	5×10^{-1}

Since stimulated emission and absorption are equally probable processes the experimental evidence indicates that even if we had an inversion concentration of 1 mole/l. of triplet 1-bromonaphthalene a high-energy flash would only induce a relatively small proportion back to the ground-state. On the other hand, the use of a resonant cavity could provide amplification of the stimulated emission if the increase in mode intensity per traverse due to stimulated emission were greater than the losses due to absorption and scattering in the medium and the mirrors. The threshold inverted population density necessary for oscillation may be expressed[11]:

$$Mc = \frac{8\pi\nu^2\alpha}{c^2 g(\nu_c) L A}\,\frac{1{,}000}{N}\ \text{moles/l.}$$

where L is the distance between the mirrors, and α is the fractional loss per pass when the amplifying medium is neutral, $g(\nu_c)$ is a shape function representing the emission spectrum which we have assumed to be Gaussian in form. Mc is calculated for a series of phosphors taking $L = 1$ cm, as used by Morantz[1], and assuming $\alpha = 0{\cdot}01$, which is probably a lower limit. As can be seen from Table 2, the required triplet concentrations are all greater than 10^{-1} mole/l., 100 times the total concentration of phosphors

used by Morantz. Stockman *et al.*[12] have suggested that the fluorescence of organic compounds might provide a more probable method of obtaining an oscillatory condition.

We thank Dr. K. R. Lea for interesting discussions on this topic.

Equilibria in Water–Alcohol Mixtures

In order to describe accurately the kinetics of nucleophilic substitutions carried out under alkaline conditions in aqueous alcoholic solutions, in which both hydroxy and alkoxy groups are introduced, it is necessary to know the equilibrium constant (K) of the reaction:

$$R\,OH + OH^- \rightleftharpoons RO^- + H_2O$$

$$K = \frac{[OH^-]\,[ROH]}{[OR^-]\,[H_2O]}$$

in order to calculate the respective concentrations of the two ions.

Caldin and Long[1] have reported investigations on ethanol–water mixtures containing sodium hydroxide in which TNT was used as an indicator. The purple colour obtained is supposedly due to the TNT anion produced by the equilibria:

$$BH + OH^- \rightleftharpoons B^- + H_2O \;(BH^- = \text{TNT})$$

$$BH + OEt^- \rightleftharpoons B^- + EtOH$$

the concentration of B^- varying with the ratio $[OH^-]$ $[OEt^-]$. The procedure is similar to that of Hine and Hine[2], who used 4-nitrodiphenylamine as indicator. We have been unable to reproduce the results of Caldin and Long and have some evidence that TNT does not ionize in the simple manner shown here.

However, where the two reactions:

$$R' - X + OH^- \xrightarrow{k'_2} R'OH + X^-$$

$$R' - X + OR^- \xrightarrow{k''_2} R'OR + X^-$$

occur simultaneously it is possible to obtain values of k'_2 and k''_2 and also of K directly from kinetic measurements providing the concentrations of $R'OH$ and $R'OR$ can be measured.

If the two reactions proceed independently of each other the ratio of rates will equal the ratio of products and will be constant throughout the reaction:

$$\text{that is, } \frac{k''_2[OR^-]}{k'_2[OH^-]} = \frac{[R'\,OR]}{[R'\,OH]} = Y \qquad (1)$$

Y may be determined experimentally, but k'_2 and k''_2 are not directly measurable since $[OH^-]$ and $[OR^-]$ are not known. However, an overall rate constant k_2 for the conversion of $R' - X$ can be measured, such that:

$$\frac{d[R'X]}{dt} = k_2[R'X]\,([OH^-] + [OR^-])$$

$$\text{and } k_2 = k'_2\,\frac{[OH^-]}{[OH^-] + [OR^-]} + k''_2\,\frac{[OR^-]}{[OH^-] + [OR^-]}$$

substituting from equation 1

$$k_2 = k'_2[OH^-]\left(\frac{1+Y}{[OH^-] + [OR^-]}\right) = k'_2[OH_0^-]\left(\frac{1+Y}{[OH_0^-] + [OR_0^-]}\right) \qquad (2)$$

where $[OH_0^-]$ and $[OR_0^-]$ are initial concentrations.

On the assumption that k'_2 is unaffected by the addition of alcohol, the value of k'_2 found from a separate experiment in water may be substituted into equation (2), and since k_2 and Y are known experimentally for any particular water–alcohol mixture and $([OH_0^-] + [OR_0^-])$ is equal to the known concentration of alkali taken, the values of $[OH_0^-]$ and hence $[OR_0^-]$ are readily determined and enable equilibrium constant K and also the rate constant k''_2 to be calculated.

The chlorotriazinyl derivative (I) (0·05 M) was allowed to react in mixtures of water and ethanol containing 0·048 N sodium hydroxide at 60° C to give the results shown in Table 1. Total conversion was measured by electrometric titration of liberated chloride, the formation of II(a) by

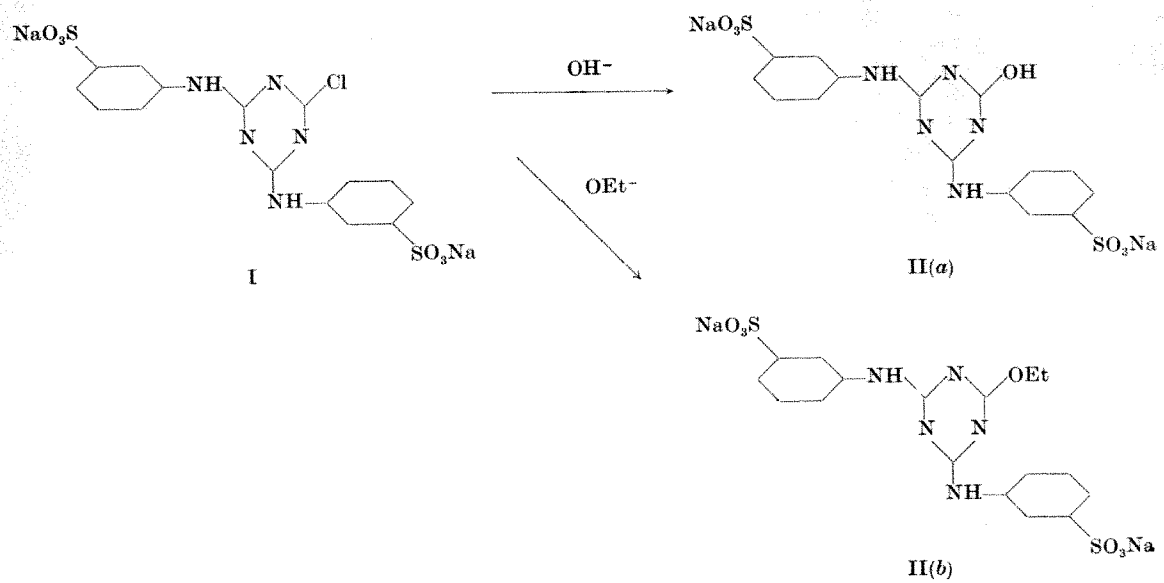

Table 1

Vol. % EtOH	10	15	20	30
k_2 (min^{-1} mol^{-1} l.)	0·39	0·42	0·53	0·62
Y	1·2	1·75	2·6	3·3
K	0·17	0·13	0·17	0·27
k''_2 (min^{-1} mol^{-1} l.)	1·3	0·95	1·3	1·5

k'_2 = 0·21 min^{-1} mol^{-1} l.

The values of Y were constant throughout any one experiment.

potentiometric titration of the $-OH$ group and II(b) by difference.

Pocker[3] reports a value of c. 4 (equivalent to Y) for the final ratio of the products of reaction of isopropyl bromide in 60 per cent ethanol at 70° C.

The assumption that k'_2 is independent of ethanol is equivalent to assuming that the activity coefficients of the reactants are also independent of ethanol, or alternatively that they all vary to the same extent. The constancy of the values of K and k''_2 appears to justify the assumption up to 20 per cent ethanol, but some allowance for variation of activities may be necessary at higher alcohol concentrations and we are examining this possibility.

Characterization of the Products of the Action of Bee Venom Hyaluronidase

Previous workers[1] have reported that bee venom contains a hyaluronidase, but the products of its action on hyaluronic acid have not been characterized. In the work recorded here bee venom was obtained from several thousand bees using a novel method of collection. Trays of bees, preferably >15 days old, were induced to sting into thin sheets (<0·005 in.) of silicone rubber by subjecting them to a mild electric shock. Under these conditions the bee can withdraw its stinging apparatus and the venom is deposited as a globule on the underside of the sheet where it quickly dries to a crystalline form. The bees themselves appear to become ravenous and will devour large quantities of honey, after which they appear to suffer no adverse effects. In fact, marked bees have been noted working normally on the combs 12 days after venom extraction. The venom crystals (about 0·1 mg/bee) retain their hyaluronidase activity for at least a year if stored at 2°.

Sodium hyaluronate (205·9 mg; $[\alpha]_D^{20} - 68·5°$, c, 0·4 in 0·05 M phosphate citrate buffer pH 4·75) which had been isolated from umbilical cords was dissolved in 0·05 M phosphate citrate buffer (6 ml.; pH 4·75) and incubated for 24 h at 37° with bee venom (47·5 mg) in physiological saline (9 ml.). After neutralization with dipotassium hydrogen phosphate, the digest was boiled, centrifuged and the supernatant freeze-dried. This product, in water (5 ml.), was applied to a 'Dowex 21K' (H.COO$^-$) column[2] (l. 265 mm, diam. 11 mm). Stepwise elution with 270 ml. portions of 0·015 M, 0·05 M, 0·15 M, 0·3 M, 0·5 M, 0·8 M and 1 M formic acid as shown in Fig. 1 gave fractions I (4·3 mg), II (63·3 mg), III (60·5 mg) and IV (0·4 mg) located with the carbazole reagent[3]. Fractions I, II and III were homogeneous on a paper chromatogram irrigated with butan-1-ol/acetic acid/water (44 : 16 : 40) and had mobilities corresponding to those of a disaccharide (Rglucurone 0·5), a tetrasaccharide (Rglucurone 0·27), and a hexasaccharide (Rglucurone 0·18), respectively. The oligosaccharides gave positive reactions with the Morgan–Elson spray[4], indicating that an N-acetylglucosamine residue carries the reducing group in each oligosaccharide, and suggesting that bee venom hyaluronidase is a β-hexosaminidase.

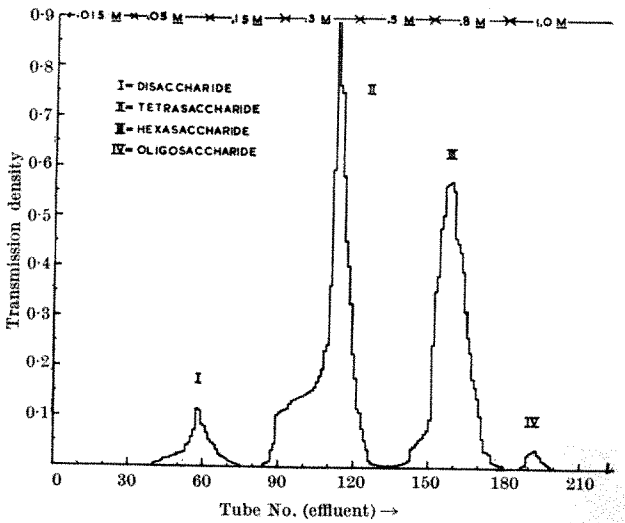

Fig. 1. Ion exchange separation of oligosaccharides on 'Dowex 21K' (H.COO$^-$)

Molecular weight determination using alkaline hypoiodite[5] confirmed the designations of tetrasaccharide (found, 742 : $C_{28}H_{44}N_2O_{23}$ requires 777) and hexasaccharide (found, 1111 : $C_{42}H_{65}N_3O_{34}$ requires 1155) to components II and III respectively. The tetrasaccharide did not consume bromine[6] and no ultra-violet absorption[6] was detectable at 232 mμ, indicating the absence of α,β-unsaturation. Infra-red spectral data[7] confirmed that both the tetrasaccharide and the hexasaccharide were of the saturated type and that in this they resembled similar oligosaccharides obtained by the action of testicular hyaluronidase[2] on hyaluronic acid. Assay of the uronic acid content with carbazole[3] revealed 44·9 per cent in the tetrasaccharide and 45·9 per cent in the hexasaccharide. After hydrolysis with 3 N hydrochloric acid at 105° for 4 h the hexosamine[8] contents were 43·6 and 41·7 per cent (calculated as glucosamine), respectively, and indicated equimolar ratios of uronic acid and hexosamine in both oligosaccharides. The tetrasaccharide had $[\alpha]_D^{25} - 52·2°$ (c, 0·46 in water) while the hexasaccharide showed $[\alpha]_D^{25} - 66·1°$ (c, 0·56 in water).

Partial hydrolysis and de-N-acetylation of the tetrasaccharide (2·2 mg.) was effected with N sulphuric acid (0·25 ml.) for 50 min at 90°. After neutralization (barium carbonate), and centrifugation, part of the diluted supernatant was reacted with the Elson–Morgan reagents[8]. The absorption maxima of the chromogen produced with the deacetylated tetrasaccharide appeared at 510 mμ compared with 530 mμ for reference glucosamine. These results are indicative of 1→3 glycosidic linkages[9] in the oligosaccharide, which is also supported by its pronounced alkali lability. The foregoing evidence and the fact that the bee venom tetrasaccharide showed identical properties, and had an infra-red spectrum indistinguishable from that of a tetrasaccharide produced by testicular hyaluronidase action, indicates that the major products of exhaustive treatment of hyaluronic acid with bee venom hyaluronidase are the tetrasaccharide GpAl$\xrightarrow{\beta}$3 GNAcl$\xrightarrow{\beta}$4 GpAl$\xrightarrow{\beta}$3 GNAc and the hexasaccharide GpAl$\xrightarrow{\beta}$3 GNAcl$\xrightarrow{\beta}$4 GpAl$\xrightarrow{\beta}$3 GNAcl$\xrightarrow{\beta}$4 GpAl$\xrightarrow{\beta}$3GNAc. Bee venom hyaluronidase should prove useful in future structural investigations of hyaluronic acid since with the isolated hexasaccharide it gave only the tetrasaccharide and a disaccharide and showed no evidence of a transglycosylation reaction. Bee venom also appears to degrade chondroitin sulphate A and C, heparin and blood group A and B substances. The nature of this action and whether it is due to the same β-glucosaminidase have yet to be determined.

We thank the Nuffield Rheumatism Research Council for financial support, Prof. K. Meyer for the gift of the tetrasaccharide and Prof. M. Stacey for his interest in this work.

BIOCHEMISTRY

Effect of Ultrasonics on the Adenosine Triphosphatase Activity and Actin-binding Ability of L-Myosin and Heavy Meromyosin

Asakura[1] recently discovered that *F*-actin retains its native properties under ultrasonic vibration. In a more recent investigation Ohnishi and Ohnishi[2] reported that the ATPase activity of glycerinated muscle fibres increases under the same conditions. It would appear, therefore, that both structural muscle proteins are resistant to ultrasonic treatment. Physicochemical studies on the effect of ultrasonics on L-myosin and the meromyosins have shown in this laboratory that L-myosin and heavy meromyosin were readily fragmented, whereas light meromyosin was relatively resistant to vibration[3]. The effect of ultrasonics on the biochemical properties of L-myosin and heavy meromyosin will be described in this paper.

L-myosin[4] and heavy meromyosin[5], 6·0 mg/ml., in 0·6 M potassium chloride, *p*H 7·0, were vibrated in the model *U*–20 biosonic apparatus (Will Corporation) at 20 kc/s in the cold room. The temperature of the myosin solutions was kept below 10° C during vibration.

ATPase activity was measured in a water bath of 25° C with magnetic stirring in the test tubes. For the determination of the ATPase activity of L-myosin or heavy meromyosin in the presence of calcium, incubations were carried out in systems containing: 0·1–0·2 mg protein/ml. 35 mM potassium chloride, 10 mM histidine buffer, *p*H 7·0, or 10 mM *tris*(hydroxymethyl)aminomethane buffer, *p*H 9·0, 10 mM calcium chloride, and 5 mM ATP. For the determination of the magnesium-activated actomyosin ATPase activity, the system contained: 0·25 mg L-myosin/ml., 0·025 mg *F*-actin/ml., 36 mM potassium chloride, 10 mM histidine buffer, *p*H 7·0, 1 mM magnesium sulphate, and 1 mM ATP. All the determinations were performed in duplicate for a period of 2–5 min. Care was taken that not more than 20 per cent of the added ATP was hydrolysed. The inorganic phosphate liberated was determined by the method of Rockstein and Herron[6]. The results are expressed as μmoles of inorganic phosphorus liberated per mg of L-myosin, heavy meromyosin, or actomyosin per min.

Actomyosin formation at high ionic strength was determined in a system containing: 1·5 mg L-myosin/ml., and 0·3 mg *F*-actin/ml. or 3·0 mg heavy meromyosin/ml. and 0·6 mg *F*-actin/ml., 0·5 M potassium chloride, 20 mM histidine buffer, *p*H 7·0, and 0·5 mM magnesium sulphate at 25° C. The actomyosin formation is expressed according to Weber and Portzehl[7] as ATP sensitivity.

Actomyosin formation at low ionic strength was determined by measuring the amount of *F*-actin bound to L-myosin as described previously[8]. In order to increase the sensitivity of the determination, the *F*-actin was labelled with isotopic calcium[9], and the amount of bound *F*-actin was determined by radioactivity measurements. It was also shown previously that no exchange of the labelled *F*-actin-bound calcium occurred in the presence of L-myosin and magnesium at low ionic strength[9]. The system contained 0·5 mg L-myosin/ml., 0·05 or 0·1 mg ^{45}Ca-*F*-actin/ml. (4,980 counts/min/mg *F*-actin), 40 mM potassium chloride, 10 mM histidine buffer, *p*H 7·0, and 1 mM magnesium sulphate at 25° C. The precipitated actomyosin was separated immediately by centrifugation and any remaining actin in the supernatant was determined by drying 3-ml. samples of the supernatant in stainless steel planchets under infra-red lamps and counting in a windowless gas-flow counter (Tracerlab). All countings were performed in duplicate. The actomyosin formation at low ionic strength is expressed as g *F*-actin-bound per g of L-myosin at the two different *F*-actin concentrations used. No sedimentation of *F*-actin was found in the absence of L-myosin.

Actin was purified according to the procedure of Mommaerts[10].

Fig. 1 shows the effect of ultrasonics on the ATPase activity and actomyosin formation of L-myosin. In the course of vibration, L-myosin simultaneously loses its calcium-activated ATPase activity, both at *p*H 7·0 and 9·0, and its magnesium-activated ATPase activity in the presence of *F*-actin. These ATPase activities of L-myosin are lost to a greater extent than its ability to combine with *F*-actin both at high and low ionic strength. For example, the actomyosin formation is almost unchanged after 20 min of vibration, whereas the different ATPase activities are decreased by about 50 per cent. Fig. 2 shows that heavy meromyosin is affected by ultrasonics in the same way as L-myosin in regard to its ability to combine with *F*-actin at high ionic strength and its calcium-activated ATPase activity at *p*H 7·0.

These results show, therefore, that the ATPase activity of L-myosin does not withstand ultrasonic vibration, contrary to its resistancy when present in the myofibrils[3]. They show, furthermore, that vibration affects

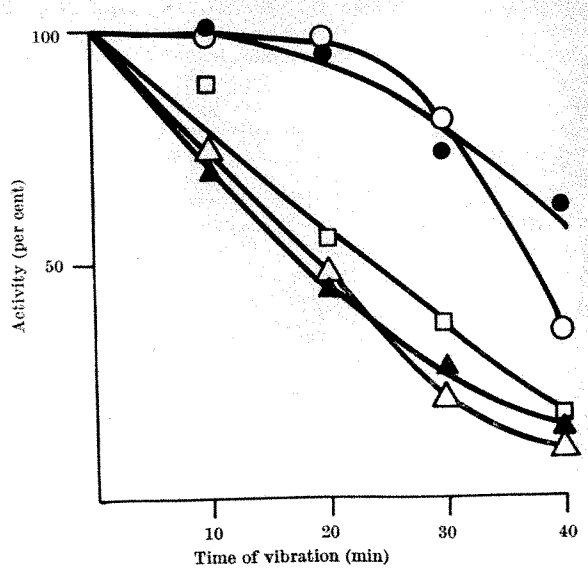

Fig. 1. Effect of ultrasonic vibration on the characteristic properties of L-myosin. ○, actomyosin formation at high ionic strength (100 per cent = 112); ●, actomyosin formation at low ionic strength (100 per cent = 0·088 and 0·173 for the two different actin concentrations); □, magnesium-activated actomyosin ATPase activity (100 per cent = 0·26 μmoles inorganic phosphorus/mg protein × min); △, calcium-activated L-myosin ATPase activity at *p*H 7·0 (100 per cent = 1·03 μmoles inorganic phosphorus/mg protein × min); ▲, calcium-activated L-myosin ATPase activity at *p*H 9·0 (100 per cent = 1·26 μmoles inorganic phosphorus/mg protein × min)

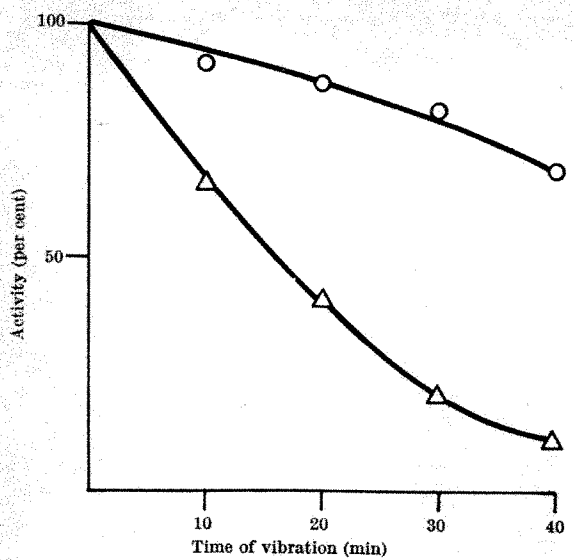

Fig. 2. The effect of ultrasonic vibration on the characteristic properties of heavy meromyosin, ○, actomyosin formation at high ionic strength (100 per cent = 120); △, calcium-activated ATPase activity at *p*H 7·0 (100 per cent = 1·29 μmoles inorganic phosphorus/mg protein × min)

differently the ATPase activity and actin-binding ability of both L-myosin and heavy meromyosin. We have reported earlier that L-myosin isolated from iodacetamide-treated actomyosin reacted with actin but did not show ATPase activity[11]. It appears, therefore, that the site(s) of L-myosin or heavy meromyosin which interact with ATP and actin are different.

Effect of Orotic Acid on the Synthesis of Citrovorum Factor and of Methionine in Liver of the Chick

IN a dietary condition in which only B_{12} of the vitamins and methionine of the amino-acids are active for growth in the chick, it has been demonstrated that orotic acid is a growth factor[1]. One biochemical hypothesis on the effect of orotic acid in B_{12} and methionine deficiency is that orotic acid acts in the metabolism of the 1–C unit.

In the work recorded here the part played by orotic acid on the metabolism of 1–C unit has been investigated, considering its effect in comparison with B_{12} and with methionine on the utilization of β-carbon of serine for the conversion of folic acid to citrovorum factor (CF) and for the biosynthesis of the methyl group of methionine. The experiments were carried out *in vitro* on liver homogenates of B_{12}-deficient chicks or dietary treated with vitamin B_{12}, or with methionine, or with orotic acid.

New Hampshire × White Leghorn chicks from a commercial hatchery were used. The animals were put into four groups of 25 chicks each, and, beginning from one day of age, one group received the vitamin B_{12}-deficient diet[2] and the other three groups were kept on the same diet supplemented for each 100 g with 10 μg vitamin B_{12}, 150 mg DL-methionine, and 10 mg orotic acid respectively. The chicks were maintained in standard electrically heated batteries with screen wire floors. Food and water were supplied *ad libitum*.

At the end of the test period (5 weeks), 6 chicks of each group were killed, the livers were removed and immediately tested for folic acid to CF conversion and methionine synthesis[3]. The quantity of CF and methionine formed, considered as the measure of enzyme systems, was valued microbiologically.

CF was assayed with *Leuconostoc citrovorum* A.T.C.C. 8081. Bacto 'CF assay Medium' (Difco Laboratories Inc.) was used as basal medium and 'Leucovorin' (Lederle) as the standard. The cultures were incubated for 72 h at 37° C and growth was measured by titrimetric procedure.

Methionine was assayed with *Leuconostoc mesenteroides P*60, A.T.C.C. 8042. Bacto 'Methionine' assay 'Medium' (Difco Laboratories Inc.) was used as basal medium and DL-methionine was used as standard. The growth was measured titrimetrically after an incubation period of 72 h at 37° C (Table 1). Nitrogen was determined on each homogenate by the usual micro-Kjeldahl technique.

As shown in Table 1, analysed for statistical significance, the livers of chicks treated with dietary vitamin B_{12} ($P < 0{\cdot}01$), with methionine ($P < 0{\cdot}05$), with orotic acid ($P < 0{\cdot}001$), converted folic acid to CF more effectively than those of chicks fed the unsupplemented deficient diet. These results indicate that the enzyme system which leads to the synthesis of CF from folic acid and β-carbon of serine is influenced by methionine and by orotic acid, as well as by B_{12}.

Table 1 shows that the livers of chicks treated with vitamin B_{12} ($P < 0{\cdot}01$), with methionine ($P < 0{\cdot}05$), and with orotic acid ($P < 0{\cdot}05$) synthesize methionine from homocysteine and serine more effectively than those of deficient chicks. These results indicate that all three substances are involved in this synthesis.

The effect of dietary methionine on the CF and methionine formation could be due to a better biosynthesis of the specific enzymes and demonstrates the sensitivity of these processes to the amino-acid deficiency.

The action of B_{12} could be attributed not only to an increased biosynthesis of enzymes[4] and to a metabolic regulation of cofactors concerned with 1–C metabolism[5], but also to a direct coenzymatic mechanism[6,7].

Table 1. SYNTHESIS OF CITROVORUM FACTOR AND METHIONINE BY LIVER HOMOGENATES FROM CHICKS FED B_{12}-DEFICIENT DIET AND SUPPLEMENTED WITH B_{12}, WITH METHIONINE, WITH OROTIC ACID

Supplements to 100 g deficient diet	Body-weight after 5 weeks	Nitrogen content mg/g of liver	μg CF formed per g of liver	μg methionine formed per g of liver
None	257 ± 8·06* (25)†	28·6 ± 1·48* (6)†	19·74 ± 1·87* (6)†	437·7 ± 27·8* (6)†
10 μg vitamin B_{12}	328 ± 8·18 (25)	30·3 ± 1·87 (6)	31·77 ± 3·32 (6)	653·9 ± 67·2 (6)
150 mg DL-methionine	339 ± 7·74 (25)	29·7 ± 2·87 (6)	28·84 ± 3·63 (6)	535·5 ± 27·3 (6)
10 mg orotic acid	315 ± 7·21 (25)	31·4 ± 1·19 (6)	41·18 ± 1·58 (6)	658·6 ± 94·1 (6)

* Standard error of the mean. † No. of animals.

Reaction mixtures contained: 5 ml. 20 per cent liver homogenate in 0·08 M sodium potassium phosphate buffer *p*H 6·3 along with 5 ml. same buffer and aliquots of solutions containing 10 mg L-serine, 10 mg L-homocysteine, 100 μg folic acid; total volume to 11 ml. Incubation was at 37° C under N_2 for 2 h.

With regard to orotic acid, it is not possible with the preliminary results at our disposal to define the action mechanism of this substance.

Orotic acid could in fact act indirectly in the biosynthesis of specific enzymes through an increase of soluble RNA involved in the transport of amino-acids[8], or, more directly, as a precursor of the pyrimidine coenzymes in the metabolic processes connected with the utilization of β-carbon of serine. This is in part justified by the observation that CMP plays a part in a reaction in which the serine is involved[9].

Nature of Humic Acids

The idea that humic acids are heteropolycondensates[1] of phenolic substances with or without the participation of amino-acids is now widely accepted. Three possible sources of the phenols are postulated: (1) phenolic materials such as flavonoids leached from the plant debris; (2) phenolic units formed during the decomposition of lignin; (3) phenolic substances synthesized by soil micro-organisms which may have been utilizing carbohydrates. However, attempts to identify the units in the condensate have been hampered by the absence of degradative procedures, which yield monomers with unchanged substitution patterns and intact carbon side-chains. Previous chemical investigations have, therefore, been primarily concerned with elemental analysis and the determination of active groups[1,2] which are mainly carboxyl and phenolic hydroxyls and possibly smaller quantities of quinonoid and primary alcohol groupings.

The indication that the first step in the biological degradation of humic acid[3,4] was a reductive step led us to re-investigate chemical reductive methods. Sodium amalgam which had been used previously in the reduction of humic acid[5] was found most successful. The humic acid was dissolved in sodium hydroxide and reduced with sodium amalgam in an atmosphere of oxygen-free nitrogen at 100°–110° C. The reaction mixture was acidified and the phenols extracted with ether. Yields of 10–14 per cent of phenolic material were recovered after the first reduction. Repeated reductions gave a total yield of phenol material corresponding to 30–35 per cent of the original material and the residue gave a further yield of phenols on fusion with potassium hydroxide at 280° C.

After successful reduction of humic acid from a podzol[6] under *Pinus sylvestris*, humic acids extracted from a cultivated chernozem near Prague, Czechoslovakia, a rendzina at Swyncombe, Oxfordshire, collected by Mr. J. Elston, a humic soil developed under the moss *Bryum argenteum*, collected from Signy Island, South Orkneys, by Dr. M. W. Holdgate, and a sample of humic acid extracted by Mr. P. Howard from an oak–ash mull at Humphrey Head, Lancs., were also reduced. The phenols were separated by two-way chromatography on thin-layer plates of silica gel using acetic acid (10 per cent v/v)/chloroform and ethyl acetate (45 per cent v/v)/benzene. In Table 1 the phenolic materials which have been identified from the different samples are recorded. It must be emphasized that at this stage these identifications are provisional only, and depend on chromatographic evidence and colour reactions.

The chromatographic patterns differ in humic acids of different origins and provide a 'finger-print' technique, which may remove some of the present confusion which arises from a lack of criteria for the characterization of this class of compounds.

The contribution of lignin from the overlying vegetation to humic acid formation was shown by the presence of relatively unchanged lignin residues. Vanillic, syringic, *p*-hydroxybenzoic, guaiacyl- and syringyl-propionic acids have been identified. Syringyl residues occur in humic acids formed under deciduous hardwood vegetation (oak) but are absent under coniferous softwoods (pine), where vanillic acid predominates. The assumption that these are lignin-derived components was supported by the complete absence of such residues in humic acid developing in a lignin-free environment below Antarctic clumps of the moss *Bryum argenteum*.

Other degradation products which may be used to distinguish between different humic acids include phloroglucinol, methyl-phloroglucinol, protocatechuic acid, resorcinol, 3 : 5-dihydroxybenzoic acid, pyrogallol and 2 : 4-dihydroxytoluene. Several of these can be obtained by degradation of model substances of the C_6—C_3—C_6 type. They may represent a flavonoid contribution of the parent vegetation or, alternatively, could be derived from soil microbial syntheses where 1–3–5 substitution patterns are quite common.

Reductive cleavage of fully methylated podzol humic acid suggests that the isolated monomers are linked by ether bridges. The phenolic hydroxyl groups of vanillic, protocatechuic and *p*-hydroxybenzoic acid are protected during methylation and these units are released unchanged. Units of the 'flavonoid' group are replaced by partially methylated derivatives (mono-methoxy-phloroglucinol, *m*-methoxyphenol, etc.), indicating that these possess some free unbonded phenolic hydroxyl groups as well as those involved in linkage.

Table 1

		Source of humic acid					
		Podzol	Humic acid (L. Light and Co., Ltd.)	Rendzina	Chernozem	Mull humus (oak)	Antarctic moss humus
Possible flavonoid units	Phloroglucinol	+ + +	+ + +	Trace	+ +	−	+ +
	Resorcinol	+ + +	+ + +	+	+ + +	+ +	+ +
	Methyl-phloroglucinol	+ +	+ +	Trace	+ +	−	+
	2 : 4-Dihydroxytoluene	+ +	+ +	Trace	+	−	+
Possible lignin units	*p*-Hydroxybenzoic acid	+	+	+ +	+	+ +	−
	Vanillic acid	+ +	+ +	+ + +	+ +	+ +	−
	Syringic acid	−	−	+ +	+	+ +	−
	Protocatechuic acid	+	+	+	+	+	−
	Guaiacyl-propionic acid	+	−	+ +	+	−	−
	Syringyl-propionic acid	−	−	+	+	−	−
	Pyrogallol	+	+	+	+	−	−
	3 : 5-Dihydroxybenzoic acid	+ +	+	Trace	+	−	+

The reductive cleavage of saccharo-humic acid, which is often discussed in humic acid studies, did not reveal any phenolic units. This confirms the widely accepted view that saccharo-humic acid is quite unrelated to soil humic acids. A native spruce lignin supplied by Dr. Handley, of Oxford, was readily reduced by the same technique to give a mixture of more than 30 phenolic compounds, including *p*-hydroxybenzoic acid, which indicates the probable existence of non-methylated phenol residues in soft-wood lignin, and a number of substituted phenyl residues with C_1, C_2 and C_3 side-chains.

Presence of Ribonucleic Acid in the Initial Yolk Globules of Oocytes of *Aplysia depilans* L.

Previous work carried out with the electron microscope has indicated that the formation of yolk globules of some species of Mollusca and Echinodermata occurs by aggregation of protein particles[1,2]. Experiments have also indicated the possibility of obtaining in neoplastic cells an artificial aggregation of the particles[1–3]. Work on oocytes has shown the ribosomal nature of the particles, and it is thus possible that RNA is present in the product of protein synthesis.

Investigations have been carried out in order to solve this problem. The vitellogenesis of oocytes of *Aplysia depilans* L. (Mollusca, Opistobranchia), in which the final yolk globules (Fig. 2, *g″*) are formed by products coming from the transformation (Fig. 1, *g′*) of initial large yolk globules (Fig. 1, *g*), which are found in relatively young oocytes[4], has been examined.

The following stains were used for light microscopy: Unna-Pappenheim, Dominici, toluidin blue; for fluorescent microscopy, acridine orange. Control with ribonuclease ('Crystalline' of Light and Co.) for all methods was carried out. In this way observations of the presence of RNA in the aforementioned initial yolk globules was made possible. Einarson's method was also used; but it was not found to be suitable. With Unna-Pappenheim's method, there have been indications that a diminution of the pyroninophilia of the globules is due to digestion with ribonuclease. Clear-cut results have been obtained with Dominici's method and with treatment with acridine orange. In the final yolk globules the tests always gave negative results.

Further tests made on other material—whether germinal or somatic—could perhaps render it possible to generalize the idea that ribonucleoproteins, after the incorporation of amino-acids, are traceable, at least in an initial phase of formation, in the products of protein synthesis. More information on the function and destiny of cytoplasmic ribosomes ('cytoribosomes')[2] could therefore be obtained.

Localization and Fractional Determination of Neutral Deoxyribonuclease Activity in Cat Serum

The biological role, biochemical and enzymatic characteristics and cellular localization of DNases in higher mammals are still little understood. The existence of numerous isozymes suggests that the DNase activity manifested by most tissues could be related to one or several molecular forms of one or several enzymes or their inhibitors. In this respect we present a preliminary investigation concerning the localization of DNase activity in the serum of the cat fractionated on gelose and starch gel, and the concentration and fractional determination of this activity by chromatography on substituted celluloses. When compared with various mammalian sera, the cat's serum has a very high DNase activity and therefore constitutes good material for examination[1]. Blood was obtained by cardiac puncture from animals anæsthetized with ether. The serum was obtained immediately after retraction of the clot and kept in the refrigerator. It was fractionated by starch-gel electrophoresis according to Smithies[2,3] and by agar-gel electrophoresis according to Grabar and Burtin[4].

Running a DNA gel (200 μg DNA/ml. 1·5 per cent gelose solution) over the electrophoresis plates makes it possible to reveal directly the DNase activity of fractions after incubation for 16 h at 37° C., by staining of the non-hydrolysed DNA by a methyl green solution (1 per 1,000 in a *tris* buffer 0·1 M, *p*H 7·4).

It is also possible to prepare an electrophoretic gelose support containing 100 μg DNA/ml., in which case the protein migration is not disturbed, and enzymatic activities are revealed immediately after incubation for 2 h at 37° C by a methyl green reaction. This method ensures more exact separation and selection of the active zones (Fig. 1).

Serum chromatography is carried out on DEAE cellulose in a continuous gradient, and on CM cellulose in a discontinuous gradient, by the classical procedure of Sober and Peterson[5,6].

Every chromatographic fraction is lyophilized and dissolved in 0·5 ml. *tris* buffer 0·1 M,

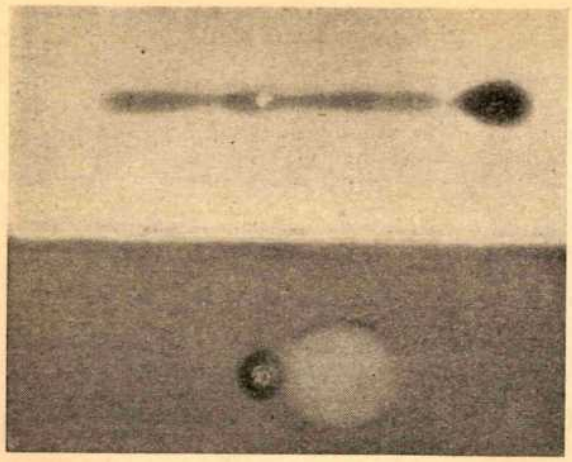

Fig. 1. Electrophoresis of serum of the cat on agar gel with DNA. Demonstration of activity of DNase by methyl green, as compared with protein migration

*p*H 7·4. DNase activity is examined and evaluated by a semi-quantitative method based on the proportionality between the enzyme concentration in a given medium and the importance of enzyme diffusion in an agar gel containing DNA[7]; its determination is effected by Kurnick's method[8]. Determination of the protein values is carried out by Lowry's method[9].

Figs. 2 and 3 show the fractionation of serum proteins on DEAE cellulose and on CM cellulose.

In the two cases the DNase activity is found in two separated fractions. Electrophoretic analysis of these fractions, whether on agar gel or on starch gel, leads to their identification as α_2-globulins; these electrophoretic media, however, do not allow their separation.

The recovery of protein is 81 per cent on DEAE cellulose and 87 per cent on CM cellulose.

The results obtained by the method of Lowry are identical to those obtained by ultra-violet absorption at 278 mμ.

Fractions IV, V and VI (DEAE cellulose) include 58 per cent of the total proteins; fractions I and II (CM cellulose) include 70 per cent of the total proteins.

The sum of the DNase activities in each fraction equals about 75 per cent of the initial DNase activity (DEAE and CM cellulose). Each of the peaks obtained was re-chromatographed; in all cases elution was effected under the same conditions in terms of *p*H and ionic strength as in the initial chromatography.

The detection and quantitative evaluation of DNases by diffusion are not disturbed by the presence of inhibitors or by physicochemical conditions of environments unfavourable to enzyme activity. This method by diffusion, therefore, is justified in the case of electrophoretic determinations in the presence of buffers with a borate, citrate or such similar base.

Our results can be compared with those of Becking *et al.*[10], who succeeded in separating two fractions of crystallized pancreatic DNase I by chromatography on CM cellulose; Baumgarten *et al.*[11] demonstrated that crystallized DNase I can be separated by paper electrophoresis into three well-defined components.

Our results are not in favour of the existence of organic DNase inhibitors in cat serum because the recovery of DNase activity on the basis of each fraction is satisfactory. Nevertheless, no definite conclusions can be formed in this respect except by detailed examination of the enzyme kinetics of each of the fractions obtained; this requires a higher degree of purification of the enzymes in question.

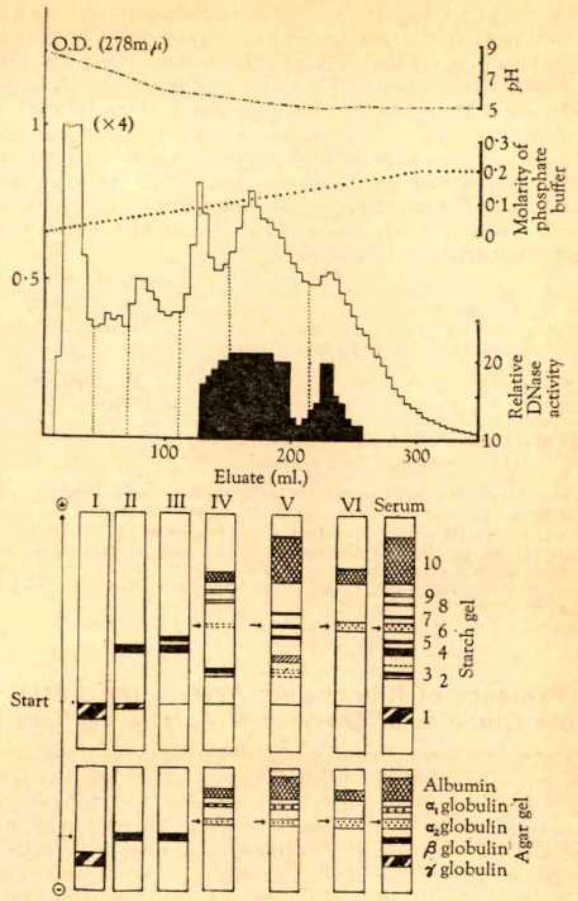

Fig. 2. Chromatography of serum of the cat on DEAE cellulose, with continuous gradient; 9 g DEAE cellulose, 4·5 ml. serum (proteins 67 mg/ml.; DNase activity 1·5 KU/ml.); in black, relative DNase activities. Arrow corresponds to a DNase activity in electrophoretic analysis of fraction electrophoresis

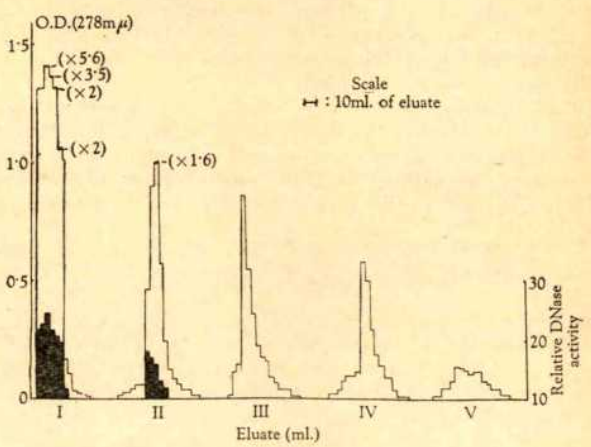

Fig. 3. Cat serum chromatography on CM cellulose, with discontinuous gradient; 3 g CM cellulose – 2 ml. serum (proteins 67 mg/ml., DNase activity 1·5 KU/ml.); in black, relative DNase activity. Buffers used: (I) sodium acetate 0·02 M, *p*H 4·6; (II) sodium acetate 0·08 M, *p*H 6·0; (III) sodium phosphate 0·1 M, *p*H 7·0; (IV) sodium phosphate 0·1 M and sodium chloride 0·5 M equal parts, *p*H 9·2; (V) sodium carbonate 0·3 M, *p*H 10·6

For similar reasons it is impossible to establish whether the two isolated fractions have identical enzymatic characteristics comparable to isozymes, or different characteristics[12].

Some preliminary tests have proved that, unlike cat serum (and mice sera), the serum in rabbits and rats shows

localization of the DNase activity in the electrophoretic range of post-albumin α_1-globulins.

PHYSIOLOGY

Identification of Inhibitory Neurones in the Hippocampus

In their recent article in *Nature*, Andersen, Eccles and Løyning[1] claim to have unequivocally identified the basket cells of the hippocampus as the inhibitory neurones of this brain structure. They claim that "there is no alternative" to this interpretation and that it therefore "seems possible for the first time to give an example from the mammalian nervous system of a recurrent inhibitory pathway where both the inhibitory neurone and its synapses are histologically identifiable".

The conclusions reached by the authors are based on three main premises. The correctness of none of these is fully substantiated by the findings presented in their article.

Premise (1) postulates that the inhibitory neurone should possess "an axon with extensive ramifications . . . distributed to a large number of pyramidal cells". Quite apart from the fact that cells other than basket cells located in the stratum oriens fulfil these criteria (for example, the neurone No. 1 in Fig. 8 of Lorente de Nó's[2] paper), the observations made could just as easily be explained by assuming a rather large number of inhibitory neurones distributing their axons to a moderately small number of pyramidal cells.

It is, however, premise (2) which rests on the shakiest foundations. The authors assume that the synaptic terminals of the inhibitory neurone end on the soma of the pyramidal cell. So far as can be judged from the findings presented, this assumption is based on the laminar profiles of the responses evoked by commissural, septal and 'local' stimulation (Fig. 1*D* of ref. 1). This profile shows peak positivity of a late response component in the pyramidal layer. However, the same profile would result if excitatory post-synaptic potentials (EPSP's) were developed on the apical dendrites. In fact, this explanation would better agree with the laminar profile observed. As Fig. 1*F* of Andersen's *et al.* paper[1] correctly shows, a 'source' developed by a hyperpolarizing potential at the soma level should give rise to two 'sinks', one in the apical dendrites, the other near the alveus. The experimental findings, however, show only one 'sink' in the apical dendrites.

Furthermore, no evidence is given to indicate that the positive wave recorded extracellularly in the pyramidal layer is associated with inhibition of unit discharge and thus may safely be equated with the intracellularly recorded IPSP's. That the two are identical is an assumption for which there exists no proof. The authors themselves note a discrepancy in the duration of these two potentials which they try to resolve by assuming that the shorter duration of the extracellularly recorded potential is due to the fact that the extracellular current flow lasts for a shorter time than the intracellularly recorded hyperpolarization.

However, inhibitory potentials of the same duration as the intracellularly recorded inhibitory post-synaptic potentials (IPSP's) can be observed extracellularly with responses evoked by entorhinal stimulation, as we have shown in our own experiments[3,4]. These potentials are clearly associated with inhibition of pyramidal cell discharge (ref. 4, Figs. 8 and 9). The laminar profile of this extracellularly recorded inhibitory potential showed a peak in the apical dendritic layer (ref. 4, Fig. 5) whereas the cell layer often acted as a 'sink' (ref. 4, Figs. 8 and 9). The synapses producing this inhibitory potential therefore seem to be located predominantly on the apical dendrite and not on the soma. This excludes the basket cells from consideration and makes it likely that other hippocampal interneurons with axons ramifying mainly in the apical dendrites are responsible for these inhibitory potentials. Candidates for this role can be found in the stratum oriens as well as in the apical dendritic layer (for example, ref. 2, cell No. 5 in Fig. 6, cells No. 1, 3 and 6 in Fig. 7 and cell No. 1 in Fig. 8). We have, furthermore, given evidence suggesting that axo-somatic synapses on pyramidal cells may be excitatory rather than inhibitory[4], although we do not claim that our observations provide incontrovertible proof for this interpretation. Nevertheless, one can certainly say that the question whether the basket cells are excitatory or inhibitory neurones still remains unresolved.

Premise (3) assumes that the responses analysed are mediated by three separate inputs. This is very questionable. 'Local' stimulation must have activated the terminals of the commissural pathways and therefore we are dealing at the most with two different afferent inputs, rather than three as claimed.

There seems, therefore, to be no basis for the claim that experiences by Andersen *et al.*[1] have unequivocally identified the basket cells as the inhibitory neurones of the hippocampus. Such a conclusion is merely one among several possible, but unproved, interpretations to be considered, especially since all the known experimental evidence cannot be reconciled with this view.

P. Gloor

Montreal Neurological Institute and the

McGill University, Montreal.

[1] Andersen, P., Eccles, J. C., and Løyning, Y., *Nature*, **198**, 540 (1963).
[2] Lorente de Nó, R., *J. Psychol. Neurol.* (Leipzig), **46**, 113 (1934).
[3] Gloor, P., Sperti, L., and Vera, C. L., *Coll. Intern. Centre Nat. Recherche Sci.*, No. 107, Paris, edit., C.N.R.S., 147 (1962).
[4] Gloor, P., Sperti, L., and Vera, C. L., *Electroenceph. Clin. Neurophysiol.*, **15**, 379 (1963).

We welcome this critical comment by Dr. Gloor because it gives the opportunity of clearing up some misunderstandings and of refuting Dr. Gloor's statement that there is "no basis for the claim that experiences by Andersen *et al.* have unequivocally identified the basket cells as [the] inhibitory neurones of the hippocampus". The word [the] is in brackets because we made no claim of exclusiveness; otherwise we accept Dr. Gloor's formulation of our position.

We deny Dr. Gloor's statement that premise (2) "rests on the shakiest foundations". Any appearance of insecurity derives from a failure to appreciate the degree of assurance which can be attained, under favourable geometric conditions, when interpreting an assemblage of extracellular potentials together with the associated

intracellular potential. The favourable geometric situation is provided in the hippocampus by the arrangement of the somas of the pyramidal cells practically in a single layer parallel to the ventricular surface and with their apical dendrites perpendicular thereto. Dr. Gloor states that the extracellular 'laminar profile' of our Fig. 1*E* with a sharp peak of positivity at the soma could be due to an active synaptic depolarization generating EPSP's in the apical dendrites. We need not discuss in detail the merits of this alternative explanation of the 'laminar profile'; it is sufficient to recognize that from it arises the prediction that intracellular recording from the soma would discover a depolarization, the electrotonically transmitted EPSP; whereas, in fact, we reported that a large hyperpolarization was found in 76 of the 79 cells recorded from successfully. We submit that the laminar profile in conjunction with this intracellularly recorded hyperpolarization admits of no interpretation other than an active synaptic hyperpolarization of the somatic region of the pyramidal cells, that is, of inhibitory synaptic action concentrated on the soma. Such a location would give a source for current flowing extracellularly into two sinks, one in the region of the apical dendrites, the other in the opposite direction in the region of the basal dendrites, as was actually shown diagrammatically in our Fig. 1*F*. Dr. Gloor denies the existence of the latter sink on the irrelevant grounds that it is not negative to the indifferent earth electrode. Its existence is of course indubitably established by the slope of the extracellular laminar profile from the positive peak at the soma layer (about + 2 mV) to a relatively negative level in the stratum oriens (about + 0·5 mV).

It is strange that Dr. Gloor maintains that the extracellular positive wave at the pyramidal layer cannot be safely equated with the intracellularly recorded IPSP's unless it can be shown to be associated with inhibition of unit discharge. This was frequently observed, but not reported. Surely it is sufficient that the extracellular positivity is concurrent with the large hyperpolarization of the IPSP, or is Dr. Gloor doubting whether IPSP's are inhibitory? There is a precise correlation (within 1 msec) between the onsets of the IPSP's and of the positive potential recorded outside the soma in response to all three inputs. However, as we stated, the development of a later negative potential in the apical dendrites obscures the prolonged low hyperpolarizing current that would be expected for inhibitory synapses generating an IPSP with a half decay time of 50–80 msec in a membrane that has a time constant of about 10 msec[1].

It is irrelevant for criticism of our paper that Dr. Gloor cites his own evidence from extracellular observations that a source on apical dendrites with a sink on the soma is "an inhibitory potential" and that in the stratum oriens there are various neurones having axons projecting up to the apical dendrites. We made no statements for or against other inhibitory sites on the pyramidal cells. Our exclusive statement referred to the synapses responsible for the large IPSP's generated in the somas of pyramidal cells by the inputs used in our experiments. However, it will be appreciated from the foregoing discussion that intracellular recording is desirable before positive extracellular potentials are attributed to inhibitory synaptic action. It is a minor point that, in criticizing our claim to have used three separate inputs, Dr. Gloor states that the: "Local stimulation must have activated the terminals of the commissural pathways". This statement is incorrect. The commissural pathway projects to the hippocampal region under examination from a direction opposite to the site of the locally stimulating electrodes[2].

Having disposed of Dr. Gloor's criticisms we reassert that the amazing concentration of basket cell synapses on the pyramidal cell somas provides the only structures that could produce the powerful inhibitory synaptic action that is specifically exerted on these somas. In a parallel investigation on the cerebellum, it has likewise been shown that the concentration of basket cell synapses on Purkinje cell somas gives the structural basis of the powerful inhibitory action on Purkinje cells[3].

Medullary Vagal Effects of *d*-Lysergic Acid Diethylamide in the Decerebrate Cat

Despite the fact that 2-brom-*d*-lysergic acid (BOL-148) and *d*-lysergic acid diethylamide (LSD-25) are both potent anti-metabolites of serotonin *in vitro*[1,2], they do not exhibit similar behavioural or pharmacological effects *in vivo*. LSD-25 has been shown to produce bradycardia, a decrease in respiratory rate and hypotension in the pento-barbitalized, intact cat[3]. This is in contrast to the hypertension and tachycardia produced in spinal animals. The explanation advanced for these effects has been that in the intact animal the hypertension and tachycardia, due to peripheral vasoconstriction, are masked by more potent effects of LSD-25 on higher centres. BOL-148 was also shown to have no effect on heart rate and a weak non-specific effect on blood pressure in the intact anæsthetized cat in doses up to 1 mg/kg (ref. 3). In the decerebrate cat, ergot alkaloids cause hypotension and bradycardia via medullary vagal centres[4,5]. Therefore, we attempted to study possible vagal effects of LSD-25 and BOL-148 in the decerebrate cat.

Forty cats, 2–4 kg, were used. Tracheal, arterial and venous cannulations and placement of subcutaneous electrodes were carried out under ether anæsthesia. Decerebration was accomplished by suction through the superior colliculi following ligation of the common carotid arteries and compression of the vertebral arteries. Adequacy of decerebration and intactness of the lower brain stem were judged by the presence of decerebrate rigidity and rhythmic spontaneous breathing. Following decerebration, at least 1 h elapsed before recording in order to eliminate the influence of the anæsthetic. Blood pressure was measured by means of a strain gauge. Respiration was recorded by a transducer attached to the side-arm of the tracheal cannula. Lead II of the standard electrocardiogram was routinely recorded with the animal supine. These parameters were recorded simultaneously on a Sanborn Poly-Viso. Drugs were dissolved in saline (1–2 mg/ml.) and administered intravenously within 30 sec.

Table 1. Summary of Pulse Rate, Blood Pressure and Electrocardiographic Findings in the Decerebrate Cat following LSD-25

No. of animals	Dose (mg/kg)	Pulse rate (heart rate/min) Control	Pulse rate (heart rate/min) Maximum	Blood pressure (mm/Hg) Control	Blood pressure (mm/Hg) Maximum	Abnormal rhythm No.	Abnormal rhythm Aver. duration
4	0·2	160 ± 12	108 ± 20	$\frac{160 \pm 20}{90 \pm 30}$	$\frac{120 \pm 22}{50 \pm 20}$	0/4	—
4	0·3	153 ± 45	110 ± 46	$\frac{140 \pm 40}{90 \pm 32}$	$\frac{103 \pm 10}{60 \pm 30}$	1/4	2 min
12	0·4	175 ± 40	93 ± 42	$\frac{135 \pm 30}{80 \pm 20}$	$\frac{90 \pm 15}{40 \pm 15}$	10/12	20 min

Table 1 summarizes the results obtained with LSD-25 (0·2, 0·3 and 0·4 mg/kg): bradycardia, hypotension and a decrease in respiratory rate were observed. In one of the 4 cats administered 0·3 mg/kg, transient auriculo-ventricular (A.V.) nodal rhythm was produced lasting 2 min. At 0·4 mg/kg dose level, 10 of the 12 animals developed

conduction disturbances. *P–R* prolongation followed by complete heart block or A.V. nodal rhythm with retrograde auricular conduction was observed, although the latter disturbance was seen more frequently. Fig. 1*A* is an electrocardiographic tracing illustrating this effect. The change in conduction lasted 6–28 min, averaging 20 min in duration. Artificial respiration was maintained prior to and following drug administration in 4 animals to rule out possible secondary effects due to anoxia. These cats all developed similar conduction abnormalities following the administration of LSD-25. An immediate return to regular sinus rhythm, and improvement in blood pressure and respiration were noted following either bilateral vagotomy or atropinization (1 mg/kg). (Fig. 1*B*).

In 4 cats the vagii were sectioned in the neck, and in 4 other animals atropine (4 mg/kg) was given 15 min prior to administration of LSD-25. In these animals, no conduction disturbances were observed. The changes in blood pressure and cardiac rate were not so marked as in those preparations without pre-treatment.

To rule out the carotid sinus mechanism as the mediator of the effects observed, 4 cats were subjected to bilateral excision of the carotid bifurcation. LSD-25 (0·4 mg/kg) produced effects similar to those observed in animals with carotid sinuses intact.

BOL-148 (0·4 mg/kg) produced mild, transient slowing of heart and mild hypotension lasting not more than 60 sec. The effects seen with 1·0 and 2·0 mg/kg were more pronounced and lasted 3–5 min. At the higher dose-levels QRS changes and *T* wave inversion were observed in the electrocardiogram (Fig. 1*C*). No A.V. nodal rhythm or second degree heart block with A.V. dissociation was produced even with the larger doses of BOL-148. Bilateral vagotomy resulted in an increase in heart rate if done at the height of these changes, but pre-vagotomized animals were not protected as they were with LSD-25.

Marked differences in the *in vivo* action of LSD-25 and BOL-148 are illustrated in this study. LSD-25 appears to have a medullary stimulating action, as contrasted with BOL-148 which probably has direct cardiac toxicity when administered in large doses. BOL-148 has little or no effect on medullary vagal centres. Both LSD-25 and BOL-148 appear to penetrate the brain with little difficulty[6], although selective uptake by specific brain sites cannot be ruled out from these studies. Serotonin antagonism cannot explain the differences observed since BOL-148 is as potent an antagonist to serotonin as LSD-25 (ref. 7). Cholinesterase inhibition does not appear to be the mechanism involved since LSD-25 and BOL-148 are only weak inhibitors of true cholinesterase, although they exhibit marked pseudo-cholinesterase inhibition[8]. It is interesting to note that the dose of LSD-25 required in this study to produce cardiac conduction disturbances in the decerebrate cat approximates the amount of LSD-25 needed to produce clear-cut behavioural effects in the unanæsthetized cat[9].

Crab Axons showing a Prolonged Repolarization Phase

A FURTHER type of response from isolated crab axons has been recorded by a new technique. The method is to thread an isolated axon through two holes in a fine polythene tube. The axon outside the tube is treated with isotonic sucrose solution and then raised into paraffin oil. Inside the tube test solutions can be flowed over the axon membrane. The effect is to produce an isolated 'node' of excitable membrane. Non-polarizable potassium chloride wick electrodes provide stimulating and recording connexions on each side of the 'node'. This method gives the normal variety of responses from different fibres[1]. In one type of fibre, when bathed by normal sea-water, the action potential shows a very prolonged repolarization phase of 25 msec with two discrete segments of 1 msec and of 24 msec, and during the later segment a supernormality develops, that is, during the falling phase of the first action potential a second action potential can be elicited by a weaker stimulus. The absolute refractory period extends for a period of 2 msec, up to the end of the first phase of the repolarization. Following this for 3–5 msec a period of typical subnormality leads to the period of supernormality which can last as long as 30 msec (Figs. 1 and 2 *a* and *b*).

When the 'node' is stimulated by direct current there is a repetitive response. Before the first action potential a normal local potential develops, but the following action potentials arise at a level of depolarization greater than the amplitude of the first local potential. Therefore no pacemaker potentials can be seen, that is, the later action potentials grow out of the falling phase of the preceding action potential (Fig. 2 *c*). With strong direct currents the amplitude of subsequent action potentials is greatly influenced and oscillatory processes become noticeable.

If a second current pulse is applied during the second segment of the repolarization its shape and time relations can be altered, cathodal current lengthening and anodal current shortening the repolarization. During the repolarization phase and the refractory period the ratio of the 'inward' to 'outward' resistance, as measured by small current pulses, is smaller than in normal fibres. All the evidence at present available suggests that the later prolonged segment of the repolarization is due to a low level of increase of potassium permeability. If then the level of rectifica-

PHARMACOLOGY

Mechanism of the Antagonism by Tetraethylammonium of Neuromuscular Block due to *d*-Tubocurarine or Calcium Deficiency

Tetraethylammonium salts (TEA) can antagonize the neuromuscular block caused by either calcium insufficiency or by *d*-tubocurarine[1]. The release of acetylcholine from motor nerve endings appears to be dependent on the presence of calcium ions[2,3], and neuromuscular block produced by calcium deficiency would appear to be caused by a reduced transmitter output. In this way the block differs sharply from that produced by *d*-tubocurarine, which does not affect acetylcholine release[4]. On the basis of indirect evidence Stovner[5] suggested that the 'decurarizing' action of tetraethylammonium salts may be the result of an increased liberation of acetylcholine from the motor nerve endings. That tetraethylammonium salts may have such an action is supported by the results of Koketsu[6] and Frank[7]. The study reported here provides quantitative evidence to support this theory.

The isolated rat phrenic nerve diaphragm preparation has been used in this work; the method being essentially that of Burgen, Dickens and Zatman[8]. The acetylcholine released from one hemidiaphragm in the presence of eserine (10^{-5} g/ml.) has been assayed on the blood pressure of the anæsthetized rat or on the eserinized leech muscle. The nerve was stimulated by supramaximal rectangular pulses (10 per sec; 0·3 msec) for periods of 15 min, separated by 10 min rest periods. Control experiments indicated no significant difference in the output of acetylcholine between five such consecutive periods of stimulation. When the diaphragm was suspended in Krebs solution containing normal amounts of calcium, significant increases in the amount of acetylcholine accumulating were found in experiments in which tetraethylammonium salts

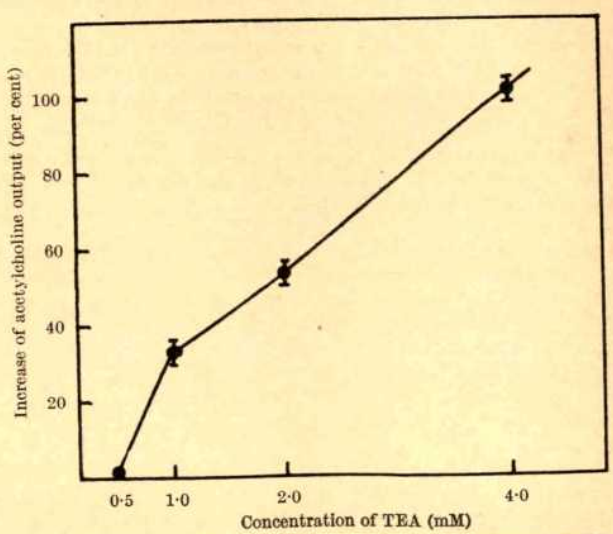

Fig. 1. Effect of varying concentrations of tetraethylammonium iodide (TEA) on the amount of acetylcholine recovered after stimulation of the rat phrenic nerve-diagram suspended in Krebs solution (10 pulses/sec; 15 min). Ordinate: acetylcholine recovered expressed as a percentage increase over control values (mean of five experiments ± *S.E.*). Abscissa: concentration of TEA (mM)

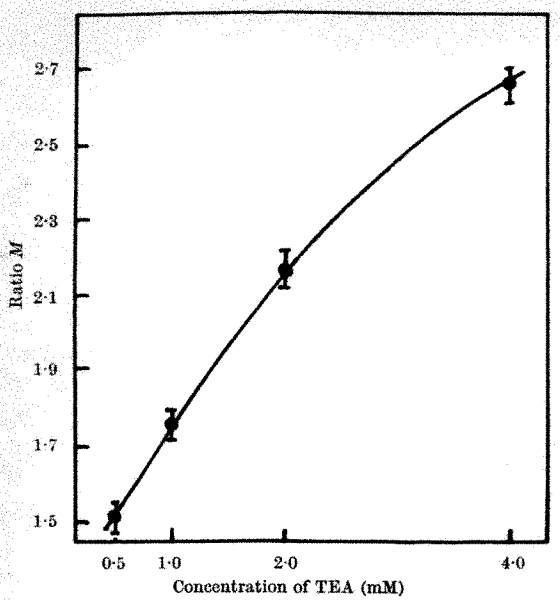

Fig. 2. Antagonistic effect of varying concentrations of TEA to *d*-tubocurarine. Ordinate: antagonistic effect as measured by ratio M (mean of five experiments ± *S.E.*).

$$M = \frac{\text{half-paralysing dose of tubocurarine in presence of TEA}}{\text{half-paralysing dose of tubocurarine in absence of TEA}}$$

Abscissa: concentration of TEA (mM)

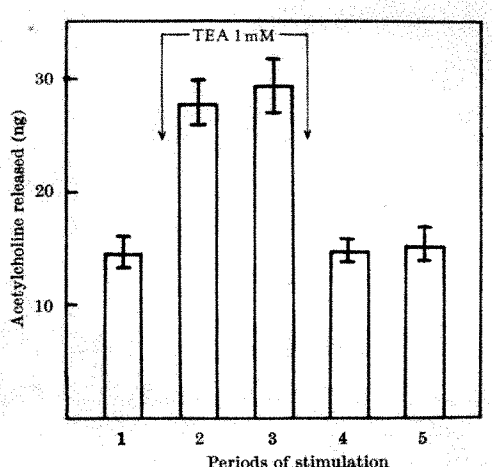

Fig. 3. Effect of 1 mM TEA on the amount of acetylcholine recovered after stimulation of the rat phrenic nerve-diaphragm suspended in low calcium Krebs solution. Ordinate: ng acetylcholine recovered (mean of five experiments ± *S.E.*). Abscissa: periods of stimulation (10 pulses/sec; 15 min). Each period of stimulation preceded by 10 min rest. TEA present during second and third periods

were present at concentrations of 1–4 mM, but not with lower concentrations. Considering the apparent lack of inhibitory effect of tetraethylammonium salts on cholinesterases, both *in vitro*[8] and *in vivo*[5], this increased accumulation of acetylcholine must be attributed to an increased liberation of transmitter. The magnitude of the effect was estimated by comparing the output of acetylcholine during the second and third periods of stimulation, when tetraethylammonium salts were present, with that of the first, fourth and fifth periods, when tetraethylammonium salts were absent. Fig. 1 shows the relationship between concentration of tetraethylammonium salts and the increased output of acetylcholine.

A measure of the antagonistic effect of tetraethylammonium salts to *d*-tubocurarine was obtained in other experiments using identical stimulation frequency. Antagonism was expressed as the ratio (M) of the concentration of tubocurarine producing 50 per cent reduction of contraction height in the presence of tetraethylammonium salts to the concentration producing a similar degree of paralysis in the absence of tetraethylammonium salts. Fig. 2 shows the relationship between concentration of tetraethylammonium salts and this ratio M.

There is a significant positive correlation between the increased amount of acetylcholine released and the anti-tubocurarine activity of tetraethylammonium salts ($r = 0{\cdot}957$, $P < 0{\cdot}001$).

It was found that calcium insufficiency resulted in a neuromuscular block which was associated with a reduced release of acetylcholine. This is consistent with the findings of Del Castillo and colleagues[2,3]. Tetraethylammonium salts, in a concentration which antagonizes the neuromuscular block caused by calcium deficiency, restored the output of acetylcholine to approximately normal values (Fig. 3).

This work therefore provides quantitative evidence to support the theory that the antagonistic action of tetraethylammonium salts to neuromuscular block caused by either *d*-tubocurarine or calcium insufficiency may be attributed to an increased release of acetylcholine from motor nerve terminals.

Attempts are now being made to elucidate this action of tetraethylammonium salts in greater detail.

We thank Prof. D. R. Wood for advice and assistance. One of us (B. C.) also thanks the Medical Research Council for financial support.

Absorption of Chlorhydroxyquinoline

There has been some uncertainty about the fate of halogenated derivatives of oxine in the body[1], but only a small part of an oral dose of chlorhydroxyquinoline could be detected in the urines of rats[1,2]. In further experiments, traces were found in the blood of rats but the amount could not be estimated.

More recently, investigations have been conducted in species other than the rat by means of the classic method for estimating phenols using Folin and Ciocalteau reagent or Gibbs's reagent. Substantial portions of oral doses have been found in the urines, as shown in the examples presented in Table 1.

Table 1. Urinary Levels following the Oral Administration of Chlorhydroxyquinoline

Species	Dose (mg)	Urines collected (h after dosing)	Amount in urine (mg) and % of dose
Rabbit	200	0–24	39 (19·5)
Rabbit	200	0–24	37 (18·5)
Rabbit	200	0–24	24 (12·0)
Calf	8,000	0–48	2,071 (25·9)
Man	250	0–8	26 (10·4)
Man	250	0–8	76 (30·4)
Man	250	0–8	89 (35·6)
Man	750	0–1·25	121
		1·25–2·25	31
		2·25–5	65
			217 (28·9)

The oral LD_{50} for mice has been found to be approximately 800 mg/kg and the intraperitoneal LD_{50} in this species was about 300 mg/kg. Other toxicity results are summarized in Table 2.

The gastro-intestinal tract of the guinea pig seems to be unusually susceptible to irritation by high concentrations of chlorhydroxyquinoline.

Partial absorption may be advantageous in an agent intended for the treatment of amœbic and bacillary

Table 2. Toxicology of Chlorhydroxyquinoline

Species	Dose (mg/kg) and route	Period of dosing (days)	Signs of toxicity
Rat	200 (oral)	97	Only moderate diarrhœa. Blood and other organs normal
Rabbit	300 (oral)	7	None
Rabbit	2·5–10 (i.v.)	4	None
Guinea pig	300 (oral)	3	7 of 8 died. Examination showed gastric lesions in 6 and enteritis in 1.
Guinea pig	150 (oral)	7	3 of 9 died. Examination showed gastric lesions in 2 and intestinal lesions in 1. All tests normal in survivors
Guinea pig	100 (oral)	5	None
Pig	200 (oral)	3	None
Pig	500 (oral)	7	None
Man	70 (oral)	10	None

dysentery, provided that high levels are attained in the large bowel.

Circulating levels of a drug like chlorhydroxyquinoline, which has a direct effect on *Entamoeba histolytica*[2,3], may protect the liver in amœbic dysentery. Furthermore, it would appear that in Africa *Shigellae* are being isolated from the blood of patients with bacillary dysentery sufficiently often to suggest that invasion of the blood stream is perhaps more common than is generally believed.

HÆMATOLOGY

Hexokinase Activity as a Function of Age of the Human Erythrocyte

The human erythrocyte normally survives in the circulation approximately 120 days. The factors which limit the cell's survival are unknown. An important factor may be an age-related diminution in the activity of one or more enzymes vital to the cell[1]. A decrease in the activity of a key glycolytic enzyme, or enzymes, might be of particular importance because the mature human red cell derives virtually all its energy through glycolysis. Certain inherited enzymatic defects, both in the anaerobic glycolytic and in the pentose phosphate pathways of the human red cell, are associated with shortening of the life-span of the cell[2–5].

Many of the enzymes of the human red cell, both glycolytic and non-glycolytic, apparently decrease in activity as the cell ages *in vivo*[6–10]. The activities of two enzymes of glucose metabolism, glucose-6-phosphate dehydrogenase (G-6-PD) (ref. 7) and glyceraldehyde-3-phosphate dehydrogenase (GA-3-PD) (ref. 8) have been reported to decrease markedly. The decline in the activity of G-6-PD, which catalyses the initial step of the pentose phosphate pathway, is well documented[7,8,11]. Evidence concerning GA-3-PD, which catalyses a key step of anaerobic glycolysis, is conflicting. Data reported by Lohr and co-workers[8] suggest that the activity of GA-3-PD in the human red cell decreases strikingly as the cell ages *in vivo* and that the relative decrease in the activity of this enzyme is even more marked than that of G-6-PD. Our preliminary data with respect to GA-3-PD[11] have not supported the findings of Lohr *et al.* It has been suggested that the reaction catalysed by GA-3-PD may be a rate-limiting step of anaerobic glycolysis[10,12]. Available evidence, however, suggests that the initial phosphorylation of glucose, catalysed by hexokinase, is the rate-limiting step of overall glycolysis in erythrocytes of normal individuals[9,13,14].

We have carried out preliminary investigations of the relationship between the age of the human red cell and the activity of hexokinase. Erythrocytes from seven normal adult males were separated by centrifugation into fractions containing relatively young and relatively old cells. A slight modification of a previously described method[15] of repeated centrifugation was used: 450 ml. of whole blood, instead of 250 ml., were centrifuged initially, and four serial centrifugations, instead of three, were performed. Dialysed hæmolysates were prepared as described previously[16]. Hexokinase activity was assayed by a modification of the method of Slein, Cori, and Cori[17]. The assay, as applied to hæmolysates, is described in detail elsewhere[16]. The per cent reticulocytes in the fractions of red cells and the activity of G-6-PD (assayed by a modification of the method of Glock and McLean[18] similar to that used by Zinkham and Lenhard[19]) in the hæmolysates were utilized as indicators of the separation of red cells with respect to age. The effectiveness of centrifugation as a method of separating relatively young red cells, which are less dense than are more mature cells, from relatively old erythrocytes has been well documented[9,15,20–22]. Centrifugation yields samples of intact erythrocytes the fractions of which are processed similarly. We have examined other methods for separating young and old human red cells[21–23]. The method used in this work is the one we have found most satisfactory. Less than 1 per cent of the hexokinase activity in hæmolysates of any of the fractions of red cells obtained by this method of separation is attributable to contamination by leucocytes or platelets[24].

Table 1. Normal Human Erythrocytes separated by Differential Centrifugation into Relatively Young and Old Fractions

Subject	Hexokinase activity*		G-6-PD activity†		Reticulocytes (%)	
	Young cells	Old cells	Young cells	Old cells	Young cells	Old cells
1	17·3	13·7	259·0	181·1	1·9	0·1
2	18·0	14·5	196·1	161·7	6·9	0·9
3	14·9	12·8	157·2	95·3	6·2	0·5
4	29·6	13·8	401·7	211·1	5·4	0·7
5	13·8	10·0	283·4	205·1	3·3	0·0
6	13·6	8·6	284·9	159·2	5·0	0·3
7	14·4	10·6	260·0	177·6	9·3	0·1
Mean	17·4	12·0	263·2	170·2	5·4	0·4
Significance	$0·02 < P < 0·05$‡		$0·01 < P < 0·02$		$P < 0·001$	

* Hexokinase activity, μmoles glucose phosphorylated/g hæmoglobin/h.
† G-6-PD activity, μmoles nicotinamide-adenine dinucleotide phosphate reduced/g hæmoglobin/h.
‡ Evaluated by Student's *t*-test of Fisher (ref. 26).

Results are shown in Table 1. The differences in the reticulocyte counts and in the activities of G-6-PD indicate that significant separation of red cells with respect to age was achieved. The activity of hexokinase in hæmolysates of fractions enriched with relatively young cells was significantly greater than that in hæmolysates of fractions containing relatively old cells. The data indicate that the activity of hexokinase in the human red cell decreases markedly as the cell ages *in vivo*.

We have found that the activity of hexokinase in hæmolysates is increased during phlebotomy-induced reticulocytosis in normal individuals[25]. Increased activity of hexokinase persists after subsidence of the reticulocytosis, suggesting that not only reticulocytes but also young non-reticulated erythrocytes have activity of hexokinase greater than that of more mature cells.

Hexokinase occupies a strategic position in the metabolism of the human erythrocyte. A decrease in the activity of hexokinase may be of importance in senescence of the cell *in vivo*. Decreased activity of hexokinase may underlie certain of the other metabolic alterations[8,9,15] that occur during red cell ageing and may contribute to ultimate lysis of the effete cell.

Available methods for separating young and old human erythrocytes are not ideal. The potentially important role of hexokinase in contributing to senescence of the human

erythrocyte should be further evaluated as improved methods of separation are developed. Methods that would permit clear definition of changes occurring late during the red cell's life span would be of particular value.

This work was supported mainly by the Medical Research and Development Command, Office of the Surgeon General, Department of the Army, under contract *DA*-49-193-*MD*-2413 with the University of Chicago and, in part, by the Douglas Smith Foundation of the University of Chicago. The investigations were made possible through the co-operation of inmate volunteers and the administrative staff of the Illinois State Penitentiary, Stateville Branch, Joliet, Illinois.

Production of Specific Anti-E Autoantibodies in Experimental Iso-immune Hæmolytic Anæmia in Man

IN 1961 we reported the results of studies on a case of acute, iso-immune hæmolytic anæmia experimentally induced in a $C^wDe/Ce(R_1{}^wR_1)$ volunteer transfused with plasma containing exceptional anti-CD antibodies[1]. Antibody sensitization of the recipient's erythrocytes was detected by the direct antiglobulin test (Coombs) up to day 133 following the plasma transfusion. Positive tests for antibody-coated red cells were obtained in the serum + albumin (a mixture of equal parts of human serum and 30 per cent bovine albumin) slide sensitization test through the 98th post-transfusion day. The study of the recipient's post-transfusion serum specimens for free, circulating antibodies in titration procedures employing serum + albumin revealed three distinct periods of antibody activity especially with the $cDe/ce(R_0R_0)$ primary test cells. The first of these appearing between the first hour and the ninth post-transfusion day was interpreted as surplus antibodies remaining from those transfused in the anti-CD plasma, the second between post-transfusion days 14 and 98 as indicative of eluted or released antibodies and the final between days 105 and 140 as possible auto-immune antibodies representing the product of active immunization by the recipient himself. The peak titres of the free, circulating antibodies in the second and third periods of increased antibody activity were definitely higher than those obtained in the first, immediate post-transfusion one. In view of the Rh genotype of the recipient (C^wDe/Ce), the serologic specificity of the transfused antibodies (anti-CD) and the observation that the antibodies in the third peak were reactive against the C and D antigens in the Rh system, no conclusive proof of the auto-antibody nature of these antibodies could be established on the basis of blood group specificity.

In an attempt to substantiate that specific Rh auto-antibodies could be produced by an antigenic stimulus provided by the Rh antigens of the host's own erythrocytes altered by their saturation with specific Rh iso-antibodies, additional transfusion experiments were performed. A large volume of sterile ACD plasma containing anti-CD antibodies from the same donor (*Bak*) used in the initial investigation was prepared from donations made following her fifth pregnancy and by plasmaphoresis during her sixth pregnancy. This latter pregnancy terminated again, as had the four preceding ones, in a full-term, macerated, stillborn fœtus. The titre and avidity of her anti-CD antibodies determined in the serologic characterization experiments against the cells of the recipients selected for these experiments were considerably higher than in the plasma used for the earlier investigation. The three volunteers in these experiments were selected primarily on the basis of their Rh genotypes. One belonged to the Rh group $cDE/cE(R_2R_2)$, another to $CDe/cE(R_1R_2)$ and the final to cde/cde (rr), a non-reactive control included to determine the survival of the transfused anti-CD antibodies. Individuals possessing the $cDE(R_2)$ chromosome were chosen on the premise of their being potential candidates for the production of anti-E auto-antibodies.

Antibody-coated red cells were detected in the cDE/cE (R_2R_2) recipient's circulation until post-transfusion day 168 by the direct antiglobulin test and through the 105th day in the slide serum + albumin sensitization test. The sera from this recipient's blood specimens collected in the immediate post-transfusion period contained free, circulating antibodies against his red cells from a pre-transfusion sample which had been preserved in glycerol at $-25°$ C and against test cells of Rh genotypes cDe/ce (R_0R_0) and Cde/cde (R′r). This finding, together with the strongly positive antibody-erythrocyte sensitization tests in the same period, indicated saturation of all his available red cell Rh antigen receptors with the transfused anti-CD antibodies.

Antibody eluates were prepared in human serum diluent by a modified heat elution technique from the red cells of blood samples collected from the cDE/cE (R_2R_2) recipient throughout the post-transfusion observation period. Examination of these eluates in titration procedures using serum + albumin as a diluent and test cell suspending medium revealed the presence of specific anti-E antibodies first appearing on the 70th post-transfusion day. This anti-E activity was detectable throughout the remainder of the observation period, which was terminated on post-transfusion day 229. That these eluted antibodies were indeed anti-E specific was shown by the fact that only test cells from three unrelated individuals of Rh genotype cdE/cde (R″r) were agglutinated. Test cells containing all the known major human blood group antigens other than the D antigen of the Rh system were consistently negative.

In the examination of these antibody eluates against the pre-transfusion specimen of cells from the recipient himself, activity was detected from the 1st hour post-transfusion through the last day 229. This was also found with test cells of the Rh genotype $cDe/ce(R_0R_0)$, indicating the presence of anti-D antibodies in addition to anti-E. The

activity of the eluted antibodies against his own cells was greatest in the period between post-transfusion days 126 and 229.

Thus, we believe this experiment has yielded evidence of the production of specific anti-E auto-antibodies as obtained in eluates prepared from the cells of a cDE/cE (R_2R_2) recipient transfused with exceptionally potent anti-CD antibodies. A more detailed report of these findings will be published elsewhere.

This investigation was supported by a resarch grant, *HE*–04917, from the National Heart Institute, U.S. Public Health Service.

PATHOLOGY

Ribosomes Active in Protein Synthesis in Human Reticulocytes: a Defect in Thalassæmia Major

The most prominent abnormality in thalassæmia major appears to be a decreased synthesis of hæmoglobin A[1,2]. Ingram and Stretton[3] have suggested that this defect in synthesis may be associated with an alteration in the amino-acid sequence of the hæmoglobin which does not alter the electrophoretic mobility of the tryptic peptides. However, no abnormalities have yet been detected in any of the types of hæmoglobin found in thalassæmia[4]. An alternative hypothesis[1–3] proposes that the defect involves only an altered rate of synthesis of hæmoglobin A.

In rabbit reticulocytes, protein synthesis appears to occur on a relatively stable ribosome-informational RNA complex[5]. These ribosomes, active in protein synthesis, are characterized by a sedimentation coefficient greater than 78*S*. Electron micrographs indicate that the active ribosomes are clusters of 2 or more 78*S* ribosomes[6,7]. The role of ribosomes in protein synthesis in human reticulocytes has now been examined in order to investigate the nature of the defect in synthesis of hæmoglobin in thalassæmia major. Compared with ribosomes isolated from reticulocytes of patients with sickle-cell anæmia and various non-hæmoglobinopathies, ribosomes of reticulocytes of thalassæmic subjects have a significantly decreased capacity to incorporate leucine into protein.

Blood was obtained from patients with a reticulocytosis following loss of blood, or with thalassæmia major, sickle-cell anæmia, or acquired hæmolytic anæmia. There was no significant difference in the reticulocyte count in the group of patients with thalassæmia major compared with the sickle-cell anæmia subjects (Table 1). The cells were separated from the plasma and incubated at 37° C in a modified Krebs–Ringer–bicarbonate medium[5] containing, as a radioactive amino-acid, uniformly labelled ^{14}C-leucine (1·51 mc./mmole) or tritiated-isoleucine (32·3 mc./mmole). At intervals up to 45 min, aliquots of the suspension were removed to determine counts incorporated into acid-insoluble material[5]. At 30 min, an aliquot of the cell suspension was removed, the cells recovered by centrifugation and then lysed by a short exposure to a hypotonic solution[5]. This procedure preserves the leucocytes and disrupts only the red cells. Ribosomes were recovered from the lysates by centrifuging at 105,000*g* and suspending in a solution of $1{\cdot}5 \times 10^{-3}$ M magnesium chloride, 5×10^{-2} M potassium chloride and 10^{-3} M *tris*, *p*H 7·5. The ribosomes were characterized by their sedimentation characteristics in sucrose density gradients[5,8]. Radioactivity incorporated on the ribosomes and into an acid-insoluble form was determined by techniques detailed elsewhere[5].

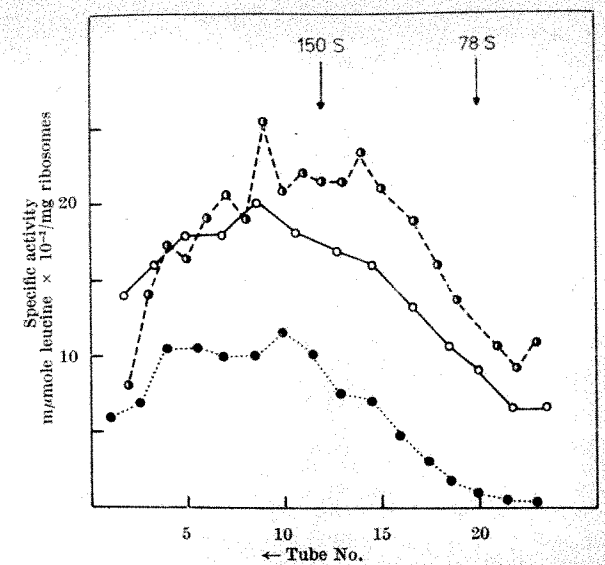

Fig. 1. Sucrose density gradient analysis of the distribution of ribosomes isolated from human reticulocytes incubated with ^{14}C-leucine as indicated in the text. The pattern of incorporation of isotope is similar in these three illustrative studies. (◑- - - ◑, sickle-cell anæmia; ●. . . . ●, thalassæmia; ○——○, congenital spherocytosis). Note that all classes of ribosomes of the reticulocytes of the thalassæmia major have a lower specific activity than the other two examples

The distribution of ^{14}C-leucine incorporated on ribosomes isolated from reticulocytes of thalassæmic and non-thalassæmic subjects was analysed by the sucrose density gradient technique. In all investigations, the ^{14}C-leucine was incorporated primarily in association with ribosomes with sedimentation coefficients greater than 78*S* (Fig. 1). In each group, the amount of ribosomes recovered was

Table 1. Human Reticulocyte Ribosome Content and Amino-Acid Incorporation

Group*	Reticulocytes %	Ribosome content		Leucine incorporation		Isoleucine incorporation
		Total (mg/10^{10} retic)	> 78*S*† %	Ribosomes	Soluble protein	Ribosomes
				mμM/mg ribosomes‡		
Thalassæmia major	6 ± 0·8§	1·10 ± 0·27	28 ± 3	0·57 ± 0·09	191 ± 45	0·05 ± 0·02
Sickle-cell anæmia	8 ± 0·8	0·70 ± 0·05	30 ± 5	1·93 ± 0·08	252 ± 55	0·01
Non-hæmoglobinopathy	17 ± 5·0	1·05 ± 0·80	30·5 ± 5	2·66 ± 0·57	262 ± 125	0·02 ± 0·01

* The values for ribosome content and leucine incorporation are based on studies of nine thalassæmia major, seven sickle-cell anæmia and seven non-hæmoglobinopathy subjects. The values for isoleucine incorporation are based on examination of four thalassæmia major, one sickle-cell anæmia and five non-hæmoglobinopathy subjects.

† Percentage of ribosomes sedimenting with a coefficient of sedimentation greater than 78*S* as estimated by analysis of sucrose density gradient patterns.

‡ Millimicromoles of amino-acid incorporated per milligram of ribosomes recovered.

§ Mean value ± *S.E.*

similar (Table 1). In addition, there was no significant difference in the proportion of the ribosomes which had sedimentation coefficients greater than 78*S*, a measure of the ribosomes which are clustered (Table 1). Thus, the defect in synthesis of hæmoglobin A in thalassæmia major does not reflect an alteration in the class of ribosomes active in protein synthesis or a deficiency in the proportion of ribosomes which are clustered.

It was found that there is a significantly lower incorporation of leucine on the ribosomes of reticulocytes from patients with thalassæmia major compared with that on the ribosomes of reticulocytes of non-thalassæmic subjects ($P < 0{\cdot}001$) (Table 1). This decreased level of leucine incorporated could not be attributed to a lower rate of incorporation of the amino-acid. In all instances, radioactivity associated with the ribosomes reached a plateau value in 5 min, while the incorporation of ^{14}C-leucine into supernatant protein continued to increase for the 45-min period of incubation. The rate of incorporation of ^{14}C-leucine into supernatant protein was somewhat lower with reticulocytes from thalassæmia major than with cells from the sickle cell anæmia ($P < 0{\cdot}05$) or the non-hæmoglobinopathy subjects, but this latter difference was not statistically significant.

Isoleucine is present in hæmoglobin F, but is not found in hæmoglobin A. If the biochemical defect in thalassæmia is related primarily to the synthesis of hæmoglobin A, it would be anticipated that isoleucine would be incorporated by reticulocyte ribosomes of thalassæmic subjects in amounts comparable to that found in non-thalassæmic subjects. The incorporation of tritiated-isoleucine on the ribosomes of reticulocytes from thalassæmic patients was generally greater than that on the reticulocyte ribosomes from non-thalassæmic subjects. Four patients with thalassæmia major were examined in this manner. In three, hæmoglobin F comprised more than 60 per cent of the total hæmoglobin, while the fourth had 2 per cent hæmoglobin F. The subject with the low level of hæmoglobin F had the second highest level of tritiated-isoleucine incorporated on the ribosomes.

The results recorded here indicate that there is a selective defect in the capacity of reticulocyte ribosomes of thalassæmic subjects to incorporate ^{14}C-leucine. It is likely that in normal subjects more than 90 per cent of the protein synthesized by human reticulocytes is hæmoglobin A (ref. 4). The present findings, therefore, suggest that thalassæmia major involves a selective decrease in the capacity of reticulocyte ribosomes to form hæmoglobin A. This defect may reflect an alteration in the RNA directing hæmoglobin synthesis (messenger RNA). This alteration could involve a decrease in the amount of messenger RNA associated with the ribosomes or a messenger RNA which is modified so as to lead to a decrease in the rate of hæmoglobin A synthesis[9].

This work was supported by grants from the U.S. Public Health Service. We thank Prof. James A. Wolff and his staff for permitting us to examine their patients.

Effect of Liver Regeneration following Partial Hepatectomy on the Uptake of Tritiated Thymidine in the Pituitary Gland of the Rat

THE role of the pituitary gland in liver regeneration following partial hepatectomy is not clearly defined. It has been reported that hypophysectomy has no effect on rat liver regeneration following partial hepatectomy[1]. There are conflicting reports as to the effect of thyroidectomy on rat liver regeneration[1,2]. Variance of the foregoing reports suggested a necessity for further investigation of the inter-relationship existing between the regenerating liver, pituitary and thyroid glands. In another report from our laboratory, the thyroid gland demonstrated a marked increase in uptake of tritiated thymidine several days after peak incorporation in the regenerating liver following partial hepatectomy[3]. This communication is concerned with the inter-relation of the anterior pituitary gland and liver regeneration as studied by means of tritiated thymidine incorporation.

Twenty female Sprague-Dawley rats (Charles River Laboratories, Wilmington, Mass.), weighing 126–154 g at the time of partial hepatectomy, were used. They were housed in individual cages in air-conditioned quarters and were fed Purina chow and water *ad libitum*. The animals were divided equally into experimental and control groups; the periods selected for study were from 0–21 days. The experimental animals were partially hepatectomized with removal of two-thirds of the liver by the method of Higgins and Anderson[4]. Control animals were sham-operated by opening the abdomen and manipulating the liver. An intraperitoneal injection of 1 μc. of tritiated thymidine (the tritiated thymidine had a specific activity of 1·9 c./mM and was purchased from Schwarz Bioresearch, Inc., Orangeburg, New York) per gram of animal body-weights was given 4 h before death. All animals were killed between 1 p.m. and 3 p.m. to minimize any variation in diurnal mitotic activity[5]. Intraperitoneal injection of tritiated thymidine was given to the zero-time animals 4 h prior to death. After death, the liver, thyroid and pituitary glands were excised, weighed, fixed in formalin, embedded in paraffin, cut at 5μ, and mounted on glass slides for autoradiography. Autoradiography, using Kodak *NTB*-2 emulsion, was performed according to the method of Messier and Leblond[6]. After a 4-week exposure, the autoradiograms were developed, fixed and stained with hæmatoxylin and eosin.

The degree of labelling in the liver cells was obtained by counting the number of labelled nuclei with 8 or more silver grains in 5 random fields in different areas of the tissue. At least 2,000 cells were counted in each field. The average number of labelled nuclei in the liver per 1,000 cells was obtained. The number of labelled thyroid parenchymal cells was obtained by counting labelled and unlabelled nuclei in 5-step sections of both the left and right thyroid lobes; there was little difference in the degree of labelling of the two lobes. The number of labelled nuclei with 8 or more silver grains in approximately 20,000 parenchymal cells was counted in the thyroid and pituitary gland sections and the values reported represent an average value for 10,000 cells.

Results are given in Table 1. Thymidine counts in the cell nuclei of the regenerating liver are found to increase between 12 and 24 h post-partial hepatectomy, reach a maximum at 24 h, and return to normal values by 6 days. The results are in general agreement with the recent autoradiographic study of regenerating liver by Grisham[7]. The counts in the anterior pituitary gland showed an increase from 6 days post-partial hepatectomy and reached a maximum on the 14th day with 324 labelled nuclei per 10,000 cells. By the 21st day post-partial hepatectomy, this value was reduced to near-normal values. The pituitary glands from the sham-operated animals were found to have no period of greatly increased counts of tritiated thymidine; however, there was a period of

slightly increased counts between 4 and 21 days which is probably the result of the recovery from the sham operation. The cells of the posterior pituitary gland, when observed, showed very few counts of tritiated thymidine. However, the study was not designed to include the posterior pituitary gland. Results of tritiated thymidine labelling in the thyroid (Table 1) show increased labelling between 10 and 21 days, with peak labelling of cell nuclei at 14 days following hepatectomy. The increased thymidine counts in the anterior pituitary gland begin at 6 days post-partial hepatectomy, whereas in the thyroid gland the increased thymidine counts are noted to begin 10 days post-partial hepatectomy.

Table 1 Effect of Partial Hepatectomy on the Tritiated Thymidine Uptake in the Liver, Pituitary Gland and Thyroid Gland of the Rat

Regeneration period	Liver (labelled cells/1,000 cells)		Pituitary gland (labelled cells/10,000 cells)		Thyroid gland (labelled cells/10,000 cells)	
	Control	Experimental	Control	Experimental	Control	Experimental
0	4	6	0	0	0	0
12 h	2	3	0	1	0	1
24 h	3	321	4	8	0	2
36 h	2	151	7	1	0	1
3 days	4	112	0	9	0	1
4 days	6	58	11	12	0	0
6 days	24	3	21	69	1	0
10 days	2	3	19	179	1	14
14 days	1	3	15	324	0	33
21 days	0	4	13	27	0	16

Thymidine is a specific precursor of DNA[8], the principal nucleic acid in the cell nuclei. Histological localization of the tritiated thymidine makes it possible to determine sites of DNA synthesis[9]. The results suggest peak DNA synthesis in the thyroid and pituitary glands occurs 14 days post-partial hepatectomy. The increased pituitary gland activity begins just before increased activity is noted in the thyroid gland. It is possible the increased thyroid activity may be secondary to stimulation from the pituitary gland. However, the effect of the pituitary gland on liver regeneration may not be mediated entirely through the thyroid gland. Carriere[10] has presented evidence that the pituitary gland alone plays some definite part in liver cell growth. Treatment of thyroidectomized rats with growth hormone produced growth and formation of increasing numbers of liver polyploid nuclei despite the absence of thyroid hormone. The increased tritiated thymidine incorporation in the pituitary and thyroid glands following the active phase of liver regeneration may be a recovery mechanism to restore normal body processes. Examination of hæmatoxylin and eosin sections of the anterior pituitary gland showed no detectable morphologic changes during the increased tritiated thymidine incorporation in either the sham-operated or experimental groups.

Adenosine Triphosphate : an Inhibitor of Generation of Thromboplastin

In a series of experiments designed to investigate the possible existence of a relationship between energy metabolism and blood clotting mechanisms, the inactivation of human thromboplastin by adenosine triphosphate (ATP) has been noted (Table 1). The thromboplastin system is assayed for activity by determining the clotting time after adding 0·1 ml. of the reaction mixture, described in Table 1, to 0·1 ml. of 1 : 10 citrated (0·1 M trisodium citrate) substrate plasma. The substrate plasma had been recalcified exactly 15 sec earlier with 0·1 ml. calcium chloride. At maximum generation of thromboplastic activity, 0·08 ml. of ATP (0·1 M) or saline is added to the test system. This approach allows removal of 0·1 ml. of the reaction mixture for a clotting time assay before addition of ATP or saline. Concentration of ATP in the reaction mixture following removal of the 0·1 ml. aliquot is 0·0087 M.

Several assays of clotting time before addition of ATP are made possible by using separate control runs. At the specified intervals, subsequent to addition of ATP, an aliquot of the reaction mixture is tested for thromboplastic activity as previously indicated. Incubation was performed at 37° C. ATP was obtained from Nutritional Biochemicals Corp., Cleveland, Ohio. As a confirmatory check on purity, ATP was chromatographed on Whatman No. 1 paper with a solvent consisting of 100 ml. 0·1 M phosphate buffer, *p*H 6·8; 60 g ammonium sulphate; and 2·0 ml. *N*-propanol. The compound appeared free of contamination. The thromboplastin generating system, without ATP, had a 20·7-sec clotting time after 20 min of incubation. At that time, the system with ATP had been depressed to a clotting time of 107·5 sec (Table 1). It is evident from the progressive increase of the clotting time, as compared with the control, that an inactivation of thromboplastin activity is occurring which cannot be due to inherent instability of the thromboplastin molecule. A difference in *p*H as a cause of the effect of ATP was ruled out by maintenance of the same hydrogen ion concentration in the experimental and in the control. That the inactivation is not caused by a significant effect of ATP on thrombin or fibrinogen is demonstrated by a clotting time of 23·0 sec on addition of 0·2 unit of human thrombin to the test system at the 60 min incubation interval.

Table 1. Adenosine Triphosphate Inactivation of Generation of Human Thromboplastin

The thromboplastin generating (TPG) system consisted of 0·19 ml. human serum diluted 1 : 10 with 0·85 per cent sodium chloride, 0·19 ml. barium sulphate adsorbed plasma (100 mg barium sulphate per ml. of oxalated plasma) diluted 1 : 10 with saline, 0·19 ml. phospholipid as a platelet substitute (Azolectin, Associated Concentrates, Inc., Woodside, New York), 0·19 ml. calcium chloride (0·025 M), 0·14 ml. sodium chloride 0·85 per cent, and 0·04 ml. imidazole buffer (*p*H 7·2). Plasma and serum are centrifuged at 3,000 r.p.m. for 15 min for purpose of removing platelets. The results represent the mean of 12 experiments. Time of addition for ATP or saline to the system is indicated in the respective columns of data.

Incubation time (min)	Clotting time: TPG system (sec)	TPG system plus ATP (sec)	TPG system plus ATP (sec)
0	> 120	> 120	ATP
3	79·5	80·0	> 520
6	13·5	13·5	520
7	Saline	ATP	> 520
8	13·7	34·3	> 520
12	14·9	80·0	> 520
16	17·6	97·3	> 520
20	20·7	107·5	> 520

Prior to addition of thrombin, the system had shown a 112·8-sec clotting activity. A unit of thrombin is defined as that concentration per ml. which will give a 15-sec clotting time under standard conditions. ATP does not inactivate the clotting activity of pure thrombin. Addition of 0·3 unit of human prothrombin to the system did not alter the ATP-induced inactivation. Nor is it possible that the inactivation can be due to a calcium-chelating action of ATP because calcium concentration in

excess of the combined complexing capacity of ATP and citrate failed to prevent the effect of ATP. Since pyrophosphate (0·0087 M), a possible ATP derivative, failed to inhibit the reaction in presence of excess calcium ion and since adenosine monophosphate (0·0087 M) was essentially without activity, it must be concluded that the inactivation phenomenon is based on a function unique to the high-energy phosphate bonds of the adenosine molecule.

Although the inactivation of thromboplastin by the common currency of energy metabolism could be of considerable portent to an understanding of the physiological mechanisms controlling fluidity of the blood, the magnitude of the effect did not seem adequate to explain previous observations on the pronounced inhibitory action of ATP on the plasma recalcification time. Furthermore, a site of inadequate inactivation of an already formed thromboplastin molecule does not readily lend itself to an adequate physiological control mechanism. On the basis of these considerations, the effect of ATP on generation of thromboplastin was examined. Introduction of ATP as the first reactant in the system depressed thromboplastin generation to a minimum clotting time of 520 sec (Table 1). Other than the sequence of addition of ATP, all other conditions are similar to those of the previous investigation. A comparision of the magnitude of this effect on generation of thromboplastin to the maximum effect noted when ATP was introduced after the thromboplastin was at maximum activity strongly indicates the principal site of the ATP action to be on a thromboplastin precursor. The enhanced activity of ATP which is added to the system before thromboplastin generation cannot be due to increased destruction of the low levels of thromboplastin which are present during initial stages of generation. This was proved by experiment where the serial addition of small, but progressively increasing, increments of human thromboplastin to ATP gave the same picture as the middle column of Table 1. On completion of the serial addition of thromboplastin, a system identical in composition to the other systems had been achieved.

Reports from this laboratory have demonstrated an enhanced thromboplastin generation in the ageing subject who has been afflicted with a myocardial infarction[1,2]. These results have indicated the physiological mechanism for prevention or control of generation of thromboplastin to be located at an intracellular site[1]. It is, therefore, of some importance to note that the concentration of ATP used in these experiments is comparable with the level found in the normal cardiac cell by Fleckenstein, Janke and Gerlach[3].

If deposition and organization of fibrin or thrombi on the arterial wall were accepted as a cause of arteriosclerosis, as indicated more than a century ago by von Rokitansky[4] and more recently by work by Clark[5], Duguid[6], Harrison[7], Heard[8] and others, then it would seem possible for defective cellular energy metabolism to be of ætiological significance to an enhanced thromboplastin activity and arteriosclerotic sequelæ.

IMMUNOLOGY

Adsorption of Rabbit Antibody by Rat Tissue Mast Cells and Other Cells *in vitro*

From observations obtained on guinea pig mesenteries dissected out from animals which had been passively sensitized *in vivo* with rabbit anti-ovalbumin, Humphrey and Mota[1] concluded that the antibody is reversibly adsorbed to the mast cell surface. When normal tissue mast cells isolated from the peritoneal fluid of albino rats were incubated with rabbit anti-human γ-globulin and afterwards treated with human γ-globulin characteristic morphological changes and release of some of the stored histamine occurred at the same time[2]. None of these authors has been able to provide direct evidence for the presence of cell-fixed antibody on mast cells by means of the fluorescent antibody technique. However, White[3], using this technique, demonstrated recently that some of the antibody-containing fractions from rabbit sera were indeed fixed to the mast cell surface in guinea pigs. The work reported here deals with quantitative aspects of antibody adsorption by rat mast cells as compared with the adsorptive capacity of other tissue cells.

Peritoneal mast cells were obtained from normal albino rats by differential centrifugation, as already described earlier[4]. After centrifugation these cells were washed 4 times with buffered physiological salt solution containing 2 per cent rat serum. The spleen, lymph nodes, and liver of the same animals were cut into fragments with scissors, immersed in physiological solution and then passed through a stainless steel sieve. The same washing procedure was used for both the mast cells and the cells passing through the sieve. Rabbit antiserum to human serum albumin, containing 'cytophilic antibody'[5], was prepared by repeated intravenous injections of human serum[5]. ^{131}I-human serum albumin (^{131}I-HSA) was obtained from the Radiochemical Centre, Amersham, England. The technique used for estimating cytophilic antibody fixed on to cells was the same as that of Boyden and Sorkin[5]. For each experiment one portion of a given type of cells was incubated with normal rabbit serum (control), another with rabbit anti-human serum.

Table 1. Adsorption of Antigen (^{131}I-HSA) by $5{\cdot}5 \times 10^6$ Normal Rat Mast Cells and Spleen Cells

The cells had been treated first with 70 per cent ethanol and then with 0·5 ml. rabbit antiserum or normal serum.

Type of cell	Treated with normal serum and washed four times (c.p.m.)	Treated with anti-serum and washed four times (c.p.m.)
Mast cells	1	456
Spleen cells	9	21
Spleen cells (0·5 ml. 20 per cent susp.)	34	2,648

0·5 μg ^{131}I-HSA was added to each tube (=5,365 c.p.m.)

Table 2. Adsorption of Antigen (^{131}I-HSA) by $2{\cdot}8 \times 10^6$ Normal Rat Mast Cells and Other Cells treated with 0·5 ml. Rabbit Antiserum or Normal Serum

Type of cell	Treated with normal serum and washed four times (c.p.m.)	Treated with anti-serum and washed four times (c.p.m.)
Mast cells	8	3,822
Spleen cells	4	263
Liver cells	5	4,820
Mesenteral lymph node cells	1	308
Red cells (0·1 ml. packed cells)	10	1,622

0·5 μg ^{131}I-HSA was added to each tube (=10,162 c.p.m.)

In the first series of experiments, restricted to spleen and mast cells, the capacity of cells to adsorb antibody was evaluated with cells which, after treatment with 70 per cent ethanol at room temperature for 10 min, had been incubated with rabbit anti-human serum at 0° C for 1 h. The results of a typical experiment of this type are listed in Table 1. The data obtained show that both spleen and mast cells treated *in vitro* with rabbit antiserum against HSA are capable of specifically adsorbing ^{131}I-HSA. In further experiments treatment with ethanol was omitted.

The results of such an experiment are recorded in Table 2. They show that liver and mast cells have a high capacity to adsorb cytophilic antibody and then specifically ^{131}I-HSA. Spleen, lymph node and red blood cells show distinctly lower values. The comparison of the results obtained with and without ethanol treatment reveals that unfixed antibody treated mast cells display a greater capacity to adsorb ^{131}I-HSA than cells treated with ethanol. The results demonstrate that mast cells, liver, spleen, lymph node and red blood cells of the albino rat treated *in vitro* with rabbit antiserum against human serum albumin are capable of specifically adsorbing ^{131}I-HSA. Moreover, the uptake of antibody by liver and mast cells was nearly ten times that of the other cells, which may at least partly be due to differences in cell size.

Immunization against *Cryptococcus neoformans* by Capsular Polysaccharide

It has been reported[1] that crude *Cryptococcus neoformans* capsular polysaccharide when injected by the subcutaneous route was incapable of protecting mice against a lethal challenge dose of the parent organism. Purified polysaccharide, on the other hand, elicited a minimal protective response which was markedly increased by coupling to an ion exchange resin adjuvant. Both polysaccharides were obtained by direct recovery from cell-free culture medium. More recently it was shown indirectly that the protective antigen appeared to be concentrated in an area of the capsule immediately surrounding the cell wall[2]. It was therefore of interest to determine if fractionation of the capsule by repeated grinding would provide antigens with increased stimulatory properties.

C. neoformans, isolated *BRI*, was grown in asparagine medium at 28° for 4 days. The cells were killed (0·5 per cent formalin for 24 h), separated from the culture medium by centrifugation, and washed five times with saline solution. Afterwards, the cells were ground in a ball mill (flint balls) at 4° C for 24 h, washed free of loosely bound polysaccharide and reground. A total of five such procedures were carried out. The cells after the last grinding were approximately 90 per cent decapsulated when examined microscopically in india ink. Less than 1 per cent of the cells appeared to be ruptured. Polysaccharide was recovered from each fraction and purified by procedures described earlier[1].

The results presented in Table 1 substantiated the earlier reported indirect evidence for the existence of an immunizing antigen in close proximity to the cell wall of this organism. When the same immunization regimen was used in a second series of animals (Table 2), it was established that the specificity of the most active fraction (Cap-5) appeared to be species specific, but not strain specific.

In a third series the polysaccharide was administered as before with the exception that spleen weights and serum hæmagglutination titres were monitored at intervals. The antibody determinations were made by a modification of the technique described by Landy *et al.*[3]. The results of this experiment (Table 3) complement the protection studies by demonstrating that antibody stimulation as reflected by these parameters appeared to be responsible, at least in part, for the observed protective effect. Whether this finding was due entirely to a qualitatively different antigen or represented merely a concentration effect is beyond the scope of this communication.

Table 1. Effect of Mechanically-Fractionated *Cryptococcus neoformans BRI* Capsular Polysaccharide Administration on Survival to Homologous Challenge

Group	Polysaccharide from	Survivors on post-Challenge days 10	20	30	$P <$
1	Original CFF	13/20	0/20	0/20	
2	Cap-1	18/20	4/20	0/20

ANATOMY

Olfactory Relationships of the Diencephalon

The dominant part played by olfaction in the behaviour of lower mammals has long been appreciated, but it is only comparatively recently that the underlying physiological mechanisms have begun to be elucidated. There is now a considerable body of evidence implicating cer-

tain of the accepted olfactory projection sites, such as the amygdala and the pyriform cortex in emotional and reproductive behaviour[1,2], and more recent work has shown how directly the more peripheral parts of the olfactory pathway may regulate reproductive function[3,4]. It has generally been assumed that the anatomical link between the olfactory system and the hypothalamus is by way of the well-defined efferent pathway from the amygdala, the stria terminalis. However, in the past few years a number of experimental neuroanatomical studies have cast doubt on the essential place of the amygdala in the olfactory system, and have led us to re-examine the primary and secondary connexions of the olfactory bulb.

In the first group of experiments the olfactory bulb of one side was removed in several rats to determine the total olfactory projection on the telencephalon. Sections of these brains stained by the Nauta and Glees methods show severe degeneration in the anterior olfactory nucleus, the lateral olfactory tract and in the anterior limb of the anterior commissure. The lateral olfactory tract distributes fibres to the anterolateral part of the olfactory tubercle and to the superficial layers of the pyriform cortex back to the level of the caudal end of the amygdala. The amount of degeneration overlying the amygdala becomes progressively reduced towards the cortical amygdaloid nucleus, and it appears that few, if any, fibres reach medially as far as the medial nucleus of the amygdala. The degenerating fibres in the anterior limb of the anterior commissure can be traced to the deep layers of the pyriform cortex of the same side and to the opposite olfactory bulb. No evidence has been found for a projection to the bed nucleus of the stria terminalis, or its apparent continuation, the central nucleus of the amygdala. This failure to find a projection to the amygdala by way of the anterior limb of the anterior commissure is in agreement with two recent studies using the Nauta technique[5,6]; earlier reports of such a connexion were based on Glees-stained material, which, as is now known, commonly shows pseudo-degeneration bilaterally in these sites[7].

Despite the fact that the pyriform cortex represents the major site of projection of the olfactory bulb, comparatively little is known of its further connexions[8,9]. In an attempt to define the efferent projection of this area superficial lesions restricted to the pyriform cortex were placed in a second group of rats. In all these experiments heavy fibre degeneration has been found extending medially into the lateral preoptic region. After lesions of the rostral part of the pyriform cortex degeneration passes back into this region, but in addition some fibres can be traced further caudally into the basal and lateral amygdaloid nuclei and into the posterior parts of the pyriform cortex by both a superficial and deep pathway. From lesions in this caudal part of the pyriform cortex degenerating fibres extend forwards through the lateral and basal amygdaloid nuclei (in which some fibres are clearly terminating) and through the anterior amygdaloid area, to reach the lateral preoptic region. From this part of the preoptic region fibres are distributed rostrally to the olfactory tubercle, the horizontal limb of the diagonal band nucleus and to the cortex below and in front of the genu of the corpus callosum; and caudally, through the medial forebrain bundle, to the lateral hypothalamic area as far as the mid-tuberal level, and, mainly by way of the inferior thalamic peduncle, to the dorsomedial and lateral habenular nuclei of the thalamus. The projection to the thalamus is bilateral, a small proportion of the fibres crossing to the opposite side. In addition to these sub-cortical projections, efferent fibres also pass caudally to the entorhinal area, and forwards, in close relation to the lateral olfactory tract to the ipsilateral olfactory bulb as recently described[10], and commissural fibres cross to the opposite side in the posterior limb of the anterior commissure. Control experiments with lesions involving the cortex immediately above the rhinal sulcus (including the temporal and insular regions) give a quite different pattern of degeneration, and indicate that the degeneration described here is not consequent on the interruption of fibres simply passing through the pyriform area. In view of the close similarity in the distribution of degeneration in these experiments with that previously described after lesions of the amygdala[10], it should also be stressed that our pyriform lesions have never penetrated deeper than the subcortical white matter, and in each case care was taken to exclude possible injury to the amygdala.

Lesions of the amygdala itself (with or without direct involvement of the pyriform cortex) give rise to degeneration in two distinct subcortical projection systems. The first of these, commonly known as the longitudinal association bundle or ventral amygdalo-fugal pathway, has exactly the same course and distribution as the subcortical projection fibres of the pyriform cortex outlined here. Whether the degeneration seen after these lesions is entirely due to the interruption of fibres arising in the pyriform cortex and passing through the amygdala, or whether the amygdaloid nuclei themselves also contribute to this projection system cannot be determined from the present material. But clearly any degeneration found within this system after amygdaloid or preoptic lesions must take into account the involvement of efferent fibres from the pyriform area. Indeed all accounts of afferents to the dorsomedial nucleus from the basal forebrain areas could be explained on this basis because the descriptions of the course of such afferents correspond to that described here for the fibres from the pyriform cortex[11,12]. The second efferent pathway from the amygdala is the well-known stria terminalis; this bundle, which always shows severe degeneration when the baso-lateral group of nuclei is damaged, distributes fibres to its own bed nucleus, and to the medial preoptic and anterior hypothalamic areas of the same side. This description of the distribution of the stria terminalis agrees closely with that of Nauta[10], and like him we have been unable to find evidence for the bilateral projection to the ventromedial hypothalamic nuclei described by Adey *et al.*[13,14].

Experiments with lesions in the preoptic region effectively interrupt fibres from both the rostral and caudal parts of the pyriform area (together with other fibres in the medial forebrain bundle) and consequently show particularly heavy degeneration in their terminal projection sites; but, in addition to this involvement of the efferent fibres, considerable numbers of degenerating fibres are seen running caudally in the stria terminalis and in the longitudinal association bundles. The fibres in both pathways can be traced to the basal, lateral and medial amygdaloid nuclei. The description of caudally directed fibres in the stria terminalis is in agreement with other reports[15–17], but the ventral pathway, which does not appear to have been recognized as a source of afferents to the amygdala, is probably more important from a functional point of view as it contains considerably more fibres. Analysis of a large number of other experiments makes it clear that most, if not all, of these fibres arise from within the field of distribution of the medial forebrain bundle, and especially from the hypothalamus and preoptic areas. The reciprocal relationship between the amygdaloid region and the hypothalamus suggests that the ventral pathway is essentially a laterally directed extension of the medial forebrain bundle, and that the stria terminalis should be regarded as a dorsal component of this bundle which has become separated from the main part of the medial forebrain bundle by the development of the internal capsule.

Perhaps the most significant finding of this investigation is that the pyriform cortex sends a substantial projection to the hypothalamus and to the dorsomedial and lateral habenular nuclei of the thalamus. The importance of the first of these observations is that it provides evidence

for a direct relationship between the olfactory system and the rostral hypothalamus, with only two synapses interposed between the olfactory receptors and the cells of the hypothalamus. Physiological investigations have clearly indicated that there must be a close connexion between the sensory systems and the hypothalamus, but hitherto no unequivocal neuroanatomical evidence for a considerable projection to the hypothalamus from a major sensory system has been forthcoming. As the pyriform cortex represents the principal site of termination of secondary olfactory fibres, a corollary of this finding is that the hypothalamus must be considered as one of the main sites of induence of the olfactory system. At the same time it may provide an anatomical basis for the known relationship between olfaction and reproductive behaviour, and in this context it is relevant to note that the pyriform cortex projects primarily on the anterior hypothalamus, which appears to be the critical area involved in several aspects of the hypothalamic control of reproduction[18].

The observation that the pyriform cortex projects to the dorsomedial nucleus of the thalamus is of interest for three reasons. First, it shows that the thalamus is related to the olfactory system in much the same way as it is to other sensory pathways, and from this it follows that part, at least, of the orbito-frontal area of the cortex may be thought of as a sensory projection field for olfaction—although clearly not in the same way as the primary sensory areas. Secondly, in recent years afferents to the dorsomedial nucleus have been described from a number of basal forebrain areas (including the amygdala). As the pathway taken by the fibres from these various sources is identical with that described here for the projection of the pyriform cortex on the dorsomedial nucleus, and as the projection fibres from the pyriform cortex either pass through or in close relation to these other sites, it seems likely that the degeneration found in the dorsomedial nucleus in previous studies can be attributed, in part at least, to the interruption of fibres arising in the pyriform cortex. The question whether the amygdala and other such structures also contribute afferents to the dorsomedial nucleus cannot be resolved at present.

The third point of interest arising out of the present findings is their implication for our understanding of the phylogenetic development and functional significance of both the dorsomedial nucleus and the frontal cortex. As is well known, the dorso-medial nucleus and the frontal cortex increase considerably in the primate brain while at the same time the pyriform cortex undergoes a relative regression. As it is probable, however, that the part of the dorsomedial nucleus which is in receipt of afferents from the pyriform cortex is homologous with only the medial, magnocellular element of this nucleus in the primate, the apparent discrepancy between the increase in the development of the dorso-medial nucleus as a whole and the frontal cortex in ascending phylogeny, in contrast with the marked decrease of the olfactory system, presents no real problem. While perhaps unexpected, the finding of a direct projection of the pyriform cortex to the dorso-medial nucleus of the thalamus is not really surprising in view of the direct connexion of the hippocampus with the anterior thalamic nuclei. There is in fact an interesting similarity in the whole diencephalic projection of these two phylogenetically old cortical areas. Not only do they both send efferent fibres directly to the thalamus, but both also project to the hypothalamus, the pyriform cortex principally to its rostral part and the hippocampus to the mammillary bodies in its caudal part. While there is clearly some overlap in the hypothalamic distribution of these two projections, it may be useful for our present understanding of the organization of the afferent connexions to the hypothalamus to make this generalization. At the same time it should be pointed out that the pyriform cortex is connected with the hippocampus so that at their origin there is a close relationship between these two hypothalamic afferent systems.

BIOLOGY

An Attempt to demonstrate *in vivo* Recognition of Ectopically Placed Autologous Tissues

The organization and control of growth of the normal tissues of the body has been related by Green[1] to the presence on the surface of normal cells of specific reactive sites, which are thought to be lipoproteins[2]. These he called tissue specific antigens, and these antigens were postulated to undergo a modification when cells become displaced outside their normal environment[3], and thereby alert the disposal mechanisms of the body which prevent the growth of ectopically placed autologous tissues. An attempt has therefore been made to design a system to demonstrate an immune response to ectopically placed autologous tissues.

Small portions of Wistar rat liver were excised, and after enclosing in 'Millipore' chambers of 0·45μ pore-size, were re-inserted intraperitoneally into the donor rats. The animals were killed 8–12 days later, and cell suspensions were made, after the method of Branster and Morton[4], of the spleens and livers. In some cases cell suspensions were made of the kidneys also, to act as controls. In other cases the controls were cell suspensions made from normal unsensitized spleens from animals of the same strain as the experimental rats.

After counting the cell suspensions in the improved ruling Neubaur counting chamber, the sensitized and control spleen suspensions were adjusted to equality, and a 3:1 volume of sensitized spleen suspension to liver suspension was injected subcutaneously into the flank of a normal guinea pig. The opposite flank of the same guinea pig received a similar suspension of normal unsensitized spleen and liver. The guinea pigs were killed on the third day, the skin at the site of injection was reflected, and the area of the flare excised and photographed. Guinea pigs which showed no flare at all, on either or both sides, were eliminated from the experiment.

A further experiment was designed to control the sensitization of the spleen by the contents of the 'Millipore' chamber. Here the experimental side received liver sensitized spleen and liver as before, while the control side was injected with liver sensitized spleen and autologous kidney suspension. The spleen in another experiment was

'sensitized' to an empty 'Millipore' chamber, and 'Millipore' sensitized spleen cells and liver were compared with autologous liver sensitized spleen and liver. The 'Millipore' chamber itself did not appear to activate the spleen.

Table 1

Experimental side: flares larger	Control side: flares larger	Flares equal on both sides	No. of guinea pigs used
18	3	10	31

Cells 1·5 million spleen cells, and 0·5 million antigen cells.

Adding the results of these three experiments together, the sensitized spleen and the antigen on the experimental side, and on the control side, either the sensitized spleen and a different antigen, or normal spleen and the same tissue as was used as antigen on the experimental side, the experimental side gave a greater number of larger flares than the control side.

In this group of experiments an attempt has been made to demonstrate a recognition system of ectopically placed autologous liver in a 'Millipore' chamber. It has been suggested that tissue organization and growth are partly controlled by tissue-specific antigens which undergo modification when placed outside their normal site, and that this modification is capable of activating the immune mechanism. It is believed that the prior sensitization of the spleen, which appears to elicit a larger flare in the guinea pig when injected with the sensitizing agent, as compared with the control side using unsensitized spleen, is suggestive that some such mechanism of recognition may indeed take place. It is thought that this recognition is specific and not merely a non-specific activation of the spleen, and that this was shown when larger flares were obtained when liver sensitized spleen and liver were injected and compared to liver sensitized spleen and autologous kidney.

Inability of the Kidney of the Hagfish to secrete Phenol Red

The kidney of the hagfish (*Myxine glutinosa* L.) consists of about 70 extraordinarily large Malpighian corpuscles, which through short ducts are connected with the ureters. The latter extend from the level of the heart to the cloaca. It is assumed that two ureters (Wolffian ducts) carry out functions which in higher vertebrates are performed by kidney tubules. This theory is based on an alleged histological resemblance of the hagfish ureters to renal tubules[1]. However, it has not yet been confirmed electron-microscopically that the resemblance is a real one and not only superficial.

One of the well-known properties of renal tubules is their ability of active transport of certain organic molecules. This kind of secretion has been demonstrated both in whole kidneys and isolated tubules from various vertebrates[2,3]. A similar kind of secretion is accomplished by the liver during the formation of the bile[4,5].

In order to determine whether or not the ureters of the hagfish are able to function as substitutes for tubules, living specimens of *Myxine glutinosa* were injected subcutaneously with 1 ml. sea-water containing chlorophenol red in a contraction of 10^{-4} g/ml. The animals were kept in aquaria with running sea-water, and investigated 3–48 h after the injection.

It is found that the hagfishes after 1–2 days had eliminated most of the injected dye from their tissues. Not at any time during this period did chlorophenol red appear in the urine. In most of the animals, however, the liver had a slightly red colour, and the gall bladder contained bile mixed with chlorophenol red at a concentration higher than that of the injected solution. Similar experiments with fluorescein in a concentration of 10^{-4} g/ml. also demonstrated a secretion exclusively by the liver. No fluorescein was discovered at any time after injection in the ureters by examination under ultra-violet light.

It can be concluded that in *Myxine* the ureter epithelium does not react to handle chlorophenol red or fluorescein. This is probably true also for a series of other organic compounds. Nevertheless, in some respects the ureter epithelium shows similarities with ordinary renal tubular epithelium. Thus alkaline phosphatase activity can be demonstrated[6]. This enzyme may take part in a mechanism for re-absorption of glucose. The liver of the hagfish is built like a tubular gland[7], and probably the hagfish liver tubules secrete chlorophenol red and other compounds by a transport mechanism similar to those active in the renal tubules and the liver of higher vertebrates.

Presumably the secretion of phenol red, etc., by kidneys of many animals reflects an ability to transport certain naturally occurring substances like hippuric acid[2]. If this is true, such products in the hagfish have to be eliminated by the liver and not by the kidney. The inability of the hagfish kidney to transport chlorophenol red and fluorescein seems to be a consequence of its 'atubular' condition. In hagfish urine seems to be formed without interference of secretory processes, but further data are needed to verify this theory.

Polymorphism in Living and Pleistocene Populations of the African Land Snail, *Limicolaria martensiana*

Diver[1] has shown that polymorphism in colour and pattern in living populations of the land snail, *Cepaea*, may also be distinguished in Pleistocene fossils, and although there may have been changes in the relative frequency of the colour forms, the polymorphism has persisted for thousands of years.

Examination of fossil shells of the land snail, *Limicolaria martensiana* (Sm.), obtained from volcanic ash deposits in the Katwe explosion area in the Western Rift of Uganda reveals that here also polymorphism has been maintained for a long time: radio carbon dating and surface morphology suggest that the Katwe ashes are 8,000–10,000 years old[2]. Although the *Limicolaria* shells are somewhat faded (not all the possible colour forms would be distinguishable), heavily streaked and pallid forms occur in the same horizons and their relative frequency can be compared with that of modern populations living in the same areas. As shown in Table 1, at one locality, Equator Road, streaked shells comprise 67·9 per cent of the fossil population and only 42·7 per cent of the living population. This is a statistically significant difference:

$\chi^2_{(1)} = 30{\cdot}20$ and $P < 0{\cdot}001$. In addition, the semi-streaked form is absent from the fossil population, but comprises 32·5 per cent of the modern population. About 22 miles east of Equator Road, at Kichwamba, 90·0 per cent of the fossils and 42·0 per cent of the living snails are streaked. This difference is statistically significant, $\chi^2_{(1)} = 24{\cdot}11$ and $P < 0{\cdot}001$ (Yates's correction applied). The semi-streaked form is absent from both the living and the fossils at Kichwamba. But within the living snails grouped together as pallid in Table 1, three forms are present: these would not be distinguishable in the fossil pallid snails as the differences between them, though constant, are slight.

Table 1. Relative Frequency of Colour Forms in Fossil and Living Populations of *Limicolaria martensiana*

	N	Streaked	Percentage Semi-streaked	Pallid*
Equator Road				
Fossil	165	67·9	—	32·1
Living	422	42·7	32·5	24·8
Kichwamba				
Fossil	30	90·0	—	10·0
Living	405	42·0	—	58·0

* These colour forms are figured in an earlier communication (ref. 3).

At Equator Road, living adult snails average 15 per cent less in length than fossils and the presence at high relative frequency of a colour form not found in the fossils suggests that the area has been re-populated from elsewhere. Alternatively, an evolutionary change could have occurred in which the snails became smaller and a new colour form spread into the population. Equator Road fossils are in fact more similar in size and coloration to both the living and the fossil snails from Kichwamba. At Kichwamba, the lower relative frequency of the streaked form in the living than in the fossil population could represent an evolutionary change. On the other hand, samples of living snails collected within a mile of the fossil site indicate that there may be marked variation in the relative frequency of the colour forms; but in no area have streaked snails been found to comprise more than 60 per cent of the population.

Effects of Puromycin on Morphogenesis in Amphibian Eggs and *Acetabularia mediterranea*

The effects of actinomycin *D*, an antibiotic which is a specific inhibitor of the enzyme DNA primed-RNA polymerase, on morphogenesis in amphibian eggs and in the alga *Acetabularia mediterranea* have been presented in a preceding communication[1]. It was shown that inhibition of nuclear RNA synthesis (presumably messenger-RNA synthesis) results in the inhibition of cephalo-caudal and dorso-ventral differentiation, in amphibian embryos.

Further, still unpublished, experiments by Denis on combined explants of *Pleurodeles* gastrulæ clearly show that actinomycin *D* treatment inhibits, in less than 1 h, both the inducing power of the organizer and the competence of the reacting ectoderm: RNA synthesis is thus an absolute prerequisite for successful neural induction.

In *Acetabularia*, regeneration of anucleate fragments is much less inhibited by actinomycin *D* than that of nucleate ones; this fact has been repeatedly confirmed in more recent experiments: although synthesis of nuclear RNA is required for morphogenesis (cap formation), anucleate fragments of the alga apparently contain enough informational RNA, at the beginning of the experiment, to permit the initiation of cap formation even in the presence of actinomycin *D*.

But a cap, in *Acetabularia*, is not made of RNA alone: nuclear RNA is nothing but an intermediary between the genes and the phenotypic character; its task is to carry from the nucleus to the tip of the stalk the 'information' needed for the synthesis of specific proteins, required for cap formation. It was therefore of interest to compare the effects of puromycin, a protein synthesis inhibitor, with those of actinomycin *D*, a nuclear RNA synthesis inhibitor. As is well known, puromycin is an analogue of the terminal chain of transfer RNA; in its presence, ribosomes form incomplete polypeptide chains instead of normal proteins[2].

Puromycin (10–30 μg/ml.) was tried on *Pleurodeles* and *Rana temporaria* eggs: no effect was observed until the late gastrula stage, at which time the membranes surrounding the embryos were removed. This lack of effect is probably due to poor permeability of the antibiotic, since cleavage stops very quickly when dissociated morula cells are treated with puromycin (Tencer and Bieliavsky, unpublished observations). But neurulation is definitely inhibited: the nervous system is markedly reduced, microcephaly is the rule, and the elongation of the body is reduced (Fig. 1, *a* and *b*). By and large, puromycin-treated embryos resemble actinomycin-treated ones, as one would expect.

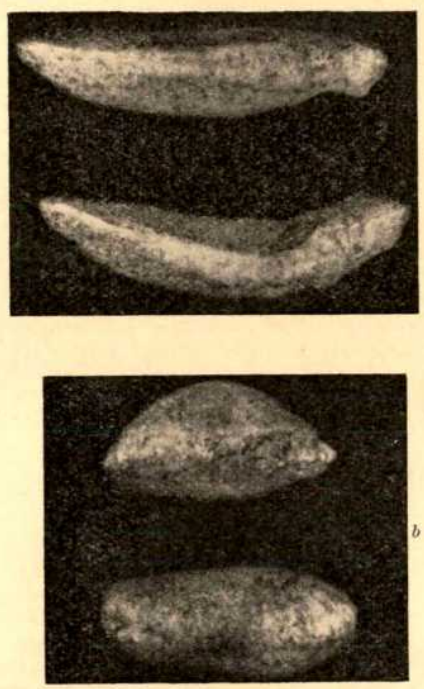

Fig. 1. *a*, Control *Pleurodeles* embryos of 4 days; *b*, *Pleurodeles* embryos treated for 4 days with 30 μg puromycin/ml.

At the same concentrations, puromycin very quickly inhibits growth in *Acetabularia*. The inhibition is almost irreversible if anucleate fragments are treated in the dark; in the light, after a 2-week treatment, very few of these fragments produce whorls or small, abnormal caps. The effect of puromycin on anucleate halves is thus much stronger and less reversible than that of actinomycin *D*. In the case of nucleate fragments or whole algæ, growth is generally resumed if the algae are returned to normal medium; after a lag period, the length of which varies with the severity of the treatment, a high proportion of malformations (heteromorphoses) is found in the algae. At low concentrations (5 μg/ml.), abnormal caps are formed (Fig. 2). At higher concentrations (10–30 μg/ml.), duplication or triplication of the apical end of the stalk can often be observed (in almost 50 per cent of the algae in one experimental series which dealt with nucleate halves

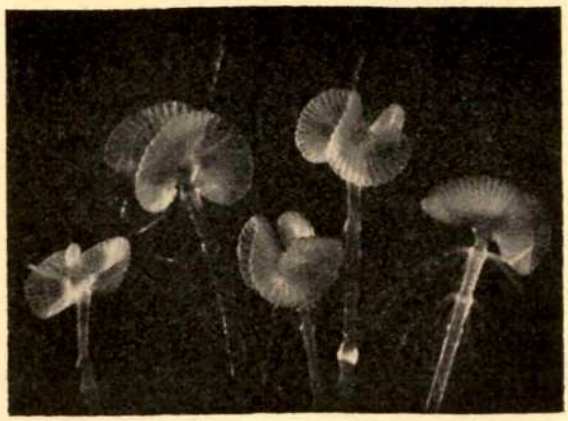

Fig. 2. Abnormal caps produced after a 4-week treatment of whole *Acetabularia* algæ with puromycin (5 μg/ml.)

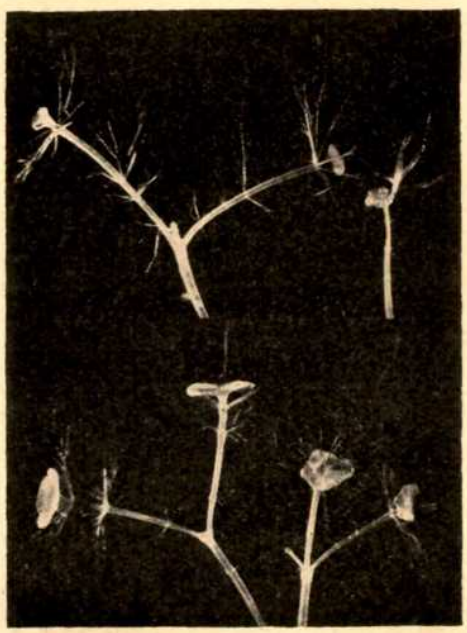

Fig. 3. Duplications of the apical end of the stalk in nucleate fragments of *Acetabularia* after a 1-week treatment with puromycin (20 μg/ml.) and a 3-week culture in normal sea-water

(Fig. 3)). In such cases, dominance of one or two of the stalks on the others is the rule, so that one never obtains more than two caps in a single alga. Less frequently, the growth of the stalk may be completely arrested and a new stalk, which ultimately forms whorls and a cap, shoots at the proximity of the rhizoid.

Inhibition of protein synthesis by puromycin therefore strongly affects the tip of the alga, where particular proteins are accumulated[3] and where incorporation of labelled methionine is considerable[4].

The orderly synthesis of these proteins, which is upset by puromycin in nucleate fragments and which is little affected by actinomycin in anucleate ones, is thus a prerequisite for normal morphogenesis.

Effect of Time of Picking on the Ethylene Production of Apples

Composite samples of Cox's Orange Pippin apples were picked from 15 trees at weekly intervals during September 11–November 21, 1962, for storage experiments. The maturity of the fruit was tested by following the course of the respiration 'climacteric' at 12° C by a simplified method previously described[1].

From the weight of the fruit, the fall in percentage oxygen, and the rise in ethylene concentration, it is possible to calculate approximate values for the rate of absorption of oxygen, and the rate of production of ethylene. Curves for these values are shown in Fig. 1. There were 11 picks in all; but for the sake of clarity alternate picks have been omitted and only 6 pairs of curves are shown. The other 5 were intermediate.

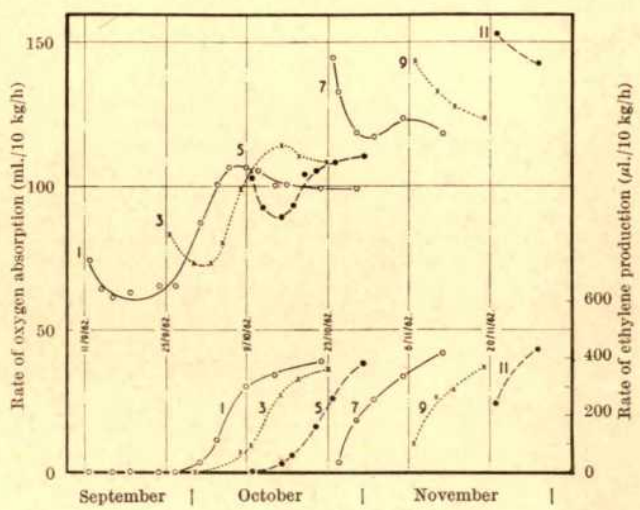

Fig. 1. Rate of oxygen absorption and of ethylene production by apples picked at fortnightly intervals

The general picture of the effect of date of picking on respiration (including the high values for very late picks) is consistent with that found by Hulme *et al.*[2] for other Cox's Pippin apples in the same season.

As regards ethylene the main points of interest are as follows:

(1) The rise in rate of ethylene production of the apples of picks 1 and 3 followed the rise in rate of oxygen absorption in the manner usually shown for apples. (In 1962 the normal picking date for Cox was considered to be about October 1.)

(2) By pick 7, oxygen absorption was at a rate associated with the peak of the 'climacteric', and there was still no substantial amount of ethylene being produced, although the rise in the rate of oxygen absorption must have begun many days earlier. Moreover, for the first few days in the laboratory, ethylene production was rising while oxygen absorption was falling. The same was true of picks 9 and 11.

(3) In picks 1–7 large amounts of ethylene were not evolved until after the fruit had been picked. (It is realized that small amounts of ethylene may have been produced much earlier[3].) However, extrapolation of the ethylene curves for picks 9 and 11 suggest that by that time considerable amounts of ethylene were being produced by the fruit on the trees.

Curves similar to 1–7 were also obtained for Cox's Orange Pippin apples from another orchard in 1961; but in that season the fruit did not remain on the trees as long as in 1962.

In recent years, doubts have been cast on the validity of the earlier concept of the coincidence of the 'climacteric' and the evolution of ethylene[4]. Evidence for the

change of view included observations that in the fruits of cherimoya and feijoa the beginning of the ethylene production lagged behind the rise of respiration by 2–4 days[5]. The results recorded here suggest that in apples (in which the 'climacteric' and ethylene production are usually considered to be coincident) a separation in time between the 'climacteric' and the rise in rate of ethylene production can be brought about by delaying picking until the 'climacteric' has been commenced on the tree.

The trees and fruit were made available by the East Malling Research Station as part of a joint experiment on the effect of picking date on storage behaviour. Dr. D. F. Meigh measured the amounts of ethylene by gas chromatography.

Penetration of Seeds by Acetone Solutes

During an investigation of the toxicity of organic solvents to seeds it was found that those of higher plants could be soaked in acetone for periods of up to six months and still germinate readily, provided that the solvent was removed before the seeds were soaked in water. There was no reduction in viability, in contrast to that reported when dehydrated moss was soaked in ethanol or acetone for 1 h[1].

Seeds of a number of plant species were soaked in 'AnalaR' grade acetone for periods up to three months, dried at 35° C for 12 h, and then germinated. Results in Table 1 show that acetone treatment had no inhibitory effect on germination nor was any reduction in the size of the plants observed. Seeds of wheat could also be germinated after ten days' soaking in benzene, chloroform or ether.

It was found that water-insoluble, but acetone-soluble, compounds applied in acetone solutions penetrated seeds and could be recovered from the seedlings. Some preliminary results on the effects of DDT applied to barley, wheat, oat and pea seeds by this method are given. DDT was a suitable choice, since it is detectable in minute amounts, and since some data on its absorption into plants were already available.

2 g of seeds of 'Rika' and 'Proctor' barley, 'Blenda' oats, 'Svenno' wheat and 'Alaska' pea were soaked with 1 ml. of a 3 per cent (w/v) solution of DDT in acetone, which was allowed to evaporate at 20° C after the seeds had been incubated in stoppered bottles at 20° C for 24 h. After ten days' germination in soil at 22° C the first leaves were cut 1 cm above ground-level, macerated, dried and extracted with hexane. DDT was measured by gas/liquid chromatography[2] using the conditions set out by Goodwin *et al.*[3].

Table 1. Effect of Three Months' Soaking in Acetone at 2 0°C on the Germination of Ten Species of Seed, Samples of 200

The apparent variability of some values was exaggerated because the count of the number of seedlings was made after 10 days. There was no noticeable difference between the viability of the two sets

Species	Percentage germination	
	Control	Acetone treatment
Barley	97	45
Linseed	94	96
Mung bean	84	92
Mustard	85	96
Oat	90	80
Pea	80	76
Ryegrass	56	65
Sugar beet	62	76
Tomato	47	91
Wheat	35	63
Mean	73	78

Table 2. Recovery of *pp'*-DDT from the Shoots of 10-day-old Barley, Oat, Pea and Wheat Seedlings

2 g of seed were soaked with 1 ml. of 3 per cent DDT in acetone which was allowed to evaporate after 24 h.

		μg DDT in shoots	μg DDT/g fresh weight
Barley var.	'Rika'	9·5	1·32
	'Proctor'	6·5	0·83
Oat	'Blenda'	3·5	2·92
Pea	'Alaska'	2·6	1·51
Wheat	'Svenno'	3·5	1·67

No DDT was found in control plants of any variety

The results are shown in Table 2. The 1·51 μg DDT/g recovered from pea plants the seeds of which had been soaked in acetone solutions can be compared with Lichtenstein's results[4], who found less than 0·01 μg/g shoot fresh weight in pea plants which had been grown in sand containing 30 μg DDT/g. This was probably due to its low water solubility (1·2 parts per billion[5]). Less than 0·05 μg DDT/g was recovered from pea plants grown under the conditions described by Lichtenstein. The presence of DDT in the extracts of the first leaves of cereals could not have been due to surface contamination as the seeds were covered with 2 cm of soil and the coleoptile completely encloses the first leaf until the tip of the coleoptile comes above ground. Nor were toxicity symptoms observed in oat seedlings grown from 2 g of seeds which had been dusted with 30 mg DDT.

The toxicity of DDT sprays to young barley plants of a number of varieties has been shown by Hayes[6] to depend on the genotype of the variety and to follow a simple resistant or sensitive pattern. These experiments were repeated with both spray-sensitive ('Freja' and 'Rika') and spray-resistant ('Proctor') varieties. Although there was a marked difference in the response of the seedlings to DDT sprays, all strains were unaffected when dosages of up to 0·6 mg DDT per seed were applied in acetone as described. Similar amounts of DDT were recovered from

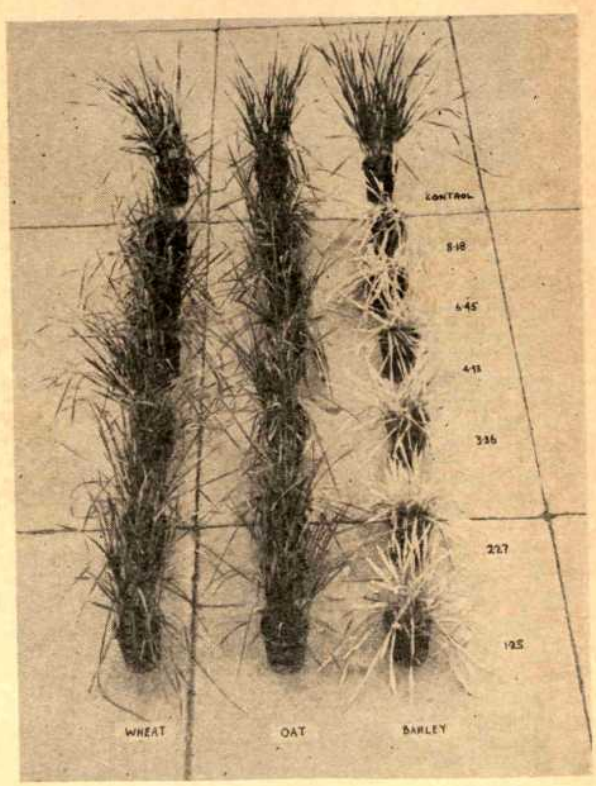

Fig. 1. Severe chlorosis of a spray-sensitive barley sprayed with a DDT emulsion at rates between 8·18 and 1·25 mg DDT/dm². Seedlings of 'Svenno' wheat and 'Rika' barley were treated after 10 days. 'Blenda' oats after 12 days' growth; all were photographed 10 days later

the shoots of spray-sensitive and spray-resistant seedlings (Table 2). Seedlings of oats ('Condor' and 'Blenda') and of wheat ('Svenno' and 'Capelle') were unaffected by DDT sprays (Fig. 1); when DDT was applied to the seeds as a 3 per cent acetone solution the oat seedlings produced were stunted and showed a characteristic mottled chlorosis, but wheat was unaffected. The difference in response of oats and barley to DDT applied as a spray or as an acetone solution affords a striking example of how the method of application can affect the response of plants to a compound.

As acetone solutions are capable of penetrating seeds it should also be possible to remove some compounds, such as germination inhibitors, from seeds using this technique.

MICROBIOLOGY

Trace Metal Control of Bacterial Flagellation

Specific alterations in the normal battery of biosynthetic processes often occur when moderate changes are made in the balance of metallic ions in the environment. In microbial systems, for example, the quantities synthesized of organic acids, porphyrins, vitamins, antibiotics, toxins, enzymes, lipids, and polysaccharides are controlled by precise balances of metallic ions that permit, but are not necessarily optimal for, vegetative growth. Likewise, the execution of such physiological processes as cell division; sporulation; germination; plasmodia and vesicle formation; and adsorption, induction, and synthesis of bacterial viruses depends on concentrations of specific metallic ions that differ from the minimum quantities needed for synthesis of protoplasm. Indeed, the tolerance of normal vegetative growth to fluctuation of the metallic ion environment is considerably greater than the fluctuation tolerated by a specific biosynthetic or physiological process[1].

The synthesis of bacterial flagella is influenced by the organic constituents and the *p*H of the culture medium, the temperature of incubation, and the age of the culture[2]. Oddly, the role of specific metallic ions has not been studied systematically, and the literature contains only a few fragmentary reports. For example, 10^{-5} M calcium is required for the functioning but not for the synthesis of flagella of *Rhodospirillum*[3], whereas 10^{-2} M calcium or aluminium suppresses motility of *Azotobacter*[4]. In the latter report, no results were presented concerning possible suppression of viability by such high concentrations of the cations. With *Chromobacterium* grown in a complex medium, the addition of various trace elements, unspecified as to kind and concentration, was reported to have no effect on flagella synthesis[5].

In the work recorded here, partially and completely flagellated strains of *Bacillus megaterium* and *B. subtilis* were grown (at 25° and 37° C) in a shaken liquid medium containing (μg/ml.) glucose, 2,000; NH_4NO_3, 1,000; Na_2HPO_4, 1,300; KH_2PO_4, 800; $MgSO_4$, 250; $FeCl_2$, 0·25; Na_2EDTA, 1·0; *p*H 7·0. Partial flagellation indicates that, in this medium, 40–60 per cent of the cells in the middle of the logarithmic phase of growth possessed flagella; complete flagellation denotes more than 90 per cent flagellated cells. The cultures were examined at various times for number of cells, per cent of flagellated cells, number of flagella per cell, and *p*H of culture medium. These results were compared with those obtained with cultures grown in the basal medium plus one of 13 metallic ions (added as salts of sodium or of chloride) or one of three metal-binding agents. The final concentrations of the 13 ions ranged in each case from 10^{-6} M to the maximum sub-bacteriostatic quantity listed in parenthesis: Cu^{+2}, Zn^{+2} (2×10^{-6}); Co^{+2}, Ni^{+2} (2×10^{-5}); Ca^{+2}, Sr^{+2}, V^{+5}, Mo^{+6}, Mn^{+2}, Fe^{+2}, B^{+3} (6×10^{-4}); Al^{+3}, Se^{-2} (12×10^{-4}). The concentrations of the metal binding agents (Na_2EDTA, L-cysteine, and L-histidine) varied from 10^{-5} to 3×10^{-4} M.

Of the 16 added substances, only manganese, iron, and aluminium affected flagellar synthesis. The qualitative effects to be described were obtained with both species of *Bacillus* at each temperature of incubation; the quantitative results were obtained with *B. megaterium* at 25° C. With partially flagellated strains, manganese in some experiments caused a moderate increase in per cent of flagellated cells (in one experiment, for example, from 45 per cent in basal medium to 60 per cent in medium enriched with 6×10^{-4} M manganese); however, this effect was not obtained consistently. With either partially or completely flagellated strains, iron and aluminium had a marked and consistent ability to suppress flagella formation.

The results of a typical experiment with a completely flagellated strain of *B. megaterium* are summarized in Table 1. It can be seen that the percentage of flagellated cells was reduced not only in cultures grown in the presence of added iron or aluminium but also in cultures which were exposed to either metallic ion after initial growth had occurred. On the other hand, cells grown for 8 h (middle of logarithmic phase of growth) in the presence of either iron or aluminium and then washed and resuspended in basal medium for 14 h did not fully regain the ability to produce flagella.

Table 1. Suppression of Flagella Formation by Ferrous or Aluminium Chloride

Age of culture (h)	Growth medium		Percentage of flagellated cells
8	Basal		97
	plus Fe		49
	plus Al		10
14	First 8 h	Next 6 h	
	Basal	Basal	90
	Basal	plus Fe	54
	Basal	plus Al	31
	plus Fe	Basal	67
	plus Al	Basal	55
22	First 8 h	Next 14 h	
	Basal	Basal	94
	Basal	plus Fe	25
	Basal	plus Al	5
	plus Fe	Basal	50
	plus Al	Basal	41

Concentration of Fe: 6×10^{-4} M; concentration of Al: 12×10^{-4} M. Percentage of flagellated cells observed by staining with Leifson's flagella stain (ref. 2).

Cultures in which the percentage of flagellated cells was suppressed by iron or aluminium or enhanced by manganese were similar to control cultures with respect to cell viability; generation time; *p*H of culture medium; and size, shape, and number (2–8) of flagella per cell. A single notable exception occurred in cultures of *B. subtilis* grown in basal medium enriched with 6×10^{-4} M each of manganese and aluminium; these cultures contained less than 10 per cent flagellated cells, but the length of the flagella was increased as much as ten-fold over normal flagella.

After these studies were completed, a report was published describing a complex medium which can be used to suppress flagella synthesis of strains of *B. cereus*, *Proteus vulgaris*, and *P. mirabilis*[6]. The active ingredient in this medium was found to be 9×10^{-4} M iron; other metallic ions were not tested. This finding, plus those described in the present report, suggest that persons engaged in studying bacterial flagella should make certain that the quantities of iron and aluminium in their culture media are sufficiently low to permit maximum flagellation in addition to adequate vegetative growth.

CYTOLOGY

A Simple Method for the Display of Chromosomes from Cultures of White Blood Cells with Special Reference to the Ox

The intensive examination of human chromosomes during the past two years has led to important discoveries in the understanding of certain disorders. Similar studies on domestic animals have barely begun. Before this can be carried out on a large scale, however, it is necessary to develop techniques which can be readily applied in the field since the standard methods used for the display of human chromosomes from cultures of the white blood cells are not necessarily directly applicable to the domestic animals. In this communication we describe the technique we have developed as a result of our interest in the chromosomes of the domestic ox.

To display the chromosomes from cultures of human white cells the following three steps are involved[1]: (1) separation of the white cells from a sample of blood; (2) culture of these isolated white cells for a period sufficient to generate enough cells for observation and also under such conditions that promote their rapid multiplication; (3) preparation of smears suitable for examination under the oil-immersion objective of the microscope.

In the past the white blood cells have been isolated by one of three methods. These are by the promotion of agglutination which hastens sedimentation of the red blood cells, by flotation methods which exploit the fact that the red blood cells are denser than the white cells, and by lysing the red blood cells, leaving the white cells intact. (For references on the methods commonly used see Christlieb *et al.*[2].) Investigators who have isolated white cells in order to subject them to tissue culture have usually favoured the first method. In some species, such as the horse, agglutination is so spontaneous that the red cells settle very quickly and leave the so-called buffy coat of white blood cells above them.

During investigations of the domestic cow, problems are encountered particularly in the separation stage. This is because of the well-known fact that the red blood cells of the cow sediment very slowly since they show little tendency for rouleaux formation. Human red blood cells, however, have some tendency to agglutinate spontaneously and this can be hastened by the addition of phytohæmagglutinin to the blood. However, this substance, in our hands, seems to have little effect on the red blood cells of the cow and therefore cannot be used to hasten sedimentation.

Other methods used for producing the same effect are, for example, the addition of dextran and fibrinogen, both of which cause red blood cells to clump. The addition of fibrinogen to bovine blood will certainly promote agglutination and can be used for the separation of white blood cells. However, it has to be added in such a high concentration that it is difficult to sterilize the fibrinogen solution in order that tissue culture methods can afterwards be used. The flotation method has been used in the past by workers who are concerned with isolating white blood cells but not necessarily concerned with their tissue culture. Consequently, problems of sterility were not intimately involved.

White blood cells can also be isolated by placing a sample of blood over a solution, for example, of bovine plasma albumin[3] or gum acacia[4], whose specific gravity lies between that of the red blood cell and the white blood cell. When the tube containing these materials is centrifuged at low speed, the red blood cells will sink through the medium and the white blood cells will stay at the interface between the plasma and the denser medium. Unfortunately, the concentrations of these solutions are very high. Albumin, for example, has to be used in a concentration of 35 per cent. Gum acacia also has to be used in high concentration and involves an elaborate series of steps in the preparation of its solution. Recently we have found that a substance 'Ficoll' (Pharmacia, Uppsala, Sweden), which is a highly polymerized form of sucrose, can provide a very dense solution which can be used for the separation of red blood cells from white blood cells. This material has sufficiently high molecular weight that only a 26 per cent solution is required to give a specific gravity of 1·094, which we have found to be optimal. This material can be dissolved in a standard tissue culture medium, such as Eagle's medium containing 10 per cent calf serum, and the resulting solution can be readily sterilized by passing it through a 'Millipore' filter. Experiments have shown that recovery of white blood cells with this method is as follows: sheep, 69·5 per cent, *S.E.* 1·67 (*D.F.* 4); cow, 69·9 per cent, *S.E.* 4·2 (*D.F.* 6). We therefore use this method routinely in our studies on the chromosomes of the sheep and the cow.

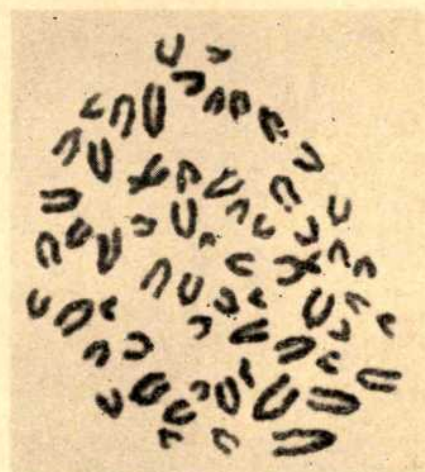

Fig. 1. Chromosomes of a female Santa Gertrudis cow. ($2n = 60$) (ref. 6)

Our method is as follows: 3 ml. of the tissue culture medium containing 26 per cent 'Ficoll' (specific gravity 1·094) is placed in a 15-ml. centrifuge tube. Two ml. of the blood sample is then placed on top of this material and the tube is centrifuged at roughly 500 r.p.m. for 5 min. The upper layer of plasma containing the white cells is then placed in a tissue culture bottle and the requisite amount of Eagle's medium containing 10 per cent calf serum is then added. Phytohæmagglutinin is also added to the bottle to promote cell division. The air in the bottle is displaced with 5 per cent carbon dioxide in air and the bottle tightly stoppered. It is then incubated at 37° C for 3 days. At the end of this period 0·05 μg/ml. of 'Colcemide' (Ciba, Summit, New Jersey) is added and the bottle incubated for a further 3 h. The cells are then removed from the bottle using trypsin and are then prepared for histological examination using an air-drying technique[5]. The smears are stained with Giemsa stain.

If the blood sample is collected at some distance from the laboratory, the blood is immediately chilled by placing

the tubes in a bowl of ice. We have found that the sample can be stored in this way for some time before use without prejudicing the tissue culture part of the experiment.

An example of the results obtained by this method is shown in Fig. 1, demonstrating the chromosomes of a cow of the Santa Gertrudis breed.

This method has also been successfully applied to blood samples from the dog, the horse, and from man; but it would appear that there is no advantage over simpler methods used in these species. Although the separation of the white cells from the erythrocytes is not complete, it should be appreciated that it is not necessary to remove all red blood cells from the sample in order to obtain successful tissue culture. Therefore, the insistence on an exact technique for preparation of pure white cell suspensions is superfluous. Another advantage of the method is that satisfactory suspensions of white cells in terms of number can be prepared from fairly small blood samples, for example, 2 ml. This is considerably less than the amount of blood usually drawn in standard work with human beings. Although this point is unimportant for the larger animals, it is very important when dealing with animals such as the cat, where the routine sample of 10 c.c. would be quite impossible to obtain.

Preparation of Bovine Chromosomes

Certain problems have induced us to prepare the chromosomes of bovine leucocytes. Using the methods of other authors[1–3] the following technique was adopted:

20·0–40·0 ml. blood were collected from the jugular vein of an ox, to which was added 2·0–4·0 ml. heparin solution (200 mg heparin, 100 mg streptomycin, 10,000 units penicillin, 100·0 ml. of a 0·85 per cent saline solution) or an appropriate amount of 'Vetren' or 'Thrombovetren' (Promonta, Hamburg). This was put in a vessel containing 0·12–0·24 ml. phytohæmagglutinin *P* or 0·4–0·8 ml. phytohæmagglutinin *M* (Difco), well mixed, stored for 20 min in a refrigerator, centrifuged afterwards for 10 min at about 900*g* and the leucocyte-layer obtained. (Bovine erythrocytes were not agglutinated by phytohæmagglutinin.)

A leucocyte-suspension of 1,000–1,200 cells/mm^3 was prepared in 20 per cent homologous plasma and 80 per cent '*TC* medium' 199 (Difco). 10·0 ml. of the suspension were filled in each of 3 culture vessels and incubated at 37° C. 48–72 h later 1·0 ml. of a 0·04 per cent colcemid solution was added to the culture with the highest colour deviation towards yellow, kept for another 3 h in the incubator, cells centrifuged off, and put in a 0·95 per cent sodium citrate solution at 37° C and maintained for 20 min at 37° C. After this the cells are again centrifuged off, five times washed with a mixture of 1 part glacial acetic acid and 3 parts absolute alcohol (fixative) and the cells in sufficient density suspended in the fixative. One drop of this was placed on an iced moistened slide, air dried for 30 min, dyed in a 2 per cent orcein-solution and solidly covered.

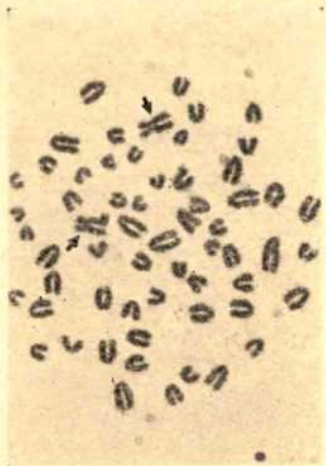

Fig. 1. Chromosomes of a female ox

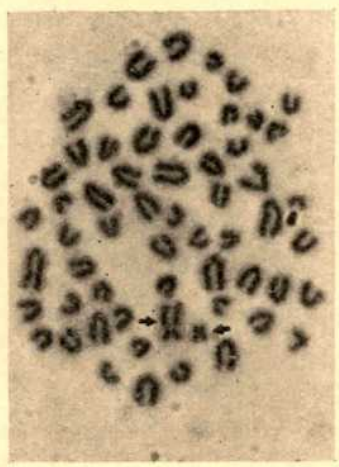

Fig. 2. Chromosomes of a male ox

Leucocytes of 4 males and 7 females were examined and 20 complete mitoses were counted of each animal. Figs. 1 and 2 show the normal diploid chromosomal rate in bovine leucocytes. Accordingly the ox cell has 60 chromosomes, 58 of which are acrocentric and obviously differ only by length of chromomeres, while 2 chromosomes are metacentric. The sex-chromosomes are marked by arrows.

GENETICS

Genetic Basis of Stem Rust Resistance in Wheat

Present-day theory postulates a gene-for-gene basis for the host–parasite relationship between *Triticum aestivum* and *Puccinia graminis tritici* Eriks. and Henn. This emanates from the work of Flor[1] on flax rust as corroborated by Person[2] for stem rust in wheat.

In its ultimate extension this theory demands as many genes for rust resistance in the wheat plant as there are genes for pathogenicity in the rust fungus. However, some genes in wheat mediate resistance to a spectrum of

stem rust races[3]. Nevertheless, the number of identified genes for stem rust resistance in wheat is so small[4], in relation to the known number of physiological races of stem rust, as to raise serious doubts on the general validity of Flor's concept when applied to stem rust in wheat. Moreover, the fact that resistant plants can be predisposed to become susceptible in the absence of the pathogen[5,6] undermines the theory's basic tenet of a 'complementarity of fit' as an essential to successful parasitism[7].

If it be assumed that specificity in this form of obligate parasitism is dependent on the host supplying some essential nutrient for which the parasite is heterotrophic[8], a more satisfactory genetic theory for rust resistance can be based on present-day theory of cell metabolism[9,10]. Resistance genes in the wheat host can then be postulated to be regulator genes which repress the biosynthesis of such metabolites specifically essential to particular biotypes of the parasite. Thermolability of resistance or induction of susceptibility by high temperature previous to infection would then depend on inactivation of the repressor protein by inductor metabolites which are formed excessively in the host during high temperatures.

On this view the genetic control of rust resistance depends on a functional system in which all three elements of regulator, operator and inductor are important.

Repressors, Cryptic Enzymes and Structural Genes

The Multiple Alleles at the MZ Locus. The fermentation of melezitose[1] by *Saccharomyces* is controlled by a gene which generates a single enzyme capable of hydrolysing the five α-glucosides, namely, turanose, maltose, sucrose, α-methyl-glucoside and melezitose[2]. The gene exists in a series of multiple alleles which differ from wild-type by the loss of capacity to react adaptively to one or more of the five α-glucosidic inductors[3,4]. Only seven (of 32 theoretically possible) alleles are known: *TMSGZ*, *TMSG-*, *TMS-Z*, *TMS- -*, *TM- - -*, *T- - - -* and *- - - - -*. (Possibly only six real alleles of *MZ* exist; the putative *TMS-Z* allele may be a double mutant—*TMSGZ* together with a gene generating a repressor of *G*.) Each of the capital letters indicates ability to respond adaptively to the inductor indicated. Each of the mutant genotypes is stable on vegetative transfer and retains its characteristics without recombination in hybrids, thus establishing each mutant as a genuine allele[5]. The adaptive enzyme generated by *MZ* by exposure to each of the different substrates is identical irrespective of the allele or the inductor; the negatives fail to respond adaptively to the inductors indicated. Cell-free preparations and whole living cells, in which the enzyme has been induced, split all five substrates at characteristically similar rates[6], indicating that permeability is not a factor in differentiating the different phenotypes; it has been inferred that the enzyme appears quickly after induction in the nucleoprotein layer[7].

The Receptor Hypothesis. The fact that fewer than the expected number of alleles exist suggests a non-random organization of the locus of the gene. for example, six or seven different patterns capable of fitting the various combinations of inductor glucosides. It has been inferred that the site of mutation is a receptor[8,9]—a folded protein capable of accommodating the specified inductors—and that an effective fitting of receptor and inductor leads to the induction of a single adaptive enzyme specified by the structural DNA component of the gene. The sensitivity of the gene to mutation suggested that the different elements forming the patterns are differentially sensitive to injury and that injury to any given element (except *G*) rendered the distal elements incapable of fitting substrate, thus producing the limited series of multiple alleles. These inferences were supported by numerous experiments on the mutagenic effects of ultra-violet radiation and X-rays and the demonstration that defective mutants reacted mutagenetically to substrate to restore the normal wild-type allele[3,5].

Repression of MZ by MG. The discovery of a 'mutant' with the apparent phenotype *T-SGZ*[6] was difficult to reconcile with these concepts. Cell-free preparations of this 'mutant' which had been exposed to sucrose hydrolysed all five substrates at the characteristic rates, indicating that the *MZ* locus was the active agent. Outcrosses to the *- - - - -* allele demonstrated that the culture carried *MG*. When *MG* was separated from *MZ* the genotypes were revealed, and the *MZ* allele was found to be *TMS-Z*; the recombinant lacking the *MG* gene (unlike the parental culture) responded adaptively to maltose. Thus, a mating of two maltose-negative parents produced segregants, one-fourth of which were maltose-positive (Table 1).

Table 1. Parental Combinations

Genotype	Phenotypes
TMS-Z MG	maltose-negative (repressed by *MG*) *amg*-positive; melezitose-positive
- - - - - mg	maltose-negative; *amg*-negative; melezitose-negative
	Recombinants
TMS-Z mg	maltose-positive; *amg*-negative; melezitose-positive
- - - - - MG	maltose-negative; *amg*-positive; melezitose-negative

Table 2. Some Interactions between Different Genes controlling Saccharidase Induction

Inductor	Gene	Gene-product	Biological function	End-product
Maltose	*MA*	Maltase	Hydrolyses maltose	Glucose (inductor of *SU*)
Maltose or α-methyl-glucoside	*MG*	A protein called 'α-methyl-glucosidase'	Represses *SU*	
Glucose	*SU*	β-Fructo-furranosid-ase	Hydrolyses sucrose and raffinose	Fructose, melibiose and glucose (inductor of *SU*)
Maltose	?	A protein called 'gluco-sucrase'	Represses *SU*	

It was inferred that *MG* generated a repressor which prevented this particular *TMS-Z* allele from responding adaptively to maltose, although it responded adaptively to turanose, sucrose and melezitose and, after induction, produced an α-glucosidase which split maltose as well as the other four saccharides. This particular allele of *MZ* was different from the alleles of *MZ* which had previously been studied, for *MG* did not inhibit the inducibility of the other alleles of *MZ* by maltose[6].

Inhibition of Genes by Non-homologous Substrates. When *TM - - -* is exposed to mixtures of maltose and sucrose, the inducibility of *TM - - -* by maltose is inhibited by the presence of sucrose[2]. It is inferred that the receptor of *TM - - -* permitted sucrose to fit its surface, without effecting the release of messenger RNA, but prevented effective contact of maltose with the surface of the receptor. Hence, non-inducing sucrose can block the inducible action of maltose.

Other similar examples[10] of substrate inhibitions of yeast fermentation are: (*a*) glucose inhibits the response of the genes *MA* and *MG* to their respective substrates; (*b*) α-methyl-glucoside inhibits the response of the gene *MA* to maltose.

Biological Function of Repressors. The *MG* gene was recognized (prior to demonstration of its repressor activity) by its capacity to generate the inducible 'enzyme' α-methyl-glucosidase[11,12] which cannot split maltose but

can split α-methyl-glucoside, a substance unknown in Nature. The gene *MA* produces maltase which can split maltose but not α-methyl-glucoside. Exposure of the double dominant *MA MG* to maltose simultaneously elicits both maltase and α-methyl-glucosidase[13]. This phenomenon suggests that 'α-methyl-glucosidase' is not elicited in Nature by α-methyl-glucoside but by maltose, but only when both *MA* and *MG* are jointly present. The simultaneous, adaptive elicitation of both proteins is interpreted to mean: (*a*) that the protein, maltase, acts to hydrolyse maltose; (*b*) that the protein 'α-methyl-glucosidase' represses a competing synthesis, thus preventing nucleotides and amino-acids from being appropriated by the competing gene-system. The hypothesis asserts that repressors[14] are full-fledged proteins controlled by a complete, separate structural gene, although in some instances a single receptor may act for both repressor and enzyme.

The *SU* gene, which produces an enormous excess of sucrase in the yeast cell, responds adaptively to glucose rather than to either sucrose or raffinose with the production of a β-fructofuranosidase. This view has recently been supported by experiments on protoplasts[7,15]. On the receptor hypothesis, all genes are inducible and act only under the influence of an inductor; if the inductor is a large molecule permeating the membrane very slowly, the natural inductor may be a smaller, more readily permeable, molecule. A gene (such as *SU*) which responds to an inductor (glucose) which is nearly always present (and which is an end-product of maltase activity) may appear to produce a constitutive enzyme although the enzyme is actually always induced. *SU* would pre-empt the nucleotides and the amino-acids necessary for maltase synthesis and, hence, a repressor of *SU* would have a real survival value by permitting the inducibility of maltase. It is proposed that *MG* controls the adaptive generation of a protein which can act catalytically *in vitro* to hydrolyse α-methyl-glucoside, but which functions biologically (and adaptively) in Nature to repress the excessive production of sucrase during adaptation to maltose. It is proposed, further, that the 'α-methyl-glucosidase' repressor protein fits the receptor of *SU* to preclude the excitation of the receptor by glucose.

Identity of Repressor Proteins and Cryptic 'Enzymes'. Living maltose- or α-methyl-glucoside-positive yeast cells, which were incapable of fermenting sucrose, were found after exposure to maltose or α-methyl-glucoside, respectively, to contain a 'covert' (cryptic) enzyme identified as a gluco-sucrase, that is, a sucrase which cannot split raffinose[10]. This gluco-sucrase appeared only in frozen cell preparations. Since the living cells, previous to freezing, could not ferment sucrose and since sucrose cannot pass through the plasma membrane, the cryptic enzyme must not have the biological function of catalysing the hydrolysis of sucrose *in vivo*, although it can catalyse the hydrolysis of sucrose *in vitro*. It is inferred, therefore, that this cryptic 'enzyme' and all other cryptic 'enzymes' are induced by repressor genes simultaneously with the enzyme generated by the principal structural gene (and by the same inductor). The function of cryptic repressor-proteins is to inhibit competing syntheses.

Receptor- and the Operon-Hypothesis. On the receptor-hypothesis, *vis a vis* the operon-hypothesis[14], the significance of repressors and repressive genes is quite different. On the receptor-hypothesis, all genes are inducible and generate enzyme only in response to contact of the receptor with the proper inductor. Genes which appear to be constitutive are induced, not by the substrate of the enzyme, but by an inductor different from it, for example, glucose acts as an inductor of β-fructo-furanosidase and galactose acts as inductor of melibiase[16]. In the latter instance, the double dominant, *ME GA*, when exposed to galactose generated both melibiase and galactokinase. If melibiose is also present, both the galactose and the glucose produced by splitting melibiose are consumed. However, an *ME ga* culture, exposed only to galactose, generates melibiase but no galactokinase. Since the only sugar available is galactose, on which melibiase cannot act, the induced enzyme has no value to the organism. This example of induction indicates: (*a*) that there is no necessary relationship between the inducer and the enzyme induced; (*b*) that the 'end-product' of enzyme action (cf., glucose for sucrase) may be an inducer of the enzyme; (*c*) that a repressor may confer a decided biological advantage.

Repressors in the Diplophase. The repressors of β-galactosidase induction are diffusible substances effective in the heterozygote[14]. The repressor generated by *MG*[17] is also effective in the diploid; one *MG* gene in the homozygous diploid, *MZ/MZ*, represses the induction of two repressible mutant *MZ* alleles by maltose.

Significance of Repressors in Ontogeny and Evolution. On the receptor-hypothesis, the original member occurring in the evolution of a gene-system is an inducible gene responsive directly to a specific substrate by the generation of an enzyme, and repressors are evolved subsequently to the original inducible gene. Gene-systems without regulator genes may exist, for regulator genes are secondary rather than primary items in evolution. The example of the repressible *MZ* alleles shows that mutations in the protein receptor may make only a single pattern (for example, the *M*-pattern) of the receptor sensitive to a specific repressor, thus increasing the possible variety of manifestations of a gene without changing the enzyme induced by the gene. Mutations of the receptor (rather than the structural DNA component of a gene) might be very important in ontogeny, and in other adaptations, because changes in the conformation of a receptor may be effected without necessitating changes in the nucleotide sequences which are so much more stable than protein conformations.

It is not possible to conclude this article without a tribute to my dear friend, the late Shlomo Hestrin, whose critical and painstaking work on induced glucosidases in yeast, both 'covert and overt', made data available more than a decade ago which could only be interpreted in the light of more recent knowledge.

VIROLOGY

Antibacterial Activity of Herpes Simplex Virus grown in Tissue Culture

ANTIBACTERIAL substances have been recovered from bacteria, actinomycetes, fungi, lichens and seed plants[1,2] but not from viruses. Gan and Warsa[3] observed that the allantoic fluid of embryonated eggs infected with influenza

virus possessed lytic activity against a variety of micro-organisms, but concluded that this lytic factor was distinct from the virus itself. In the light of the observation that herpes simplex lesions around the nose and mouth rarely, if ever, become infected despite their heavy exposure to pathogenic strains of staphylococci, a study was undertaken to determine whether herpes simplex virus exerts any inhibitory effect on the growth of staphylococci and other bacteria.

Six tissue culture adapted herpes simplex virus strains were used, 1 stock strain isolated from a patient, 4 obtained from Dr. T. F. MacNair Scott of the Children's Hospital in Philadelphia, and 1 from Dr. Stephen Millian of the laboratories of the New York City Department of Health. Bacterial strains tested were those freshly isolated from clinical specimens received at the Diagnostic Bacteriology Laboratory. Petri dishes containing equal parts of melted 1 per cent trypticase in 2 per cent agar and monkey kidney *B* medium 'Melnick' were seeded, after setting, with 0·2 ml. of a standardized inoculum of a 6-h culture of a coagulase positive strain of *Staphylococcus aureus* and spread evenly over the surface. After drying, a piece of sterile thick filter paper, 1 cm square, was dropped on to the plate and impregnated with 0·1 ml. of a tissue culture suspension of the stock herpes simplex virus strain prepared as follows. A rabbit kidney cell tissue culture tube suspended in antibiotic free monkey kidney *B* medium 'Melnick' was inoculated with virus and incubated for 2–3 days at 37° C until distinct cytopathogenicity was evident, after which the tube was frozen at −20° C overnight. The viral suspension was then thawed and dropped on the filter paper with a capillary pipette. A rabbit kidney cell tissue culture tube uninoculated with virus, but treated in a similar manner, was used as a control. Plates were incubated in an inverted position for 24 h at 37° C and observed for zones of bacterial inhibition.

As illustrated in Fig. 1, a distinct zone of inhibition was produced around the filter square impregnated with virus-tissue culture suspension as contrasted to uninoculated control tissue culture suspension where no such zone was evident. Nine other coagulase positive *Staphylococcus aureus* strains as well as a number of strains belonging to other bacterial species were similarly tested with the results noted in Table 1. As may be observed from Table 1, with the exception of nearly all strains of *Streptococcus fecalis*, *Pseudomonas aeruginosa* and *Escherichia coli*, growth of most strains belonging to the other bacterial species tested were inhibited by the herpes simplex virus. Five additional herpes simplex strains tested for antistaphylococcal activity all produced an inhibitory zone. When the 6 herpes simplex strains were grown in serially propagated cell lines such as human embryonic lung (*WI*–26), human amnion (*Wish*) and mouse embryo fibroblasts (MEF) instead of in the primary rabbit kidney cell line, staphylococcal inhibition also ensued.

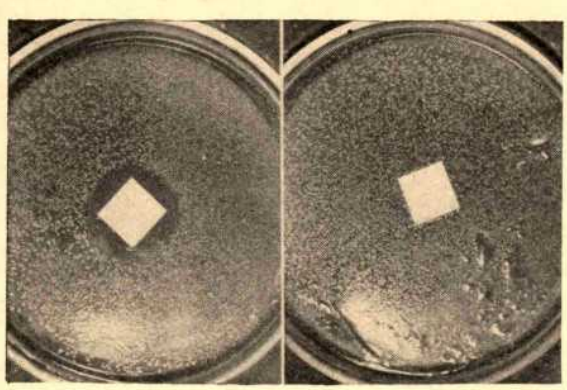

Fig. 1. Left, Inhibition of *Staphylococcus* by herpes simplex virus grown in monkey kidney cell tissue culture; right, absence of *Staphylococcus* inhibition with monkey kidney cell tissue culture, uninoculated with virus

Table 1. Effect of Herpes Simplex Virus on Growth of Different Bacterial Species

Organism	No. of strains inhibited/ No. of strains tested	Inhibitory zone (average diam. (mm))
Staphylococcus aureus	7/10	25
Staphylococcus albus	3/3	32
Diplococcus pneumoniae	5/8	27
Streptococcus pyogenes	5/5	21
Streptococcus viridans	3/4	15
Streptococcus fecalis	0/5	—
Escherichia coli	1/4	23
Aerobacter aerogenes	3/5	22
B. proteus	5/5	20
Pseudomonas aeruginosa	0/5	—

Two of the 6 herpes simplex virus strains were inoculated into the chorioallantoic membrane of 9-day-old chick embryos and intracerebrally into 2-day-old suckling mice. Chorioallantoic membrane and allantoic fluid were collected after 96 h. The mouse brain suspension, obtained at the onset of convulsions, which usually occurred 96–112 h after injection, was frozen, suspended in approximately 2 c.c. antibiotic free culture medium and ground in a mortar and pestle. On impregnation of the filter paper squares with these specimens, no zone of bacterial inhibition resulted although all demonstrated distinct cytopathogenicity when re-inoculated into fresh rabbit kidney cells. Lack of inhibition with virus derived from these sources may, however, be due to insufficient virus production in these sources since previous experiments with tissue culture suspensions revealed that bacterial inhibition occurred only when the virus titre was 10^{-7}, measured by tissue cell cytopathogenicity, whereas a one log decrease failed to elicit the inhibitory effect. Titre of mouse brain suspensions, measured by mouse pathogenicity, proved to be 10^{-3}.

Contamination of various viral strains or tissue culture materials with pleuropneumonia-like organisms or bacteriophage were considered as possible causative factors for the observed zone of bacterial inhibition. Sub-culture of all viruses and tissue culture materials on special PPLO medium resulted in consistently negative isolates. Inoculation of broth seeded with the test staphylococcus strain with the same materials and incubation over a period of a week failed to demonstrate bacterial clearing either visually or photoelectrically or any evidence of lytic plaque formation when they were applied to a surface culture of the test staphylococcus. Furthermore, the diverse spectrum of antibacterial activity observed and the characteristic high degree of specificity possessed by bacteriophages for specific bacterial species would exclude bacteriophage as a possible causative factor. The possibility that intracellular material of the tissue culture cells released as a result of their disruption by virus might have exerted an antibacterial effect was also entertained. A heavy suspension of freshly obtained, trypsinized rabbit kidney cells suspended in the same antibiotic free tissue culture medium as was utilized for the tissue cultures was disrupted by freezing at −20° C and thawing, three times, and then centrifuging at 16,000 r.p.m. for 1 h in a refrigerated centrifuge. Both the supernate and sediment of the destroyed cells material failed to produce a zone of staphylococcal inhibition when applied to filter paper squares.

Whether the observed bacterial inhibition is due to the action of the virus itself or to some product of virus-tissue culture cell interaction remains to be established.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

BIOCHEMIST (preferably with some experience of simple statistics, immunology and work with animals), to assist with routine and research work concerned with gonadotropins and gross hormone in children—The Chemical Pathologist, The Hospital for Sick Children, Great Ormond Street, London, W.C.1 (August 22).

LECTURER (with a thorough knowledge of laboratory organization and techniques, preferably with a science degree, and normally a national of the United Kingdom or the Republic of Ireland) IN PRACTICAL SCIENCE AND LABORATORY TECHNIQUES at the Technical Teacher Training College, Lyallpur, West Pakistan—The Council for Technical Education and Training for Overseas Countries, 12 Lincoln's Inn Fields, London, W.C.2 (August 23).

ASSISTANT LECTURER (preferably with some specialization in metal forming) IN PRODUCTION ENGINEERING—The Staff Officer, College of Advanced Technology, Gosta Green, Birmingham 4, quoting Ref. 7/63/6 (August 24).

ASSISTANT LECTURER (with medical qualifications registrable in the United Kingdom) IN ANATOMY—The Registrar, The University, Manchester 13 (August 24).

GRADUATE (or with equivalent qualifications, and preferably experience in microtomy or instrumentation) IN THE DEPARTMENT OF ZOOLOGY, for a technical post—The Registrar, University College of Swansea, Singleton Park, Swansea, South Wales (August 24).

LECTURER (with a medical or dental qualification, or non-medically qualified) IN THE DEPARTMENT OF ANATOMY—The Registrar, The University, Liverpool, quoting Ref. No. CV/376/N (August 24).

SENIOR RESEARCH ASSISTANT (with a Ph.D. in physics or equivalent research experience) IN THE DEPARTMENT OF PHYSICS, to work on the electrical and optical properties of low mobility solids—The Registrar, The University, Sheffield 10 (August 24).

VETERINARY RESEARCH OFFICER (Bacteriology) (member of the Royal College of Veterinary Surgeons, or equivalent, a diploma in bacteriology and at least six years experience in veterinary research work) IN THE MINISTRY OF ANIMAL RESOURCES, Republic of the Sudan—The Sudan Embassy, Appointments Section, 3 Cleveland Row, London, S.W.1, quoting Ref. 4/2206 (August 25).

RESEARCH SCHOLARS (2) (graduates in either microbiology or biochemistry) IN THE DEPARTMENT OF BOTANY AND MICROBIOLOGY, for research in certain aspects of petroleum microbiology—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (August 26).

SENIOR LECTURER (university graduate, preferably with a higher degree, experience of teaching to final degree level, and some research experience) IN PHYSICS—Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (August 26).

SENIOR LECTURER OR READER IN PHYSICS—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (August 27).

LECTURER (interested in at least one of the following: (*a*) vertebrate zoology; (*b*) ecology; (*c*) genetics; or (*d*) physiology) IN ZOOLOGY at the University College of Cape Coast, Ghana—The Assistant Registrar (Overseas), University College of Cape Coast, 15 Gordon Square, London, W.C.1 (August 28).

LECTURER (with an honours, or higher degree in zoology, evidence of competence and interest in research, and preferably experience in university teaching) IN ZOOLOGY at the University of Queensland, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, August 30).

ORGANIC CHEMIST (recently qualified graduate), for synthetic work on fungicides and systemic fungicides; and a BIOCHEMIST OR PLANT PHYSIOLOGIST (recently qualified graduate), to study the effects of plant hormones on the enzyme activity of plants in the Unit of Plant Growth Substances and Systemic Fungicides—Prof. R. L. Wain, F.R.S., Wye College, near Ashford, Kent (August 30).

PHYSICIST (with a B.Sc. degree, or equivalent, and preferably a higher degree and experience in the application of radioactive isotope techniques to medical practice) IN THE RADIOTHERAPY DEPARTMENT, Auckland Hospital, New Zealand, for radioactive isotope work—The High Commissioner for New Zealand, New Zealand House, The Haymarket, London, S.W.1 (New Zealand, August 30).

PHYSICS TECHNICIAN (experienced in electronic/mechanical workshop practice) IN THE RADIOTHERAPY DEPARTMENT, Auckland Hospital, Auckland, New Zealand, to be mainly concerned with the maintenance of the 4 MeV Linear Accelerator Unit—The High Commissioner for New Zealand, New Zealand House, The Haymarket, London, S.W.1 (New Zealand, August 30).

TECHNICIAN (male or female, F.I.M.L.T. preferably with extensive experience in histological techniques) IN THE DIAGNOSTIC SECTION, Ruakura Animal Research Station, Agriculture Department, New Zealand, to take charge of the Histological Laboratory—The High Commissioner for New Zealand, New Zealand House, Haymarket, London, S.W.1, quoting Ref. B.13/2/20/1960 (August 30).

LECTURER IN REFRACTORIES AND CERAMIC TECHNOLOGY—The Registrar, The University, Sheffield (August 31).

LECTURER OR ASSISTANT (preferably with a special interest in moral philosophy) IN PHILOSOPHY—The Secretary, University of St. Andrews, Queen's College, Dundee, Scotland (August 31).

READER OR SENIOR LECTURER (graduate in physics, chemistry, biochemistry, or engineering, with experience of research in food processing) IN FOOD SCIENCE IN THE DEPARTMENT OF AGRICULTURAL SCIENCES at the School of Agriculture, Sutton Bonington, to be responsible for the organization of the food-processing laboratories and for the co-ordination of the lecture course in food science—The Registrar, The University, Nottingham (August 31).

RESEARCH ASSISTANT (preferably honours graduate in mathematics who wishes to co-operate with engineers in studying the dynamic behaviour of fluid power transmission equipment) IN THE DEPARTMENT OF MECHANICAL ENGINEERING—Mr. J. D. Stringer, Department of Mechanical Engineering, The University, St. George's Square, Sheffield 1 (August 31).

ASSISTANTS OR ASSISTANT LECTURERS (2) (with a first- or second-class honours degree in agricultural science, chemistry, biochemistry or physics, and preferably suitable postgraduate experience) IN SOIL SCIENCE IN THE DEPARTMENT OF AGRICULTURAL CHEMISTRY AND SOIL SCIENCE, to assist in the teaching of undergraduate students and research—The Secretary and Bursar, University College, Dublin, Republic of Ireland (September 1).

LECTURER IN PHYSICS—The Registrar and Secretary, The University of Durham, 38 North Bailey, Durham (September 2).

LECTURER IN ANIMAL PATHOLOGY, for duties which include teaching and research—Dr. T. D. Kellaway, Secretary of the Appointments Committee, Department of Pathology, The University, Tennis Court Road, Cambridge (September 6).

LECTURER IN PHYSICS at Queen's College, Dundee—The Secretary, University of St. Andrews, Queen's College, Dundee (September 7).

LECTURER IN THE DEPARTMENT OF SOCIOLOGY—The Secretary, The University, Edinburgh (September 7).

RESEARCH OFFICER OR SENIOR RESEARCH OFFICER (Pasture Agronomist) (with a Ph.D. in an appropriate field or postgraduate research experience of an equivalent standard and duration, supported by satisfactory evidence of research ability) at the Cunningham Laboratory, Division of Tropical Pastures, C.S.I.R.O., Brisbane, Australia, to join a research team working on both plant and soil aspects of the nitrogen economy of tropical pastures—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 850/194 (September 7).

LECTURER (with a good honours degree in metallurgy or chemistry or equivalent qualifications, and experience or special interests in one of the following fields: extraction metallurgy, alloy thermodynamics, electrochemistry, high temperature chemistry or structural inorganic chemistry) IN CHEMICAL METALLURGY IN THE DEPARTMENT OF METALLURGY of the Faculty of Science—The Registrar, The University, Manchester 13 (September 9).

CHAIR OF CLINICAL MEDICINE IN THE DEPARTMENT OF MEDICINE of the University of Cape Town—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; and The Registrar, University of Cape Town, Private Bag, Rondebosch, Cape Town, South Africa (September 14).

LECTURER IN GEOCHEMISTRY at Victoria University of New Zealand, Wellington—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 15).

SENIOR LECTURER IN SPECTROSCOPY at Victoria University of Wellington, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 15).

LECTURER OR ASSISTANT LECTURER IN MATHEMATICS—The Secretary, The University, Aberdeen (September 16).

DEPUTY LIBRARIAN (chartered librarian, and preferably with a university degree and experience of decimal classification work)—The Vice-Principal, Lanchester College of Technology, Priory Street, Coventry (September 20).

JUNIOR RESEARCH FELLOW (with a good first in zoology) IN LOCUST PHYSIOLOGY at the University College of Rhodesia and Nyasaland, for work on the water relations of locusts—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (September 20).

CHAIR OF THEORETICAL PHYSICS at the University of Cape Town—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; and The Registrar, University of Cape Town, Private Bag, Rondebosch, Cape Town, South Africa (September 25).

ASSISTANT LECTURER (preferably with special training in either mathematics or psychopharmacology) IN EXPERIMENTAL PSYCHOLOGY—The Registrar, The University, Manchester 13 (September 30).

CHAIR OF AGRICULTURAL MARKETING—The Registrar, University of Newcastle upon Tyne, 6 Kensington Terrace, Newcastle upon Tyne, 2 (September 30).

KELVIN CHAIR OF NATURAL PHILOSOPHY—The Secretary of University Court, The University, Glasgow (September 30).

PROFESSOR OF EXPERIMENTAL PHYSICS at the University of Adelaide, Adelaide, South Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, September 30).

PROFESSOR OF INORGANIC CHEMISTRY at the University of Adelaide, Adelaide, South Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, September 30).

PROFESSOR OF PSYCHOLOGY at Victoria University of Wellington, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 30).

CHALLIS CHAIR OF PHILOSOPHY at the University of Sydney, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, November 1).

ASSISTANT EXPERIMENTAL OFFICER (interested in biochemical analysis, with a pass degree or H.N.C. or, if under 22, G.C.E. "A" level, O.N.C., or equivalent) IN THE CHEMISTRY DEPARTMENT, to help with research work on the synthesis of milk constituents and the rate of milk secretion—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, Berks, quoting Ref. 63/12.

ASSISTANT to help a research worker with a project on nucleic acid and protein metabolism supported by the British Empire Cancer Campaign—The Secretary, Department of Radiotherapeutics, University of Cambridge, Hills Road, Cambridge.

ASSISTANT WARDEN (male, single, with a university degree in zoology, an interest in ornithology, and preferably some research and/or teaching experience)—The Warden, Flatford Mill Field Centre, East Bergholt, near Colchester, Essex.

BIOCHEMIST OR BIOLOGIST, to work on problems connected with human gonadotrophins—The Director, Department of Clinical Endocrinology, Women's Hospital, Birmingham 11.

CHEMIST (male, with an honours degree in chemistry or equivalent qualification, and not less than two years postgraduate experience or training) IN THE DEPARTMENT OF AGRICULTURE, Tanganyika, for research work on coffee, including soil and plant analysis connected with nutritional problems and soil survey work—The Director of Recruitment, Department of Technical Co-operation, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting C1/RC213/145/05.

D.S.I.R. RESEARCH STUDENTS (with a first- or upper second-class honours degree in chemistry or an equivalent qualification, for example, G.R.I.C. or Dip.Tech.) IN THE DEPARTMENT OF CHEMISTRY, for work on the chemistry of clay minerals—Dr. A. B. Meggy, Department of Chemistry, Plymouth College of Technology, Tavistock Road, Plymouth.

EXPERIMENTAL OFFICER (with a degree, or equivalent, in physics or electrical engineering), to assist in research in radiation chemistry using a 3 MeV van de Graaff electron accelerator—Prof. F. S. Dainton, F.R.S., School of Chemistry, The University, Leeds 2.

POST-DOCTORAL RE-EARCH FELLOW IN THE CHEMISTRY DEPARTMENT, for work in collaboration with Prof. R. C. Cookson on applications of ultra-violet

spectroscopy and circular dichroism in organic chemistry—The Secretary and Registrar, The University, Southampton.

Research Assistant (chemist, with an interest in protein chemistry or the preparation of organometallic compounds suitable for crystallization with proteins) in the Crystallography Laboratory to work in a section dealing with protein crystallography—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1.

Research Assistant (with either a good degree in chemistry or Grad. R.I.C., and prepared to work for a higher degree) in Organic Chemistry—The Registrar, Administrative Offices, Portsmouth College of Technology, 9 Burnaby Road, Portsmouth, Hampshire.

Research Fellow (with a higher degree in science or engineering, experience in research, and preferably plant experience) in Process Engineering Metallurgy in the Department of Metallurgy, to prosecute research in his own account and join in running a Group concerned with basic research into the transfer of mass, heat and momentum under conditions important in metallurgical processes—Prof. F. D. Richardson, Department of Metallurgy, Imperial College of Science and Technology, London, S.W.7.

Technical Assistant (preferably with experience in steroid and other hormone estimations and/or a knowledge of histochemical techniques), for work related to cancer research—Dr. K. Lederis, Department of Pharmacology, Medical School, University Walk, Bristol.

Technician (Associate of the I.M.L.T. or equivalent, and preferably an interest in tissue culture or related fields, virology, etc.) with a Cytogenetic Group working on human chromosomes—The Secretary, Pediatric Research Unit, Guy's Hospital, London Bridge, London, S.E.1.

Technician (expert in preparing thin and polished sections and competent to take charge of other technical duties) in the Department of Geology—The Chairman, Geology Department, University of Ottawa, Ottawa, Ontario, Canada.

Technician (with technical experience in histology or an interest in helping with general animal experimental work), to assist with research in the Henry Dale Laboratory of Experimental Surgery at the Royal National Orthopædic Hospital, Stanmore—The Secretary, Institute of Orthopædics, 234 Great Portland Street, London, W.1.

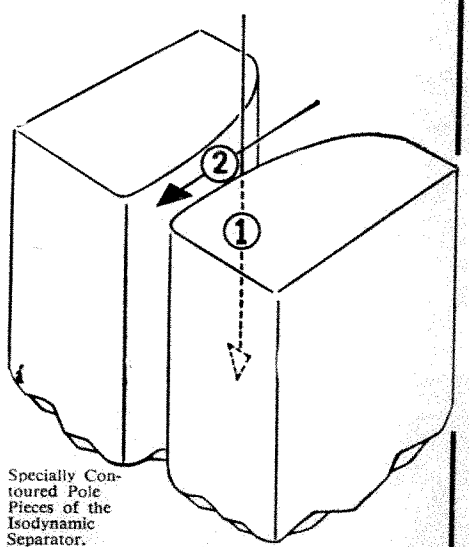
The Reason for the EXTRAORDINARY SELECTIVITY



of the FRANTZ ISODYNAMIC Magnetic SEPARATOR

The selectivity of the ISODYNAMIC Magnetic Separator is due to the special configuration of the pole pieces, which give a constant force on a particle, of given susceptibility, regardless of its position in the operating space.

Model L-1 set for Inclined Feed. Vertical Feed Attachments available.

Materials to be separated are fed into the space (1 at right) between the pole pieces, and travel parallel to their length. The more highly magnetic particles are urged into the narrow portion (2) of the air gap. The grains are then intercepted by a dividing edge which directs the fractions into separate containers.

Specially Contoured Pole Pieces of the Isodynamic Separator.

Imitations have never matched the performance of the ISODYNAMIC Magnetic Separator.

OXLEY DEVELOPMENTS CO. LTD.

OXLEY
SOLDERLESS WRAPPED JOINTS

CHARACTERISTICS

Chassis thickness, 16–18 SWG –048/064"—1.2/1.6 mm.
Capacity, less than 1.5 pF
Operating temperature, —55°C to + 200°C

The Oxley "Barb" solderless wrapped connector is a speedily assembled lead-through of outstanding electrical and mechanical characteristics.

The spill is nickel flashed and solder dipped and spun to British P.O. Specification No. M38. Insert the bush in a .156 dia. plain hole in the chassis, and press the barbed spill firmly but slowly through the bush; the latter expands, particularly on the far side of the chassis, and results in the insulator becoming an integral part of it. In addition to its excellent qualities, a considerable saving of time is effected in assembly. Supplied in sealed packets of 100 and 1000.

ACTUAL SIZE

CLASSIFIED ADVERTISEMENTS

are charged at 12s. for the first line and 6s. per line thereafter. Lines in capitals or containing words in capitals 12s. per line. Semi-displayed £4 16s. per single column inch. Colour (orange) £15 extra. 1s. is charged for the re-direction of replies to advertisements with a box number.

ADVERTISEMENTS SHOULD BE ADDRESSED TO: T. G. Scott and Son, Limited, 1 Clement's Inn, Strand, London, W.C.2. Telephone: HOLborn 4743. Telegrams: Textualist, Estrand, London.

APPOINTMENTS VACANT

ROYAL PERTH HOSPITAL
WESTERN AUSTRALIA
ASSISTANT PATHOLOGIST

Applications are invited for the post of Assistant Pathologist. The Department is under the control of the Professor of Pathology who is the Director of Hospital and University Pathology Services.

The appointee will be required to assist in the routine histopathology, performance of necropsies and to take part in a limited amount of teaching. Research interests are encouraged.

Conditions of Service: Salary within the range of £A2,970 to £A3,515 per annum, commencing rate according to qualifications and experience. Salary commences from the date the appointee takes up duty.

Other conditions of service include four weeks annual leave; long service leave (three months on full pay after each seven years service); sick leave, etc. Study leave may be granted as a privilege for some special purpose approved by the Board of Management. Contribution to the State Superannuation Scheme is required, or alternatively, the Hospital would consider subsidizing the appointed Officer's existing commitments under an approved scheme or endowment policy.

Transport Expenses: A travel grant equivalent to a minimum first-class sea passage will be provided for the successful applicant and family (under 16 years of age), together with an allowance of up to £S200 for the cost of removal of personal effects (excluding furniture or motor vehicle), or £S25 in the case of a single person, subject to a bond to remain in the Hospital's service for a minimum period of three years.

A Memorandum of Information including further details of the Department of Pathology is available upon request.

Further information concerning Royal Perth Hospital and the State of Western Australia may be obtained from the Agent-General for Western Australia, Savoy House, 115 Strand, London, W.C.2.

Applications should include date of birth, qualifications, experience, present and previous appointments, a schedule of publications, a recent photograph and the names and addresses of three referees.

Closing date: October 1, 1963.

JOSEPH GRIFFITH,
Administrator.

UNIVERSITY OF MANCHESTER

Applications are invited for the post of Experimental Officer in the Department of Chemistry in the Faculty of Science, to be concerned with preparative work involving the synthesis of inorganic molecules containing isotopically labelled atoms. Salary range: £880 by £40 to £1,200 per annum. The initial salary will be according to qualifications and experience. Duties to commence October 1, 1963. Contributory superannuation scheme.

Applications should be sent not later than September 7, 1963, to the Registrar, The University, Manchester, 13, from whom further particulars and forms of application may be obtained.

UNIVERSITY COLLEGE OF NORTH WALES
BANGOR

Applications are invited for the post of Temporary Lecturer or Temporary Assistant Lecturer in Marine Biology. Preference will be given to applicants with interests in the biology of fish. The salary scale for an Assistant Lecturer is £1,000 by £50 to £1,150; the salary for a Lecturer would not exceed £1,250. The appointment will date from October 1, 1963 or January 1, 1964.

Two copies of applications should be sent by August 29, to the Registrar, University College of North Wales, Bangor, from whom further particulars may be obtained.

GALLAHER LIMITED

Makers of SENIOR SERVICE cigarettes

will shortly be expanding their Research and Development Department with the occupation of extensive new laboratories in Belfast.

This expansion will require the services of four additional Graduate Scientists with qualifications as follows:

(1) **SENIOR CHEMIST** aged about 26 to 30 years with a good honours degree. A mature outlook is essential, and some research and industrial experience would be an advantage.

After an initial training period, and research of a physico-chemical nature on specific projects, the candidate will ultimately be expected to take charge of a group working on fundamental research of cigarettes and tobacco.

(2) **PHYSICAL CHEMIST** aged about 23 to 26 years with a good honours degree to carry out research on the chemical composition of tobacco smoke under the direction of a Senior Chemist. A practical knowledge of modern physical methods, as applied to Organic Chemistry, would be an advantage.

(3) **ORGANIC CHEMIST** aged about 23 to 26 years with a good honours degree to carry out fundamental research on the chemical composition of tobacco under the direction of a Senior Chemist. A practical knowledge of modern physical methods, as applied to Organic Chemistry, would be an advantage.

(4) **PHYSICIST or PHYSICAL CHEMIST** aged about 23 to 30 years with a pass or honours degree to carry out fundamental studies of the physical properties of tobacco leaf. Experience of the paper-making industry would be useful.

An essential quality for all the above positions is a practical outlook coupled with versatility. Ample scope will be given to use personal initiative.

All the posts carry responsibility with room for further promotion, and the initial salaries paid will be in line with the recent Royal Institute of Chemistry Remuneration Survey.

First-class working conditions will be available, and the Company operates a generous Contributory Pension and Life Assurance Scheme.

Applications, with details of career, should be addressed to:

The Chief Chemist,
Gallaher Limited,
Virginia House,
York Street,
Belfast, 15,
Northern Ireland.

PORTSMOUTH COLLEGE OF TECHNOLOGY

RESEARCH ASSISTANT IN ORGANIC CHEMISTRY

Applicants should possess either a good degree in chemistry or a Grad.R.I.C., and be prepared to work for a higher qualification. Awards of £500 per annum are initially for one year, renewable for a second or third year, subject to satisfactory progress. Research Assistants are required to undertake six hours teaching per week, for which additional annual payment of approximately £250 is made.

Application forms and further particulars may be obtained from the Registrar, Administrative Offices, 9 Burnaby Road, Portsmouth.

UNIVERSITY OF MANCHESTER

Applications are invited for a post-doctoral Research Fellowship in Inorganic Chemistry for the study of magnetic properties of transition metal complexes in association with work carried out by Professor Ballhausen in Copenhagen. It is hoped that the person appointed will spend part of his time in Copenhagen. Appointment for one year in the first instance with the possibility of renewal for two further years. Duties to commence October 1, 1963.

Further particulars and forms of application may be obtained from the Registrar, The University, Manchester, 13, to whom applications should be returned not later than September 7, 1963.

NATIONAL RESEARCH COUNCIL (CANADA)
requires a
MATHEMATICIAN-PROGRAMMER
for
NRC COMPUTATION CENTRE

DUTIES: This position at the NRC Computation Centre involves the analysis and programming of problems originating in the various scientific and engineering divisions of the Council. Duties may include the supervision of junior programmers.

QUALIFICATIONS: Applicants should hold an honours degree in mathematics from a recognized university. Preference will be given to those holding a higher degree and possessing experience in programming and numerical analysis.

SALARY: Initial salary up to $10,000 per annum depending on education and experience.

Applications should be made to the Employment Officer, National Research Council, 100 Sussex Drive, Ottawa, 2, Canada.

In reply, please quote File ER-282.

TRANSLATOR REQUIRED FOR TRANSlating technical data into English from Russian and German. Other languages an advantage, the fields being mainly metallurgy, chemistry, chemical engineering, medicine and physics. Freelance would not be suitable. Five-day week.—Please write to Personnel Officer, The British Oxygen Co. Ltd., Deer Park Road, London, S.W.19, quoting Ref. No. 55.

CAHN

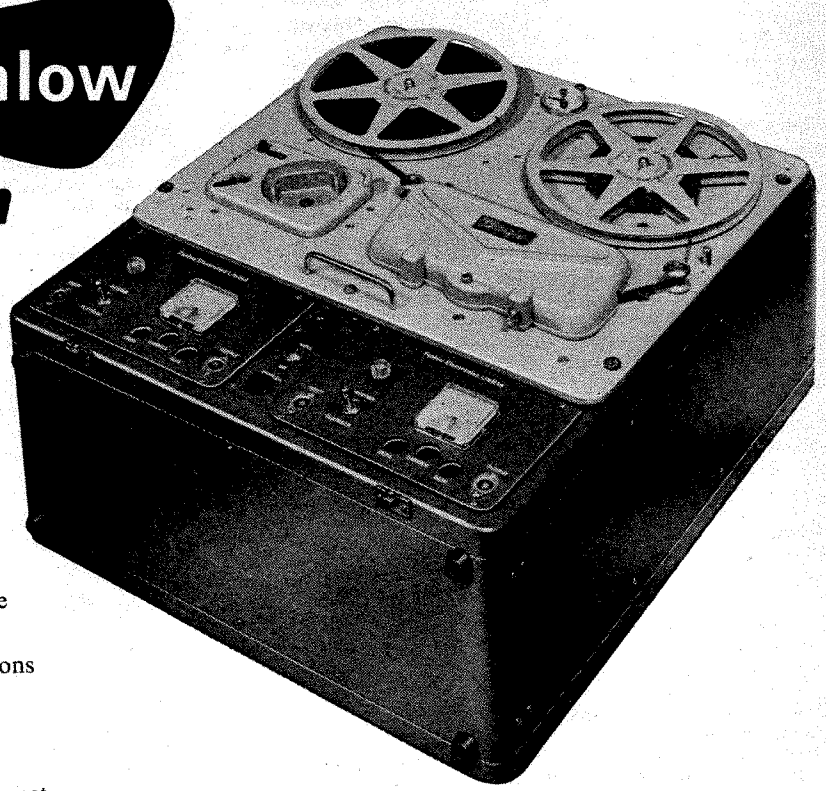
'LITTLE GEM' TGA Kit for the RG ELECTROBALANCE®

gives greater accuracy with smaller samples in THERMOGRAVIMETRIC ANALYSIS up to 650°C.

Small samples give better resolution, since their temperature is uniform, and closer to the measured temperature. They are more uniformly exposed to the atmosphere present.

The 'Little Gem' TGA Kit is **small** and **compact** and can be moved by hand. It is held in position by a laboratory clamp, heats up and cools very rapidly, and is designed for use in air at atmospheric pressure. The extreme sensitivity of the RG Electrobalance (R) made the 'Little Gem' possible. Together, linked to a suitable X–Y recorder and, if required, a temperature programmer, this equipment gives excellent results in investigations involving plastics, pharmaceutical products, biological samples and foodstuffs.

The new system permits simultaneous improvement of resolution, signal-to-noise ratio, and scanning speed, instead of improving one at the expense of the others.



Write today for full details of this remarkably efficient, accurate, but inexpensive analytical equipment to:—

ENCOURAGEMENT OF SCIENTIFIC RESEARCH IN BRITAIN

THE debate in Committee on Supply on the Vote for the Office of the Minister for Science in the House of Commons on July 15 covered a wide range of topics and brought some important statements from the Parliamentary Secretary for Science, Mr. D. Freeth. There were, however, three main subjects: the loss of scientific manpower by emigration; the stimulation of industrial research; and the Government organization for the development and control of research. All three were raised by Mr. R. H. S. Crossman in opening the debate, but neither he nor subsequent speakers, who referred to the recent report on the first subject by the Royal Society, added anything substantial to that report. Mr. Crossman urged that the important thing was to rectify any deficiencies in our universities and system of higher education which encouraged excessive emigration—it was never disputed that some emigration and immigration were desirable, and he claimed that an average increase in net expenditure on research in the universities over the next three years of not more than £30–35 million would suffice to create a completely new climate. Of this amount, £17 million would be for capital and £7 million for current expenditure and £8 million on grants to the research councils.

On this question of research expenditure, after pointing out that expenditure on university building had increased ten-fold in the past six or seven years, Mr. Freeth announced that in the next academic year the Research Councils would add to their postgraduate awards to students undergoing research training an annual sum of £200 per student, payable to the university department concerned, as a contribution to incidental training costs, such as provision of equipment. This annual sum of about £800,000 would, he believed, considerably relieve the shortage of funds for such purposes in the science departments. Mr. Freeth said that the Government was also considering extending the existing arrangements which enable certain scientists to take doctorates and who wish to pursue research abroad for a year or two, to apply first for certain appointments, such as research fellowships in the United Kingdom so that these can be taken up when they return from overseas. He believed that an extension of the present practice might well make scientists less inclined to accept offers of permanent employment when they were overseas. He also pointed out that last year the joint interviewing board of the Atomic Energy Authority and the Scientific Civil Service in North America interviewed nearly 250 people, and 86 appointments were filled compared with 56 in 1961.

That the unsatisfactory conditions available for research in Britain, and the uncertainty of resources or opportunity rather than salaries are the determining factor in the emigration of scientists was fully recognized in the debate, and this is confirmed by a report on chemists' salaries in the United States which Dr. H. Braunsberg has contributed to the July issue of the *Journal of the Royal Institute of Chemistry*. Dr. Braunsberg starts from the Royal Society's report and from a survey made by the National Science Foundation. He points out that while remuneration is an important factor so far as chemists are concerned, a man earning £1,000 or less in the United Kingdom and holding a similar position in the United States would find his increased net income largely absorbed by the higher cost of living and of medical care and insurance. At all levels, however, a man with no dependants is likely to be able to afford a higher standard of living than in Britain. As his income increases, so the potential net income in the United States over and above such expenses increases at a considerable rate. This, of course, applies particularly to the abler men whose loss causes the most disquiet, and the improvements in position, status and facilities add further incentive to leave Britain.

Nevertheless, the Government action is on the right lines, though whether it is swift enough or on a sufficient scale may be a matter of opinion. Dr. Braunsberg himself remarks that the cost of narrowing the gap between the standards of living attainable on both sides of the Atlantic sufficiently to make emigration less attractive may not be as large as is often supposed, but with any such action must go improvement in the facilities and opportunities available in Britain. It is at this stage that, as Mr. Crossman recognized, the problem is linked with the scale and organization of Britain's research effort generally, and Mr. Crossman strongly supported the granting of full university status to the colleges of advanced technology, for example. He also wanted more Government stimulus to research in industry.

Mr. Freeth, in this connexion, pointed out that national expenditure on research and development had risen from £300 million in 1955–56 to £634 million in 1961–62, or from 1·7 per cent to 2·7 per cent of the gross national product. Expenditure on research financed by Government civil departments and the Atomic Energy Authority had risen in the past three years from £64 million to just over £110 million; that financed by the research councils from just under £18 million in 1958–59 to just over £29 million in 1961–62, and expenditure on research in the universities and technical colleges from just over £23 million to just over £32 million. He also referred to the opening on July 12 at the Building Research Station of a new physics laboratory, costing more than £400,000, which would permit, *inter alia*, increased research on the problem of noise in buildings, for which purpose it includes a unit of adjoining anechoic and reverberant chambers unique in Western Europe.

Mr. Freeth then mentioned the work of the research associations, but while he agreed with the comment in the report of a Working Party of the Federation of British Industries, *Civil Research Policy**, that some amalgamations of research associations might be desirable, he made no specific reference to the report of the Industrial Grants Committee of the Department of Scientific and Industrial Research included in *Research for Industry 1962*, published in the previous week. He announced the merger of the Whiting Research Association and the Chalk, Lime and Allied Industries Research Association, and suggested that an alternative line of development of the smaller associations could be seen in the efforts of the British Hat and Allied Felt Makers and the Gelatine and Glue Research Associations to develop in international centres of technological research. He also saw a future for research associations of focal points of research in existing fields.

All this indicates a loosening of organization and a flexibility which could facilitate a re-shaping of research

* *Civil Research Policy: a Report of an F.B.I. Working Party.* Pp. iii + 11. (London: Federation of British Industries, 1963.) 2*s.* 6*d.*

associations by technologies rather than by industries, though no speaker in the debate referred to the suggestion which Mr. Holliday made to the British Association in Manchester last September. Nor is the suggestion noted in the report of the Industrial Grants Committee, though that report, and also some of the progress reports from the research associations the terms of grant of which come under review during the year, contains evidence of new thinking and a readiness to consider reorganization. The merging of the British Whiting Federation and the Chalk, Lime and Allied Industries is forecast by the Industrial Grants Committee in a section of the report entitled *Amalgamation of Research Associations*, which also describes the formation of the British Ship Research Association out of the British Shipbuilding Research Association and the Parsons and Marine Engineering Turbine Research and Development Research Association. There is also a reference to a new arrangement designed to ensure closer co-operation among the eight associations concerned with research on textiles.

Nevertheless, there seems to be considerable opportunity in this direction. Of the nine associations the terms of grant of which were renewed during the year, only one, the British Iron and Steel Research Association, has an income exceeding £1 million, and of the others only that of the British Coal Utilization Research Association and the British Ship Research Association exceed £400,000. The British Ceramic Research Association falls just short of £300,000, four are between £100,000 and £200,000, and one less than £20,000. It is scarcely surprising that with efforts on such scale the value of the research associations is questioned and the need for co-operation or for fundamental reshaping of the basis of organization pressed.

To this issue the Industrial Grants Committee in this report gives no further attention, though it remarks of the scheme for special assistance to industry, set up in 1959 for five years to help research associations increase the efficiency with which the results of their research were passed to industry and used, that it seems to have increased awareness in many sections of industry of the value of co-operative research and its application to industrial practice.

If *Research for Industry 1962* was ignored in the debate, the Federation of British Industries report, *Civil Research Policy*, was fully quoted in reference to the research associations. Mr. Freeth said that he agreed with much that appeared in the section of the report dealing with research associations, though he was concerned that the report appeared to overlook the use which was already being made in the civil field of development contracts, three of which the Department of Scientific and Industrial Research had already been authorized to conclude. Addressing industry, the Working Party expressed the view that industry in general and the medium and smaller firms in particular had still much to gain from the proper use and development of research, but while sympathizing with the smaller firm in not being able to afford much, if any, scientific staff of its own, they regret that so many seem to fail to use the help available in the research associations. It stressed the importance of all heads of companies becoming fully research minded and according adequate status to those responsible for research and development in their business.

The greater part of the report, however, is specifically addressed to the Government, and here the report comments on the slender resources of some research associations, suggesting that methods of financing may need recasting. It admits that the opinion in industry is not universally favourable to research associations and suggests that the time may be ripe for a critical reappraisal. Besides possible amalgamations, it suggests, rather on the lines of the Zuckerman report, grouping a number on a campus to facilitate sharing of services and costly equipment. It does not, however, regard the research associations as promising media for a large increase in civil applied research and development.

Apart from recommending the wider use of development contracts, the Working Party also suggests that there are possible advantages in rationalizing the work of Government research establishments so as to concentrate civil work in fewer centres. It commends the relations with industry developed by the Royal Aircraft Establishment as promoting invaluable cross-fertilization of ideas and mutual confidence, and suggests that there are possibilities of developing comparable methods on the part of other research establishments. The fundamental problem is to identify the general areas or industries offering the most promising prospects and then setting teams to work, partly in Government research establishments and partly in private companies. The method of payment it suggests is by the allocation of grants-in-aid towards research and development projects in the selected fields, and while some special methods of monitoring may have to be devised, and the contractors should expect to bear some share of the cost, the Government should be ever sensitive about possible advantages which might accrue to the company.

The Working Party's objective in making these proposals is to encourage the new technologies, and it urges that the Government must face the possibly invidious task of selecting the most suitable firm on the basis of the best chance of success scientifically and commercially. It visualizes in all a contribution of some £50 million from State funds to secure the research and development effort needed, with another £50 million from industry, this representing altogether a 25 per cent increase on industry's current spending over perhaps three or five years. This figure seemed to be accepted as reasonable in the debate, but although, as already noted, the proposals made in this section of the Working Party's report were welcomed by the Minister for Science, there was little detailed consideration of them in the debate.

There were indeed one or two further suggestions. Mr. A. Albu, who, like Mr. Crossman, referred to the importance of making wider use of the defence research establishments as expenditure on defence research fell, thought that some industrial research establishments might be used in this way and that such development contracts might be a better method of supporting such associations, particularly those covering a number of industries. Mr. Albu also suggested some development contracts might go to one or two of the colleges of advanced technology, particularly when they were located on the perimeter of an industrial estate. Mr. Aubrey Jones went even further and suggested that some research contracts might go to the universities. Most university research was already concerned with application and he thought that without disturbing the pattern of university research from outside it should be possible to make the connexion with application a little closer and more direct.

Much of Mr. Aubrey Jones's stimulating speech, however, was concerned with the organization of Britain's research effort and, like Mr. Albu, he made two or three suggestions which should be seriously considered. Mr.

Freeth admitted the importance of this aspect of the subject, which was also discussed by the Working Party of the Federation of British Industries. He pointed out, however, that the Government was still awaiting the report of the Committee sitting under the chairmanship of Sir Burke Trend. When this Committee reported in the autumn, the Government also expected to have before it the report of the Robbins Committee on Higher Education, and with the report of the Fielden Committee on engineering design expected later in July, after the debate, the Government would be better placed to consider the deployment of Britain's scientific effort and the appropriate improvement in its own organization.

Meanwhile, Mr. Freeth expressed concern at the insufficient number of technologists trained in Britain. In spite of an overall shortage of university places, the majority of the vacancies each October were in the engineering departments, and the percentage of failures in engineering was higher than in other subjects. This was a disturbing situation and the Department of Scientific and Industrial Research had this year offered an additional 100 research studentships in technology, while in the academic year beginning in October the number of awards for advanced technological training would be increased by 190, at a cost in a full year of £100,000.

Admittedly, the delay in the appearance of the report of the Trend Committee was a severe handicap to the debate, and neither Mr. Freeth nor Mr. Carr, for the Government, could have been expected to comment in detail either on the proposals advanced by Mr. Albu and Mr. Aubrey Jones, or on the Federation of British Industries report regarding the realignment of the responsibilities of the Ministry for Science, or the general organization of civil research under the Government. Much that was suggested develops ideas foreshadowed in the Zuckerman report, but nevertheless Sir Harry Legge-Bourke was not unreasonable in suggesting some acceleration of the appearance of the Trend Committee's report. Meanwhile, particularly in respect of the research associations, there seem to be specific opportunities which should be explored and suggestions which could usefully be examined in advance of that report. No excuse should be afforded for further delay in action once that report appears; and the debate on July 15 did not establish confidence that the Government is sufficiently awake to the seriousness of the whole situation and its urgency and prepared for early action once the full information it is seeking is laid before it.

CATALYSIS QUANTIFIED

Advances in Catalysis and Related Subjects
Vol. 13. Edited by D. D. Eley, P. W. Selwood and Paul B. Weisz. Pp. xiv+458. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1962.) 107*s*. 6*d*.

THE first volume of this series appeared soon after the close of the Second World War by which time it was apparent that a world-wide sprinkling of frustrated physical chemists had not only read the signs in the physics of the 'thirties, but also had attacked the central problems of heterogeneous catalysis anew. This very proper exercise directed attention to the properties of the formerly neglected partner in heterogeneous catalysis—the solid—and quickly procured the adoption of the notions of solid-state theory.

In a preface to Volume 13 of *Advances in Catalysis and Related Subjects*, P. B. Weisz remarks that catalysis, dealing with the re-arrangements of many electron atoms, is co-extensive with all chemistry and unlikely to be understood with one-electron theories devised primarily to describe the motion of electrons within solids. It is noticeable that even physicists, to force advances in metal physics with the aid of semi-empirical models, have recently resorted to the chemical ideas originated by Pauling in 1938.

Catalysis, including chemisorption, remains obstinately within the domain of chemistry and no one, outside of industrial chemistry, was more aware of this than the late Prof. W. E. Garner, to whom D. D. Eley here pays a short tribute. Garner, in all his widespread interests, remained uncommitted to schools; in time he overlapped pre- and post-quantum chemistry; in disposition and training he stood between empiricism and rationalism, while at Bristol his colleagues included on one hand Travers and Maxted, and on the other Mott and the physicists of the famous solid-state group.

F. S. Stone, who was a pupil of Garner's, contributes from Bristol a valuable article (50 p.) on the chemisorbing and catalytic properties of the oxides of the transitional metals of the first long period; acidic oxides such as alumina and the silica-aluminas are not included. He directs special attention to the thermochemistry of chemisorption, an important, experimentally difficult but recently much neglected topic, and provides a timely introduction to the more important work on photosorptive effects. The subject is developed, practice and theory, from the chemical attitudes of the 'thirties through the more physical approaches ('the electronic factor') of the forties and fifties and concludes with a section, again in more chemical vein, linking photosorption with crystal-field theory. It is to be hoped that this cycle generates an ascending helix rather than a vicious circle. Certainly the post-war period effected the belated juxtaposition with solid-state physics and an associated extension of technique and concept, but the boundary-layer theory, with its consequent subdivision of adsorbates and reactions into 'donors' and 'acceptors' of electrons, and other formalized theories are seriously lacking in chemical content. Stone brings out their value in the systematization of the surface chemistry of simple reactions involving strongly electronegative species such as oxygen but, as he implies, much more is needed to provide an understanding of processes as complex as, say, the ammoxidation of olefines. Whether ligand-field theories, the theoretical bases of which are at present undergoing a careful re-examination, will assist remains to be seen.

The effects of radiation on the catalytic activity of solids are not only of great technological importance, their study may also illuminate the crux of catalysis by solids—the nature of the interplay between valencies and defects in surfaces. R. Coekelbergs, A. Crucq and A. Frennet provide a painstaking account (79 pp.), based largely on their own work, of systems in which both the microporous solid and the gaseous reactants are simultaneously irradiated with either uranium fission fragments, gamma rays or beta rays. It is difficult to present a coherent report of this piecemeal and still infant subject, but the authors have knitted the fragments together with a short review of results by other workers and a longer survey of the generation and the characteristics of the changes produced in solids by various radiations.

"Radiation catalysis" has been demonstrated but, as the authors are aware, the uncertainty in the G values make further substantiation desirable, for example, by a detailed study of the effect of variation of surface area for one reaction. The high efficiency with which secondary electrons are formed by absorbed γ-radiation suggests that these electrons might also be included as a means of transfer of energy from solid to gas.

Random distributions of surface defects are undoubtedly important in surface chemistry, but L. H. Germer reminds us ("A New Electron Diffraction Technique, Potentially Applicable to Research in Catalysis", 9 pp.) of the power of an old technique in new guise—the diffraction of slow (0–500) electrons—to detect the presence of regular arrays of surface atoms and adatoms. Germer provides examples which should stimulate a wider interest in this erstwhile difficult technique, recently used so successfully by Farnsworth at Brown University.

"Radiation catalysis" tackles the complexity of the solid catalyst, "Polyfunctional Heterogeneous Catalysis", by P. B. Weisz, attacks the complexity of the reaction catalysed, and in 52 pages contributes a paper which is, to the catalyst designer, the most valuable in the volume; it should be compulsory reading for industrial chemists. The notions of the virtual mechanism and the polyfunctional catalyst are, of course, not new. They presume that (*a*) a complex process can be reduced to a limited set of reactions of known types, taken in appropriate sequence, (*b*) solids exist possessing the capacity to speed each reaction of the set, and (*c*) a mixture of these solids, properly compounded, will catalyse the overall process. After the mechanism has been chosen (*a*) the secret of success lies in (*c*), and it is here that Weisz and his colleagues, following other American workers concerned with new petroleum-reforming processes, have done much to provide scientific albeit qualitative, rules and practical demonstrations of them. The important advance lies in the realization and rough quantification of the part played by the diffusion of intermediates between the microporous phases of different specificity and the relation of this diffusion rate to overall and partial reaction rates. Together with our knowledge of the variation of catalytic activity in the Periodic Table, this model rationalizes the behaviour of complex catalytic processes and permits a comprehensive description of them which, as Weisz shows, may be extended to include biochemical reactions.

J. Wei and C. D. Prater have pushed the formal study of such complicated processes still further in a lengthy (186 pp.) mathematical contribution on "The Structure and Analysis of Complex Reaction Systems". The subject is introduced with a solution to the difficult practical problem of deriving accurate rate constants from the usual composition-time data for a reaction involving a group of coupled, reversible monomolecular reactions between species A_i. It is shown that the differential equations representing the rate of change of concentrations with time can be transformed into an equivalent set representing a group of uncoupled monomolecular reactions based on a set of hypothetical species B_i. Moreover, the transformation from a composition in the A system to one in the B system can be found from appropriate data so that the rate constants for the B system can be determined and then converted to the rate constants for the A system by the same transforms. These methods are afterwards extended to irreversible monomolecular systems and to certain other types of catalysed reaction; great care is taken to emphasize the practical value of the analysis in the treatment of data, and worked examples are given in detail.

Matrix algebra is used throughout and although this is interpreted, where possible, with geometric constructions and supported by four appendixes, it makes heavy going for the chemist. Yet the principles should be mastered and require only practice to become familiar as a numerical method. The deeper levels, those sections which expose the non-thermodynamic aspects of the equilibrium point and seek links with irreversible thermodynamics through Liapunov functions, require intensive study.

This is a valuable analysis of a subject which is beginning to stimulate interest again and chemists are lucky to have such a full account at their disposal. It is something of a relief to turn to chemistry with A. Farkas and G. A. Mills, who conclude this volume with an able, 50-page review "Catalytic Effects in Isocyanate Reactions". This is homogeneous, solution chemistry and it deals with the polymerization of ioscyanates and with the catalysed and uncatalysed reactions of isocyanates with compounds containing active hydrogen: these reactions are essential to an understanding of the rapidly expanding technology of polyurethane foams. In a period when the similarities between homogeneous and heterogeneous catalysis are becoming clearer, and the essential mechanism of one may ultimately be shown to apply to the other, 'all is grist to the mill' of the catalytic chemist.

This volume retains the original format and is as pleasant to handle and to read as its precursors. The scientific content remains high and will satisfy diverse interests although it presents an increasingly difficult task to the reviewer.

D. A. Dowden

THE UPPER ATMOSPHERE

Physics of the Upper Atmosphere

Edited by J. A. Ratcliffe. Pp. xi+586. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 14.50 dollars.

Proceedings of the International Conference on the Ionosphere 1962

Held at Imperial College. Pp. ix+528. (Published by: The Institute of Physics and the Physical Society; Distributed by: London: Chapman and Hall Ltd., 1963.) £5 5s.

THREE years ago there was published in New York and London (Academic Press Ltd.) a volume entitled *Physics of the Upper Atmosphere*, edited by Mr. J. A. Ratcliffe, who was then at the Cavendish Laboratory, University of Cambridge, where a school of scientific research on the ionosphere was established by Sir Edward Appleton some forty years ago. This book is essentially a collection of eleven monographs written by authors of international repute in the various branches of the subject in which they have worked. As the chapter headings indicate, the subjects dealt with cover the upper and outermost portions of the Earth's atmosphere with particular reference to the ionosphere; the influence of the Sun's ionizing radiations; the investigation of airglow, aurora and meteors; and the relationship between the upper atmosphere and geomagnetism.

As stated in the preface, the physics of the upper atmosphere was being intensively examined during the period (July 1957–December 1958) of the International Geophysical Year, when the book was being written. A twelfth chapter was therefore added to enable individual authors to supplement their accounts by the inclusion of information available up to December 1959, when the book went to press. With the passage of time, the value of the book is in no way diminished, and it forms an authoritative guide for research workers engaged in any field of study related to upper atmospheric physics.

Those who require more advanced and up-to-date knowledge of the ionosphere will find excellent material in the second volume under review. This book comprises some seventy-five individual papers presented and discussed at an International Conference on the Ionosphere held at the Imperial College of Science and Technology, London, during July 2–6, 1962, under the auspices of the Institute of Physics and the Physical Society. The Conference was divided into four sections dealing with the following subjects: "Ionospheric Constitution and Ionizing Radiations"; "Geomagnetism and the Ionosphere"; "Irregularities and Drifts in the Ionosphere"; and "The Mathematics of Wave Propagation through the Ionosphere". The fifth, and concluding, section is entitled: "Preliminary Results from the First Anglo-American Satellite UK1, Ariel". This contains

three papers in which authors working on part of the programme of the British National Committee for Space Research describe some preliminary results obtained from the above satellite, which is variously referred to as *UK1* or *S51* as well as Ariel. The initial orbit parameters of this satellite were perigee 389 km and apogee 1,210 km: and the three short papers outline the preliminary results obtained in X-ray spectrometer measurements, in plasma probe experiments, and some preliminary electron (not election as printed) density measurements above the *F2* region of the ionosphere.

Reverting to the main sections of the volume, each of these opens with a review paper by an invited speaker at the Conference, who at the end of the section also contributes a summary of the papers presented and the resulting discussion thereon. It is clear from the list of authors and the titles of their individual papers that the Conference was successful in bringing together a large number of research scientists from various parts of the world; not only from Europe and North America as might be expected, but also from Africa, Australia, India, Japan and New Zealand, where there is clearly an active interest in the general characteristics of the ionosphere, and their association with radio-wave propagation.

A possible criticism of the publication is that no less than seven of the contributions are merely abstracts. No reference is given as to whether the relevant full papers exist and, if so, where they will be published. With the exception of one which is from the United States, these abstracts are from authors in the United Kingdom and five of them are from a well-known research laboratory. This is perhaps a little unfortunate, as it might give an impression of favoured treatment against overseas authors, all of whom, with the exception mentioned, seem to have produced their full papers in time for the Conference, or at least for the publication of its proceedings.

Apart from this comment, the production of the book and its clear text and diagrams, the arrangement of the contents and the author index are excellent in every way. The organizing committee and in particular the Editor of the Institute of Physics and Physical Society are to be congratulated on the production of this volume and, together with the publishers, for its issue within ten months of the holding of the Conference.

These two volumes taken together comprise an exhaustive and up-to-date work of reference to the physics of the ionosphere, which can now be explored by direct measurements carried out in satellite vehicles.

R. L. Smith-Rose

SPACE AND METEOROLOGY

Proceedings of the First International Symposium on Rocket and Satellite Meteorology

Washington, D.C., April 23–25, 1962. Edited by H. Wexler and J. E. Caskey, Jun. (Sponsored by Committee on Space Research (COSPAR); World Meteorological Organization (WMO); and International Union of Geodesy and Geophysics (IUGG). Pp. ix + 440. (Amsterdam: North-Holland Publishing Company, 1963.) 100*s*.

RESEARCH of any kind in which rockets or satellites are used is now referred to by almost everybody as 'space research'; yet in fact much of this work is concerned not with 'space' as ordinarily understood but with the Earth's atmosphere. At the 1961 Symposium on Space Research organized by the Committee on Space Research (COSPAR), thirty-five per cent of the papers presented were directly concerned with some aspect or other of the atmosphere. Not all these papers were 'meteorological' in the now accepted and restricted meaning of this term. Many were concerned with studies of the electrical properties of the atmosphere (the ionosphere) and others were concerned with the chemical and photochemical processes which occur in the rarified air at very high levels (aeronomy); but a substantial number were concerned with atmospheric densities, temperatures, winds, turbulence and cloud systems and with the radiative processes ultimately responsible for all these things. So when, in the following year, the COSPAR Symposium on Space Research was held in Washington, the late Dr. Harry Wexler proposed that a separate symposium on rocket and satellite meteorology be held immediately before the COSPAR meetings. This volume, now dedicated to Dr. Wexler, is a report of that symposium.

The book has four sections: meteorological rockets; radiation measurements from satellites; cloud photography from satellites; other geophysical observations from satellites. Rocket soundings using grenades and vapour releases are reported on by five countries: the United States (who reports on ten grenade soundings in 1961); Great Britain (with ten grenade soundings over the period 1957–61); and smaller numbers by Japan, Italy and France. The grenade technique gives temperature and winds up to a height of about 85 km. Most of the vapour release techniques are designed to give winds from this level up to heights of 180 km or so, but Prof. Blamont describes an experiment in which temperatures at very high levels are determined from precise spectroscopic measurements on the glow from a sodium release and he concludes that the temperature at 370 km rose by 500 ± 150° K between December 1960 and September 1961. Soundings using rocket-sondes carried by 'small meteorological rockets' are reported by the United States and by the U.S.S.R. The U.S.S.R. measurements were all made during the International Geophysical Year. They extend only to a little beyond 40 km and there is no discussion, or even statement, about the accuracy of the measurements. Two 'cross-sections' are presented, but since these are based on observations from a single ship spread over a period of several weeks, in a region where day-to-day variations are considerable, these cross-sections carry no great conviction. The reports of the American studies do contain a statement (perhaps an optimistic estimate) about the accuracy of the measurements; and charts are presented of results from synoptic soundings from about ten stations over the North American Continent, at levels up to 55 km.

The second section contains three papers on the evaluation of the *Tiros* infra-red radiation data. Two of these are preliminary studies concerned with the interpretation of the data; the third is presentation and discussion of radiation measurements made during a pass over a hurricane. This section also contains one paper on the measurement of solar ultra-violet radiation and some theoretical papers, following familiar lines, on radiation balance problems. The three papers on the *Tiros* radiation data all originate from within the United States; indeed, although the data are readily available to meteorologists of all countries, no studies of these measurements have yet been published anywhere by meteorologists outside the United States. This is almost certainly because instrumental and other difficulties are so great that the present experiments can scarcely do more than indicate the possibilities and emphasize the difficulties. The *Tiros* cloud photographs, on the other hand, being of excellent quality, can be studied by anyone, without resource to an electronic computer, and there are, in Section 3, papers on this topic written by meteorologists of five countries. The novelty of clouds photographed from satellites has largely worn off and all these papers reflect the hard grind which now faces meteorologists who have to learn how to recognize what is significant and, when recognized, how to interpret and use it.

The short final section contains two factual papers describing the determination of snow and ice cover from *Tiros* photographs; and a paper presenting the results of the determination of atmospheric densities at high levels

from an examination of the changes of satellite orbits (leading to what may turn out to be a rather optimistic claim that "the general features of the air density distribution between about 180 and 700 km have now become well established").

In all, the volume contains a comprehensive account of observations and studies made during 1961 (except that only a little Russian work is included and that refers to the International Geophysical Year). Almost all the papers are in English with a Russian summary. Since practically everything has been published elsewhere it is particularly to be regretted that nothing is reported of the discussion which followed many of the papers.

R. Frith

THE ART OF PAPER ELECTROPHORESIS

Hochspannungselektrophorese ihre Anwendungsmoglichkeiten für Biochemische und Klinisch-chemische Trennprobleme

By Dr. Med. Roman Clotten, Dr. Med. Annemarie Clotten. Pp. xv+556. (Stuttgart: Georg Thieme Verlag, 1962.) DM.98

ELECTROPHORESIS on rigid substrates such as moistened filter paper has become one of the more important methods for the identification and separation of compounds, rivalling chromatographic methods. This is not because the technique in itself is more versatile, there only being a limited number of *p*H values which can be used profitably, even in the presence of complexing agents, such as borate or sulphite, but because it is rapid and because it permits a fairly ready interpretation to be made of the nature of the compounds which are being investigated, or, alternatively, a confident prediction of the possible behaviour of unknown compounds.

Rapidity, of course, means the utilization of high voltages, or more properly high-voltage gradients, and this in turn involves the real danger of electrocution, which is not stressed in this text-book, and also the problems of the dissipation of heat and of the expense of the apparatus, both of which increase out of proportion to the voltage. The dissipation of heat is indeed a major problem, and of the two current solutions the authors prefer contact cooling by solids to cooling by immiscible liquids, a choice which is probably to be commended both because of the danger of fire and of the toxicity of some of the fluids used for cooling, but which has to be weighed against other factors such as compactness and general convenience.

An increase in voltage is not only associated with a speed of separation of small molecules which is actually somewhat greater than the voltage increase, largely because of diffusion effects, but it has also become associated with laboratory prestige, possibly because of the aura of danger accompanying high voltages, and this seems to have become a motivating influence with some workers.

Clotten and Clotten have written their excellent text-book with what is undoubtedly a background of considerable experience, largely of the clinical type, and they have endeavoured to make a comprehensive gift of their technical skill to the reader, together with all the background information which they consider he should need. Indeed, they tabulate buffer mixtures, spray techniques, sizes and properties of filter papers, including, incidentally, useful tables of the residual ion-exchange behaviour of commonly used papers and other factors, some relevant, some not. They also describe hydrolysis, concentration and desalting techniques though they omit, when discussing the latter, a particularly important caution to remove those ions common both to the specimen and the buffer because of their relative lack of mobility on subsequent electrophoresis, a phenomenon often puzzling to the inexperienced.

Another strange omission, particularly when one considers the thorough descriptions of eccentric elution techniques and other minutiæ, is the authors' failure to give any attention, apart from one specialized instance, to the problems of the power supplies needed and their construction. These constitute perhaps the most expensive items to purchase but are not at all difficult to build in the laboratory at reasonable prices, particularly now that silicon rectifiers are available.

The greater part of the text is given up to the analytical procedures to be adopted for the investigation of groups of compounds such as sugars, amines, etc., both from a qualitative and from a quantitative point of view, and these are excellently documented, and are illustrated by photographs, both in black-and-white and in colour, most of which are quite excellent, and if one may say so, a welcome change from the dreadful examples which one sees so often in print.

The book is excellently produced on good quality paper with an enormous bibliography and comprehensive index, and can be recommended to anyone interested in these methods who does not mind reading German and has 98 DM. to spend.

Roy Markham

HUMAN GENETICS

Outline of Human Genetics

(Contemporary Science Books). By Prof. L. S. Penrose. Pp. xiv+166. (London: Heinemann Educational Books, Ltd., 1963, second edition). 15*s*.

THIS book is precisely what it purports to be, namely an outline, but it has managed to cover a very wide field because of admirable economy in words. Throughout, Prof. Penrose deals with just those points which are of general interest and particularly topics about which people ignorant of genetics are always asking, for example, Is natural selection still operating in spite of civilization and medical advances?

He starts with a historical survey of the subject—the story of Mr. Scott's colour-blindness in 1777 is most attractive—and then goes on to explain the essential differences between segregating and non-segregating characters. With respect to height (which has undergone such changes) it does, however, seem strange that the inheritors of Galton's laboratory cannot give us any more up-to-date estimate of the correlation coefficient between parent and child than that of 1890.

In "Genes and Populations" good use is made of tables and diagrams, and Penrose clearly realizes the difficulty that a beginner has in understanding the Hardy–Weinberg law—and, arising out of it, such subjects as heterozygous advantage and the results of inbreeding. "Association and Linkage" is for the most part conventional, but the puzzles of the Rh system are interestingly presented and help to introduce readers to the idea of geographical variation in an inherited character.

Not only beginners would benefit from "Environment and Heredity" but also all those (and there are many of them) who accept the magic formula of 'identical twins brought up apart' as the solution to any nature–nurture problem. After reading Penrose's survey they will think again.

Penrose delights in being the bane of the 'planners' in "Eugenics and Dysgenics" and is deliberately provocative with remarks such as the "heterozygous mongrel group can indeed be the genetical backbone in a human population even if the members of this group may theoretically appear to be imperfect specimens".

Practically the only new feature in this second edition is one additional chapter ("Commentary") in which he

discusses some of the advances made since 1959. These could with advantage, though doubtless with a good deal of extra trouble, have been incorporated earlier, where they belong, and what is coming in the final section should surely be referred to in the original chapters. In "Commentary" he explains in more detail how common chromosomal abnormalities, such as those causing mongolism and intersexes, are produced; mentions theories dealing with the possibility of inherited cancer; touches on pharmacogenetics; and outlines the vast amount of genetic variability which is being shown up by the complicated polymorphisms of the blood proteins. Finally, he makes the very good point that while geneticists are continually worrying about the quality of the human race we shall have doubled our numbers in the next 50 years and that birth control is far more important than the fruitless task of planning the superman.

There is no doubt that readers of *Nature* will find the book lucid, wholly understandable and interesting, for it is written (in beautiful English) by one of themselves. The query is whether he will cast a spell on intelligent non-scientists (particularly the young) who have had no previous knowledge of the subject.

C. A. CLARKE

CHANGED APPROACH TO RACE STUDIES

Races of Man

By Sonia Cole. Pp. 131+12 plates. (London: British Museum (Natural History), 1963.) 11*s.* 6*d.*

BY contrast with the transatlantic situation where several race classifications have emerged in the post-war years and where discussion of the number of races to be identified, if any, is as vigorous as ever[1], the present generation of physical anthropologists in Britain has tended to leave severely alone questions of race classification. Taking a more biological view of race than their predecessors, they have thought it less important to spend time and energy over what can only be arbitrary, the number of races and which human groups they include, and more important to enquire more deeply into the characters in which human populations differ, the ways in which they are affected by heredity and influenced by environment during development, the biological significance of race differences[2]. Thus it is that to-day the frontiers of knowledge in race matters are explored, and the most significant advances made, in departments of biology—biochemistry, genetics, serology, physiology, nutrition, growth, etc. Formerly, however, they lay in the museums, to which there was a continual inflow of skulls, photographs, measurements, etc.; material which had to be maintained in some sort of order, so that there was practical reason for concentration on classification.

That the needs of the museums may latterly have been overlooked is suggested by the emergence from the British Museum (Natural History) of this small hand-book *Races of Man*. It was written to complement the exhibit illustrating the races of man, in which the arrangement of the materials was based on Boyd's[3] original six-fold classification by blood group frequencies. The idea—an attempt at classification based on both genetic and morphological criteria—then was good. But its implementation is unfortunate. Lip service is paid to the genetic approach to race, but little besides. Indeed, were it not for the date on the title-page and some half-dozen pages in Chapters 3 and 4, one might think it had been written in the pre-war decades, so discreet is the acknowledgement of post-war thought.

It would be unfair to compare it with the authoritative introductions to physical anthropology that the British Museum has previously published—Oakley's *Man the Toolmaker* and Le Gros Clark's *History of the Primates*. Its treatment and level of presentation are much more elementary, aimed at schoolchildren and the lay public, as indeed they should be in a companion to an exhibit; but that is why especial care should have been taken in order not to give wrong impressions. It is disturbing, for example, to find so little attention to variability, both in the text and in the sketches and diagrams; so much concentration on 'types', with nowhere a discussion of the validity of that concept; so little note of the continuity of the processes of race formation. One can only hope that those who read this book will also read, say, *Human Races* by S. M. Garn, by way of an antidote.

FISH AS FOOD

Fish as Food

Edited by Georg Borgstrom. Vol. 2: Nutrition, Sanitation, and Utilization. Pp. xvii+777. (New York and London: Academic Press, 1962.) 178*s.* 6*d.*

THE effects of food depend on the amount consumed, the concentration of nutrients in meals, and the physical state of the person eating it. Recent developments lay emphasis on the central role of protein in determining the nutritional value of foods and on the importance of the proportion of the total caloric value of a diet accounted for by protein, Making allowance for biological value, protein concentration must reach certain minimal levels for the maintenance of health and even of life. For the young child protein of ideal biological value must provide about 8 per cent of the total calories of the diet. Diets of lesser protein content will lead to protein-calorie deficiency disease.

It is generally acknowledged that this manifestation of ill-health is the most important form of malnutrition throughout the world and accounts for enormous amounts of sickness and mortality, especially among children. Prevention of such malnutrition lies to some extent in making available larger amounts of food, but especially in raising the concentration of protein of satisfactory biological value in the diet. Much work is being done in nutrition research laboratories to discover special preparations which could be used as food to prevent protein-calorie malnutrition. There are many problems involved not the least of which are in connexion with costs and distribution on a national scale, and satisfactory results of laboratory tests cannot readily be assumed to ensure success in the field. There is a danger that occupation with the elaboration and use of special foods of high protein content may detract from interest in natural foods which people have used throughout many generations. One difficulty associated with the use of these products, however, is in preserving them so as to allow their wide distribution; another is the relatively high physical and monetary costs in obtaining them.

In this context fish is of special value—it can be procured without using up limited land resources, it is widely acceptable as a food, means of preserving it have been known for hundreds of years; but, above all, many kinds of fish have a very high concentration of protein. For example, 95 per cent of the caloric value of the edible part of cod comes from protein, and many fish have protein-calorie concentrations higher than pork, beef, chicken, eggs, and other foods of high nutritional value. Not only does fish contain much protein, but fish proteins are of high biological value; mackerel promotes more growth in rats than does casein. It is clear that addition of sufficient fish to even the poorest of diets would prevent protein-calorie deficiency disease.

In addition, some fish, or some parts of fish, can supply substantial amounts of vitamin A, iron, fluorine, and iodine—nutrients important in the prevention of abnormalities which at present affect considerable numbers of people throughout the world.

But, fish must be harvested and suitably preserved so as to ensure its availability to those who need it. It is well to know that while new methods such as radiation-sterilization may become important in the future, at present, there is no need for other than methods which are well established such as freezing and canning. Application of them "could satisfy all reasonable needs for years to come".

There are some potential dangers in eating fish. This food may carry a number of organisms pathogenic to man, including salmonellæ and *Clostridium botulinum;* there is the curious condition known as Haff disease in which there is excruciating pain in the muscles, probably caused by ingesting fish contaminated with algae; some people develop allergic reactions after eating some kinds of fish; some fish naturally contain materials poisonous to man. Also, those engaged in the fish industry are exposed to a number of hazards to their health.

These and other important topics are discussed in detail in the second volume of *Fish as Food*. The sea, from which so much of our fish is obtained, has no physical national barriers, and it is appropriate that those who have contributed to this book belong to half a dozen different countries. Under the sub-title *Nutrition, Sanitation, Utilization*, Georg Borgstrom has assembled impressive reviews from several authorities. The editor himself has written a considerable amount of the volume.

The book is interesting throughout, and many parts are fascinating. It would be inadequate, however, to leave its assessment there, because it is also an important book and should be studied by everyone having anything to do with human nutrition.

G. R. Wadsworth

WOOD EXTRACTIVES

Wood Extractives and Their Significance to the Pulp and Paper Industries

Edited by W. E. Hillis. Pp. xvii + 513. (New York and London: Academic Press Inc., 1962.) 114*s.* 6*d.*

As Prof. Erdtman remarks in his foreword to this book, the days are long past when wood was regarded as merely "cellulose and lignin", and it is now generally recognized, not only that woods contain a very great variety of extraneous components, but also that these components are responsible for many of the characteristic features of different timbers. The study of the extractives of wood has developed into an important branch of wood chemistry, particularly within the past 10–15 years, and the time is ripe for a survey of the present state of knowledge. This has now been undertaken by Dr. W. E. Hillis of the Division of Forest Products, Commonwealth Scientific and Industrial Research Organization (Australia), with the aid of a number of collaborators, all of whom are well known for their work in this field.

The book opens with an excellent account of the main structural features of wood and of the processes by which a tree grows. This is essential to an understanding of the part played by the minor components and their location in the tree. Particular attention is directed to the process of heartwood formation which is relevant to the question, discussed in a later chapter, of the origin of heartwood extractives. A short account, which might with advantage have been expanded, is given of the influence of extractives on wood properties and utilization.

After this introduction the remainder of the book is divided into four sections, of which three are concerned with the extractives themselves while in the final section some of the ways in which these components influence the utilization of wood for manufacture of pulp and paper are considered. In the treatment of the extractives the main emphasis is placed on the polyphenolic constituents of wood, which form the subject of seven of the nine chapters in this portion of the book. The polyphenols range in complexity from the simple C_9 and C_{15} compounds (flavonoids and hydroxycinnamic acids) to the highly complex tannins and are of such widespread distribution that it is right that they should occupy a prominent place in any discussion of wood extractives.

Dr. Hillis has performed a valuablo service in bringing together the points of view of the organic chemist, the biochemist and the botanist concerning this group of compounds. In his own contribution on the distribution and formation of polyphenols within the tree he discusses the various theories that have been advanced to account for the origin of heartwood polyphenols, and gives reasons for his own view that they are formed *in situ* from carbohydrates. E. C. Bate-Smith's chapter on the simple polyphenolic constituents of plants includes an account of his very interesting studies of the systematic distribution of these compounds—particularly the leucoanthocyanins and trihydroxyphenolic compounds—in the leaves of plants. The analogous work of Erdtman on the heartwood components of conifers, which is more directly relevant to the present book, receives only very brief mention. Other chapters in this section of the book include well-presented accounts of the chemistry of the lignans and the condensed tannins by D. E. Hathway and of the hydrolysable tannins by L. Jurd. Two chapters are devoted to the biosynthesis of polyphenols and reflect the present-day interest in biosynthetic processes in plants, the study of which has been so greatly assistep by the use of radioisotope tracer techniques.

The succeeding section of the book is entitled "Other Extractives in Wood" and consists of two chapters dealing with tropolones and wood resins respectively. J. A. F. Gardner gives a useful survey of the properties and distribution of the relatively small number of tropolones that have been found in wood, while D. B. Mutton describes the resins occurring in softwoods and hardwoods. The discussion of wood resins is confined mainly to North American timbers and no mention is made of the resinous tropical species, for example, the dipterocarps.

Finally, an account is given of a variety of problems arising in the technical processes of pulp and paper manufacture which are related to the presence of extractives in the wood. These include such diverse phenomena as the inhibition of the pulping reaction by pinosylvins, corrosion of digesters, discoloration of pulp, deposition of scale in digesters and piping, colour changes during storage of newsprint, and pitch problems in pulping. The ways in which these problems are tackled provide a good illustration of the practical value of a knowledge of the chemistry of the extractives concerned.

This book is the first major work on wood extractives that has been compiled and is an important addition to the literature of wood chemistry. Much of its value lies in the varied outlooks of the several authors, who approach their subjects from chemical, botanical, biochemical and industrial angles and yet contrive to blend their contributions into a unified whole. Its greatest weakness lies in its bias in favour of polyphenolic compounds, so that other important classes of extractives, including the terpenes (other than the resin acids) and their glycosides, carbohydrates, and nitrogenous compounds, including alkaloids, are neglected or inadequately dealt with. The production is excellent and the book is particularly well provided with literature references and indexes. It is primarily a book for research workers in this field and will give them much food for thought, but it may also be read with profit by a much wider circle.

R. H. Farmer

Annual Review of Microbiology

Vol. 16. Edited by Charles E. Clifton in association with Sidney Raffel and Mortimer P. Starr. Pp. vii+344. (Palo Alto, Calif.: Annual Reviews, Inc., 1962.) 7 dollars.

IN the introduction to the first volume of *Annual Reviews of Microbiology* the editors expressed the hope that subsequent editions would serve the need of microbiologists of diverse interests by providing summaries of work in many different fields. That the present volume deals only with a limited number of topics is not entirely the fault of the editors, who had planned a more varied list of contents, and it does not necessarily detract from its value to the average microbiologist. The specialization of subject-matter which characterizes this year's *Annual Review* has the advantage that it provides a comprehensive account of the selected topics. Thus four reviews are concerned with aspects of microbial genetics. This very important subject is discussed from various points of view, ranging from descriptions of the sex life of bacteria and *Aspergillus* to an account of the biochemical mechanisms of gene action.

Immunological topics are also given generous treatment in this book. A fascinating contribution on the elaboration of antibodies by single cells gives rise to the hope that those genetical and biochemical methods which have been so successful in studying microbial biosynthesis may eventually be applied to such systems. Such an investigation would require more knowledge than we possess at present of the specialized structure of antibody proteins; much recent progress has been made in this field and this is described in an article on the nature of antibodies and antigens. The effects of specific antibodies on tissue cells are discussed in a review of that title and also in an article on cultural characterization of tissue cells where the use of these specific reactions for the practical purposes of identifying cells is described.

A few reviews on more classical aspects of microbiology help to counterbalance the large number of articles devoted to these two specialized topics. Thus "Endogenous Metabolism of Microorganisms" and "Lipid Requirements of Microorganisms" both provide valuable summaries of information collected from widely distributed sources. A subject of personal importance as well as general interest to microbiologists is described in a survey of the methods for control and purification of water. The difficulties which beset workers with oncogenic viruses are brought out in a very clear account of the complex subject of viral leukæmias of mice.

Although this volume undoubtedly provides reviews of interest to most microbiologists it is to be hoped that next year's edition will show a return to the original editorial policy.

A. NEWTON

Histogenetische Studien an den Blüten Einiger Phanerogamen

Von Dr. Helmut Pankow. (Botanische Studien, Heft 13.) Pp. v+106. (Jena: Veb Gustav Fischer Verlag, 1962.) 14.30 DM.

THIS volume is one of a series, edited by Profs. W. Troll and H. von Guttenberg, which is intended for the publication of investigations requiring more extensive treatment than is usually possible in most botanical periodicals. The present contribution is concerned almost exclusively with histogenetic investigations on the ovary, and in particular on the ovules, in a considerable range of angiosperm species. A few gymnosperms were also examined.

In his introduction to this investigation the author rightly stresses that with regard to the morphological interpretation of the angiosperm flower there have been more speculations than serious attempts to ascertain the available facts. It is also pointed out that although in dealing with a structure so complex as the angiosperm flower no line of evidence should be ignored, there have been relatively few investigations of the development of the ovary or ovule. In his own contribution to this field, the author has now provided us with detailed well-illustrated accounts of the development of the ovules and associated structures in a number of representative species from 23 families of angiosperms.

Although the author's personal investigations constitute the greater part of the work, there is also a concise review of other investigations of gynœcium development. From his own investigations the author concludes that in many families the ovules are clearly stachyosporous, that is, originate from cauline tissue, while in other families they are phyllosporous and originate from the carpels. Too much emphasis is not placed on this distinction, and the author draws an analogy with *Selaginella* in which some species have axillary sporangia produced from stem tissue, while other species bear sporangia on leaf tissue at the base of the sporophyll.

The entire work is a valuable factual contribution to our knowledge of gynœcium development and on that basis is a useful addition to any botanical library.

A ALLSOPP

Life of the Wayside and Woodland

A Seasonal Guide to the Natural History of the British Isles. By Dr. T. R. E. Southwood. A new edition based on the work of T. A. Coward. (The Wayside and Woodland Series.) Pp. xii+290+64 plates. (London and New York: Frederick Warne and Co., Ltd., 1963.) 30*s*. net.

THIS is a new edition of *Life of the Wayside and Woodland*, based on the work of T. A. Coward. Although the greater part of the original text has had to be changed, as a result of vast research over the past forty years, this edition should have as wide an appeal as earlier ones. The book is intended to serve as a general introduction to natural history, as well as to act as a reference book for more advanced scholars, or those training to teach. It should also promote interest in, and act as a guide to, practical field study. The text throughout is straightforward. Scientific names are given where appropriate, as they are international: they do not complicate the simplicity, and should serve as a preparatory aid for more advanced study.

The major proportion of the book is made up by dividing the year into six two-monthly sections, and dealing with whatever 'life' is flourishing at that particular time. A very wide range of life is covered.

Following this major section are four appendixes. Appendix 1 gives some common galls, leaf mines and other types of leaf damage: this is most interesting and could in itself stimulate observation. Appendix 2 outlines the Berlese-Tullgren funnel operation for the extraction of animals from soil, plant debris and dung. Appendix 3 gives the names of natural history societies, while Appendix 4 gives classified lists of books for further study. This is followed by an index.

There are 32 plates in colour and 32 in black-and-white. Also there are more than 300 text figures which are very clear and give ample illustration throughout.

B. J. G. MAITLAND

Lasers

Generation of Light by Stimulated Emission. By Bela A. Lengyel. (Wiley Series in Pure and Applied Optics.) Pp. xi+125. (New York and London: John Wiley and Sons, Inc., 1962.) 55*s*.

THIS appears to be the first book specifically devoted to masers working in the optical domain. It was written during a period of great activity in the field and the author realizes that it "will necessarily have a limited useful lifetime". At the time of writing there were very few sources other than the original publications to which

a newcomer to the field might turn, although this is no longer quite the case to-day.

After an elementary introduction to some basic physics, there is a short discussion of the principles governing the operation of a laser. This is followed by separate chapters on solid-state and gas lasers describing most of the pioneering work done in the field.

The book is introductory and evidently addressed to those meeting the subject for the first time. It is unlikely to be of great help to anyone actively engaged on research, who is more likely to turn to some of the recent review articles published in *Applied Optics* and *Proceedings of the Institute of Electrical and Electronics Engineers* for his information. The author has, however, succeeded in producing a readable introduction. The book is clearly written and well produced and as such is a welcome contribution to a field in which clear presentations are not exactly abundant. L. Mandel

Light

By Prof. R. W. Ditchburn. Second edition. (The Student's Physics.) Pp. xxvi+833. (London and Glasgow: Blackie and Son, Ltd., 1963.) 75*s*. net.

Ditchburn's *Light* has established itself as one of the best English physics text-books of the post-war period. The first edition was published in 1952 and it has now been extended by chapters on geometrical optics and the inclusion of such topics as coherence and stimulated emission. The result is a scholarly treatise which will be of great value to both students and teachers at honours-degree level.

The book, containing as it does an immense amount of material, is necessarily rather condensed in spite of its 800 pages, and many students will find it rather formidable; for example, the vector analysis used in the book is outlined in 1½ pages—a useful summary for those already familiar with it, but rather difficult for the new student. Other topics are also introduced as though the reader were familiar with them; for example, St. Venant's principle is not clearly expressed (and is, incidentally, incorrectly indexed).

Many of the additions have been made by adding appendixes in smaller print at the ends of the chapters. Since some of the sections are also in this smaller type, and there are also numerous questions for students to try out, and footnotes and references interspersed through the pages, the book has rather an untidy appearance. It is to be hoped that in any future edition the author will try to cast the book in a more consistent mould.

Mistakes seem to be few. But Fig. 6. 3, as in the first edition, shows fringes only in the central maximum of the diffraction pattern of two slits; the correct pattern is shown in Fig. 9. 11. In Chapter 8, some of the Figures, for example, 8. 7, 8. 9*a* and 8. 9*b*, show rays passing through lenses in impossible paths. Moreover, on Plate 3 Figs. *c*, *d* and *e* are rather deceptive in that they show Fresnel diffraction patterns that must have been taken with different magnifications.

But then no book is perfect and the author and publishers must be congratulated in this very considerable contribution to physics teaching.

Fundamentals of Semiconductor and Tube Electronics

By Prof. H. Alex Romanowitz. Pp. xii+620. (New York and London: John Wiley and Sons, Inc., 1962.) 62*s*.

This book represents an attempt to present to the student the fundamental principles of operation of valves and semiconductor devices in a unified way, and relate these to circuitry problems.

It is doubtful whether this aim is a worthwhile one, since the principles of operation of valves and transistors are fundamentally different.

In addition to this, the relative importance of valves and semiconductors in many applications is, in my own opinion, often misrepresented. For example, in the chapter on rectifiers and power supplies, the silicon rectifier, which is fast becoming the most commonly accepted device for rectification, is not discussed at all. Most of the 36 pages of the chapter are taken up in discussion of valves, selenium and copper oxide rectifiers.

Also much of the information in the book is confusing to the student, and mistakes are far too common. On p. 101, in describing the formation of a point contact rectifier, the author speaks of "atoms of an acceptor impurity, probably phosphorus", diffusing into an *N* type crystal to form a *p–n* junction. In the chapter on "Microelectronics", the author states that the field "has advanced to the point where whole systems such as a multivibrator are grown in the laboratory from a pool of semiconductor material". In my opinion this statement is misleading to the student, leaving him with a false picture of the processes for microcircuit fabrication.

A. A. Shepherd

Progress in Inorganic Chemistry

Vol. 4. Edited by F. Albert Cotton. Pp. 575. (New York and London: Interscience Publishers, a division of John Wiley and Sons, 1962.) 115*s*.

Volume 4 of *Progress in Inorganic Chemistry* appears to be of less general interest than its immediate predecessor. The fact that all the articles are in English will be welcomed by most buyers and it looks as if the article in German in Volume 1 by Becke-Goehring will be the exception of this series. The review by Pearson and Basolo on the *trans* effect will be of wide interest and contains interesting discussions of recent kinetic studies, such as those on isotope exchange in $[Pt(NH_3)Cl_3]^-$. The nephelauxetic series by Jorgensen should again interest a broad spectrum of readers, but is not written in an easy style. Phosphonitrilic polymers have been extensively reviewed and one questions the need for the article by Schmulbach even though it is a good one. More specialized but still interesting reviews are by Vannerberg on peroxides, superoxides and ozonides and on isopolytungstates by Kepert. The last-mentioned review of a difficult subject would have benefited from a more critical approach, but the section on kinetics and the summary are useful. Polymorphic modifications of arsenic trioxide is a very specialized topic. This is reflected in the fact that half the references here are to work by the authors of the review. The general standard of presentation is high and there are few misprints. I. R. Beattie

An Introduction to Genetics

By Prof. A. H. Sturtevant and Prof. G. W. Beadle. (Dover Publication No. S306.) Pp. 391. (New York: Dover Publications Inc.; London: Constable and Company, Ltd., 1962.) 16*s*.; 2.00 dollars.

This issue is a corrected republication. When the book was first published, it was given very good reviews. Using mainly *Drosophila* and maize, with mention of other organisms to illustrate specific points, the authors gave an accurate and comprehensive picture of the behaviour of Mendelian genes and chromosomes. But this was in 1939, nearly twenty-five years ago. Genetics, like time, has not stood still.

In the preface to this inexpensive Dover edition, the authors acknowledge that there have been far-reaching changes in the subject but write: "In spite of these developments, however, we feel that the book gives a fair and balanced account of most of the field covered, i.e., of the chromosome mechanics of higher organisms. And this is an important, basic part of genetics that is often neglected or inadequately covered in recent books"; a statement which does not deny, however, that a few do adequately describe both foundations and later construction.

K. S. Dodds

HISTORY IN THE SCIENTIFIC AGE *

By Sir JOHN NEALE, F.B.A. *

Professor Emeritus in the University of London, and
Honorary Research Associate in University College,
London

AMONG the minor pleasures of growing old is the discovery—which still surprises me—that the familiar setting of one's youth may be news to a younger generation. Consequently, when the Provost of University College, London, asked me to address the Assembly of Faculties, I thought that I might agreeably discharge the obligation by exploring my memory of changes that have occurred in the study of history in the past forty years or so.

When I began my career in 1919, academic history was in what might be described as its scientific phase. The older tradition of Great Britain was in disrepute—a tradition stretching back to Clarendon in the seventeenth century and more recently displayed in Macaulay, Carlyle, Green, Lecky and Froude, which regarded history as a branch of literature. Quite naturally and rightly scholars had succumbed to the professionalizing of their subject by the great nineteenth-century German historians and by the establishment of the École des Chartes in France. In a famous phrase of the German scholar Ranke, they believed that their duty was to reconstruct the past "as it actually was"; and this involved a new critical discrimination in the choice and use of historical sources and the application of severe technical disciplines in evaluating and interpreting them. The supreme virtue of the true historian, they believed, was objectivity; scientific method was the basis of his profession.

In 1903, J. B. Bury, the newly appointed Regius professor of history in the University of Cambridge, who as a student of ancient history was peculiarly sensitive to the achievement of German historians, preached the new gospel in his inaugural lecture, entitled, "The Science of History". "History", he declared in the most frequently quoted sentence of the lecture, "is a science, no less and no more." "It is . . . of supreme moment that the history which is taught should be true; and that can only be attained through the discovery, collection, classification and interpretation of facts—through scientific research." "History is not a branch of literature." "So long as history was regarded as an art, the sanctions of truth and accuracy could not be severe."

Bury's pronouncement was immediately challenged by a young scholar, not as yet an academic historian, though he was later to occupy the famous chair then held by Bury. He was G. M. Trevelyan, a great nephew of Macaulay, whose traditions and own views led him into instant denunciation of Bury. His challenge, entitled *Clio a Muse*, was published in December 1903 and set the issue between history as an art and history as a science—as indeed did the felicitous style in which it was written, contrasted with the humdrum prose of Bury.

When I began my career, these two rival gospels confronted one another; and on the whole academic historians followed Bury and spurned Trevelyan, whom they regarded as an outsider, a graceful amateur who did not make their grade. This is not surprising. Their search for facts and objective truth had led them to work more and more in the Public Record Office and had revealed the utter inadequacy of their literary predecessors, both in critical method and choice of evidence. Basic history was being completely refashioned by professional scholars, and the new discipline was justifying itself.

But that unfortunate assertion of Bury's that "history is a science, no less and no more" encouraged academic historians to concentrate their talents on the process of research and give scant time and care to the literary problem of presenting the results to their public. History, after all, has to be communicated to someone; and if we scrutinize the writings of some of our most respected professors in the Bury epoch, we may think that had they displayed half the ability in prose they revealed in research, their readers would have received much more pleasure and no less enlightenment. Some of the more austere scholars even regarded good writing as the enemy of scholarship and were apt to think that readable history was *ipso facto* bad history. Trevelyan in his *Clio* essay declared that "the public has ceased to watch with any interest the appearance of historical works, good or bad". As late as 1930, when I was writing my biography of Queen Elizabeth, I was conscious that the title of professor was calculated to frighten people off a book; and it was this lack of interest in academic writing that led me to suppress all my footnotes—an act of self-denial which, in the climate of to-day, I would neither need, nor wish, to repeat. An anecdote will give point to my remarks. Shortly after the publication of my *Queen Elizabeth*, Eileen Power—a historian who wrote with style and charm—was dining at one of the women's colleges at Oxford. My book came under discussion, particularly the lack of footnotes, and a history don remarked: "Neale has sold the pass". "I don't know about selling the pass", retorted Eileen Power, "but he has sold twenty thousand copies".

Trevelyan's *Clio* was not a faultless argument. Being a narrative historian of the older school, he believed that "the art of narrative" was "the principal craft of the historian". Few or no academic historians to-day would subscribe to that statement—not even the most widely read among them. With even more certainty we can say that few or none would subscribe to Bury's description of history as a science: they might talk of 'scientific' method, though they would probably agree that 'scholarly' is a less misleading word.

In fact, the old controversy is dead; and if proof were needed of this, it could be found in some of the royalty statements sent by publishers to their academic authors. Professional historians may still write in the *English Historical Review* for a few experts, or in monographs on themes too technical for an extensive audience; they may edit texts published, and only publishable, by university presses; but, generally speaking, they are aware that when their research is finished, there remains the task of communication, that this is a literary problem of supreme difficulty, and that there is a reading public waiting to be wooed, which is commensurate with their skill in writing and the interest of their subject. The academic historian to-day is combining art and scholarship. When successful, he is so vastly superior to the literateur who has art without scholarship that publishers nowadays, instead of regarding professors as a costly and doubtful investment in mere prestige, court them as potential best-sellers, or at worst normal risks: and surely the crowning irony, when compared with the situation forty years ago, is that we now find the literateur adding footnotes to his narrative to create the impression—which, alas, is too often an illusion—of scholarship.

* Substance of an address delivered before the Assembly of Faculties, University College, London, on June 20.

It is worth asking how this change came about. In the nature of things the new 'scientific' gospel was bound to produce a certain asceticism, or lack of humour, in the first generation or so of converts. Equally, we might have expected a younger generation to be less enamoured of ivory towers and come down among ordinary mortals. In fact, this natural process was speeded up by a number of external happenings.

Here, as elsewhere, the First World War was the great divide. Until then—and with a time-lag afterwards—conventional history was mainly concerned with the State and the Church; with kings, statesmen, bishops, domestic and foreign policy, wars. Its hallowed divisions were political, constitutional and ecclesiastical history; and for academic purposes modern history was deemed to end in 1815, 1870 or—where minds were tinged with radicalism—1900. The history of our own times was a subject for the journalist or publicist, since *ex hypothese* the historian could only function where objectivity was attainable.

After all, the historian writes the sort of history prompted by the questions he asks, and his questions are ultimately determined by the spirit and interests of the age in which he lives. In the relatively stable society before 1914 political, constitutional and ecclesiastical history might easily satisfy historical curiosity. Economic history was arriving, and no one, after the appearance in 1919 of Keynes's disturbing best-seller, *The Economic Consequences of the Peace*, could be blind to its importance. But it found its way into the London history curriculum only in the 1920's, and then not without misgivings. The *Times Literary Supplement*'s review in 1924 of Tawney and Power's *Tudor Economic Documents*—a work produced for the London history school—commented: "Theirs is the newer history, the offspring of a democracy growing not merely self-conscious but more curious and intelligent". As for social history, that had to wait a long time to discover itself and become respectable. In 1920 or thereabouts it had no academic standing and was regarded as a subject on which ladies, with a love of the picturesque and the romantic, and no digestion for harder fare, might misguidedly write.

In his *Clio* essay G. M. Trevelyan had declared that the "presentation of ideals and heroes from other ages is perhaps the most important among the educative functions of history". It was a view that Carlyle in the nineteenth century shared with Elizabethans in the sixteenth century—a long stretch of time, indicative of the relative stability of society as well as the conservatism of history. But the years between the two World Wars, when social revolution was at work and communist Russia was influencing thoughtful as well as thoughtless people, could scarcely remain a time for heroes and hero-worship—in any event in Britain. Indeed, in the 1920's Lytton Strachey and his followers were busy debunking all the 'heroes' on whom they could lay their biographical hands.

The age of the common man was arriving; and so was a new academic subject, sociology, which in my early days was struggling to define and establish itself. In depth, sociological studies are historical, needing the historian's sense of time and circumstance for their elucidation; and the questions sociologists ask are often questions the historian can profitably borrow. In this new climate, social history has emerged as an academic study worthy of the finest historical ability, and in so doing has brought local history out of its old, antiquarian limitations and has spread into economic and even constitutional history, humanizing and enlightening these other branches of history to an astonishing degree; and yet I remember clearly how often we bristled at the term 'social history' on our Board of Studies in History, afraid that it might mean the old pretty-pretty, descriptive stuff, void of intellectual guts.

Since Bury and Trevelyan wrote their blast and counter-blast, history has broadened beyond description—certainly beyond description in a half-hour's talk. I have, for example, said nothing of psychology, which, when my career started, was an academic Cinderella in Britain grubbing in the kitchen of philosophy. Lytton Strachey applied psychology to biography and inaugurated what was called "the new biography". It was not an unmixed blessing, as I can testify, who have watched Queen Elizabeth I psycho-analysed by practitioners whose historical competence charity must veil. However, no reputable historian nowadays writes of human beings without being aware that they are creatures of flesh and blood and nerves, and maybe of neuroses: human beings are the stuff of history.

Of late, the world has been too much with us. It has set us asking all manner of questions. Mussolini and Hitler, Stalin and the ideological struggle between East and West have opened the eyes of historians, so that they see the past with a new comprehension. In politics, for example, we have become aware of a historical phenomenon which we now describe as 'ruler-cult'. With other features of our contemporary scene, it has furnished the key with which to open the world of Elizabethan England. In constitutional history, now that democracy and other political terms are used by East and West with utterly different meanings, we can no longer work and write within the framework of Aristotle's *Politics*. Instead, we are probing into the coarser realities of political power, consciously or unconsciously influenced by the Marxist atmosphere in which we live, and borrowing demographic methods from sociology and geography. The results are so striking as to make some of the constitutional and political history of yesterday seem extremely antiquated.

Alongside this broadening of historical studies has come an equally remarkable *rapprochement* with the reading public: and here also a number of casual factors have hastened a natural process. Lytton Strachey and his school of new biography in the 1920's, and the publishers who ran pell-mell after the fashion, were the first mighty influence. Then came broadcasting, with its Third Programme, where—to the great admiration of my American friends—scholars were let loose on those who chose to listen. It had a triple effect. For the more malleable performers—and let it be confessed, some proved unmalleable, and the B.B.C. commendably tolerant—it was excellent training in the art of communication, teaching them the simple but neglected truth that an author must shape his writing for his audience. So far as the audience was concerned, it removed some of the austerity from the title of professor, and wheedled listeners into reading their favourites' books. Finally, scholars were actually paid for their talks. "Bliss was it in that dawn to be alive"; to find one's talks repeated over and over again, with a supplementary fee each time, was very heaven! Scholars made the pleasing discovery that authorship could be remunerative—a wonderful stimulus to the art of writing. The day, alas, came when the number of these heavenly mansions in the Third Programme was drastically reduced; but already television had appeared: and now the public finally lost its fear of professors: indeed, some of them have rivalled film-stars in popularity. As this space-age unfolds and science impinges increasingly on the general interest, we see our science colleagues joining the historians: and the cry is still 'More professors!'.

I must devote a short time to change in the status of historical studies in our universities and our national life. When I began my career, academic historians, in comparison with to-day, were few in number, their students relatively few, and their subject, in scholarly estimation, a very poor cousin to the classics. If my recollection is correct, a majority of the professors had come to history via Greats at Oxford, and none had emerged direct from the 'Redbrick' universities. Moreover, the classics and not history, the old and not the newer universities, formed the main recruiting ground for our rulers in the higher division of the Civil Service.

All this has changed. Numbers, both of staff and students, have increased and are increasing remarkably and history has emancipated itself from subordination to the classics. On the whole, I think it is an advantage that virtually all our professional historians to-day have received their full training in honours schools of history. They think instinctively in historical terms and are more readily inclined to refashion their subject. This refashioning of the subject is a matter of great consequence. I remember being told—sometime in the 1930's—of an experiment at Harvard, intended to demonstrate the broad new sweep of history by assembling a team of scholars, each lecturing on a different aspect of the same subject. When they had assembled their team, they discovered that no one was scheduled to tell the basic narrative story of the period, and they had to conscript someone for what they whimsically called 'straight history'—and spelt, I hope, 'strait'.

'Straight history' and chronology are, of course, fundamental, but where the emphasis in historical teaching is on this sort of history, there is something in the gibe that history is merely a burden to the memory. While the world was stable and the content of history simple, there were some people who thought that laws could be discovered, governing the evolution of human society. I recollect reading a presidential address to the American Historical Association on the laws of history. A beneficent Providence hovered in the background; the idea of progress and Tennyson's endearing picture of freedom broadening down from precedent to precedent were treated as axioms. I read the lecture at the height of Hitler's career, years after it was delivered, and it seemed to me like a liberal manifesto of late Victorian days. Its laws were spurious.

The world is no longer stable and history no longer simple. Far, far more conscious of the infinite variety and detail of the human story, and of the part played by the individual, we have become acutely aware of the casual, the accidental in history. We cannot conceive of laws in any sense that our scientific colleagues would acknowledge. We may hope that good will prevail; but that is a matter of faith or optimism.

On the other hand, to a degree never equalled before, history is a source of wisdom. As one historian has expressed it: "The crowning attainment of historical study is a historical sense—an intuitive understanding of how things do not happen". As the new history probes realistically into more and more of the past, it prepares the mind for coping more successfully with the present. History does not repeat itself; but it does offer parallels with contemporary problems and can warn us of the unexpected. It makes pragmatists of us, and, except when distorted, does not encourage the doctrinaire, whom I regard as the menace of our age. For these reasons I rejoice in the dominant place that it has won for itself in our universities, and in the fact that historically trained men now readily enter the higher flights of the Civil Service. We shall make fewer mistakes as a nation because of the way their minds have been trained: and even in the executive ranks of industry, the instinct to look at questions in their historical setting and "the intuitive understanding of how things do not happen" can be, and are, of immense value.

Moreover, though history is not a science, nor quite what Trevelyan envisaged in his *Clio*, I think that both Bury and Trevelyan could be happy about its state to-day.

LITERACY OF SCIENTISTS AND TEACHERS OF ENGLISH

By A. E. DARBYSHIRE
Derby and District College of Technology

TWO recent articles in *Nature*[1] raise again the problem of standards of the English of sixth-form and undergraduate scientists and technologists and the responsibilities of those who have to teach science and English to these young men and women. In the first article, Mr. A. J. Kirkman asserts "that scientists and technologists themselves must take most of the responsibility for the low standards of self-expression in their professions, and that a major change of outlook on their part is the only thing that can bring a substantial improvement in the situation". I believe this statement shows a failure, typical of many teachers of English, to understand the point of the scientists' and technologists' use of language, and expresses an attitude of mind that teachers of English should long since have abandoned. In the second article, Prof. R. S. Scorer mildly rebukes: "The damage is done in classes called 'English' "; and he gives illustrations from his own experience (all too representative, I suspect) which show how easy it is to do the damage.

As a teacher of English myself in a large technical college, may I say how refreshingly right I think Prof. Scorer is, and how out of touch with what he calls the "situation" Mr. Kirkman seems to be? May I further suggest that if there is to be any "major change of outlook" it should come through the teachers and examiners of English setting their own house in order, and that the scientists and technologists be left alone to get on with the jobs they seem to be doing pretty well?

There is nothing outrageous, I should say, in the contention that responsibility for standards of English should rest squarely on the shoulders of those who teach English and organize examinations in it. There are many, indeed, who are prepared to accept this responsibility, and many more, I think, who would like to know precisely what it is, for there is no real agreement among teachers and examiners of English about what they are actually supposed to be doing, about what the "subject" of English really ought to be, or about the function of the teacher of English in modern industrial society.

The problem is easy to state: it is not to get the scientists and technologists to write good English according to the nowadays old-fashioned standards of most teachers of English, but to re-organize English as a "subject" so as to bring it up to date and adapt it to modern social needs. Four aspects of this problem seem to require discussion. They are: (1) the attitude of teachers of English to science and technology; (2) grammar, rhetoric and democracy; (3) English in English language examinations; (4) the wider dissemination of the results of contemporary linguistic analysis and developments in semantics.

(1) Prof. Scorer takes Mr. Kirkman (and by implication other teachers of English) to task for blaming "the bad grammar rather than his own lack of knowledge of the subject-matter for the failure of communication". This, surely, is the point. For the past four hundred years scientists and technologists have been making the kind of world in which we all now live, and in shaping modern industrial and technological society they have had an enormous effect on the English language and on our methods of communication. But in the twentieth century the teachers of English have remained aloof. The teachers of English—and the examiners who are drawn from their ranks—are normally arts graduates who by predisposition

and training are likely to be unsympathetic to science and technology, and who do not often seem to understand how the minds of scientists work. If the teachers of English have passed through an honours school at a university, they will have developed their ideas of what "good writing" is from literature, and especially from poetic literature. Now English poetry is very good indeed—its reputation abroad is much higher than it is at home—but the language of poetry is not scientific language. Many teachers of English will, consciously or unconsciously, accept the famous dictum of Coleridge that "the proper antithesis of poetry is not prose, but science", and in accepting it will tend to believe that in some mysterious way poetry is "superior" to science. There are, of course, no rational grounds for such a belief, but the intuitive methods of literature in arriving at "truths" about man and Nature are likely to seem to teachers of English to be more reliable (and easier) than scientific method or the rigours of mathematics.

Furthermore, the vast range and variety of the subject-matter of English literature tend to convince teachers of English that literary forms of expression use all the resources of language and that there is nothing that cannot be said in the words found in the *Oxford English Dictionary*. Some teachers of English are apt to be surprised, shocked, and perhaps a little hurt, to find that physicists and engineers, for example, are quite content with a mathematical expression of their concepts and see no necessity for expressing them otherwise, or that for technologists drawings, diagrams, graphs, tables and statistics can communicate just as well as words in sentences. It seems never to occur to some teachers of English that in advancing new knowledge scientists and technologists have also advanced new techniques of expressing it.

Obviously teachers of English cannot turn themselves into scientists; but they certainly can, and should, make an effort to understand what the scientists are doing, how scientists think, and above all how scientists use language and why they want to use it in that way. A student, writing a report of an experiment or, say, of a test of some technological equipment, is not producing a work of literature. He is reporting objectively on a factual state of affairs, and the "objective correlate" (to use T. S. Eliot's expression) of the form of his piece of writing is not emotionally apprehended experience which, in the writing, becomes complicated by overtones of feeling and attitude presented to the reader in verbal subtleties of style, but the facts themselves. Admittedly, the report will be a good one only if the facts are properly understood, and a great deal of bad writing comes, not from ignorance of common usage, but from the writers' inefficient understanding of the subject-matter. The job of the teachers of English is not, of course, to teach the scientific facts, but to increase in his students an awareness of what is happening when language is being used, and he cannot hope to do that very well with students of science and technology unless he knows what such students want to use language for.

(2) The standards of "correct" English, and the modifications of ancient classical notions of rhetoric to accommodate them to ideas of "good literary style" as literacy gradually became more widespread in Britain after the introduction of printing, were developed finally in the eighteenth and nineteenth centuries. They still appear, slightly diluted and vulgarized, in text-books of grammar and composition still used in schools, and, what is worse, they are still demanded in English language examinations. They are the standards of a literary aristocracy inspired by the humanist traditions of the Renaissance; they are as out of date as phlogiston; and the terminology used to talk about them is as antiquated as Julius Caesar.

Up till about the middle of the nineteenth century, large numbers of English-speaking people learnt to write English by translating from and into Latin and Greek: and that is probably the best way of learning to write English that has ever been invented; for Latin and Greek are languages sufficiently different from English to enforce concentration on matters of sentence structure and vocabulary to get the translation right, to give constant practice in adapting content to form, and the texts chosen for study gave plenty of good models of clear thinking and cultivated taste. But as a way of learning to write English nowadays it is obviously impractical, for it was an eclectic method suitable for a leisured class of aristocrats in an agricultural society where universal literacy was not important.

However, nothing of comparable efficiency has been worked out to meet the needs of our own industrial, technological and democratic society. When, in the middle of the nineteenth century, English began to emerge as a "subject" in response to a growing need for more and more literate technicians to help cope with industrial advancement, it took over the formal paraphernalia of the Latin and Greek tradition in matters of "correct" grammar and the rhetoric of "good style" and adapted it to its own uses to fix an arbitrary standard. The result was linguistic disaster, a conflict, on one hand, of the natural and spontaneous development of the language of the people on its own lines and, on the other hand, of the imposition by school-teachers of antiquated "rules", fatuous stylistic nonsense (such as not ending a sentence with a preposition), and ill-understood mimicry by the "lower orders" of the idiom of their "betters".

The point is that English as a "subject" has emphasized the formal aspects of composition and emphasized them, as it were, in a vacuum. Form without content is the great aim of English as a "subject" during the past hundred years. Here, I think, is to be found the crux of the difficulties that young scientists and technologists encounter when they have to write in the course of their work. They have been so indoctrinated with ideas of form that they are constipated with them, and nervous about putting pen to paper when they have to pay so much attention, as they rightly should, to the content of their written work. My own view is that there is too much writing in the world, and that people should write only when they have something worth saying to say. But that, it seems, is not the usual view of teachers or examiners of English, who apparently want young people to write formal, abstract, disembodied, unmotivated pieces of writing, all "correct" grammar and all "good style", but who do not care very much whether what is written has any important content or not. No wonder Prof. Scorer says that the damage is done in classes called "English".

(3) It is clear, however, that the damage is done not entirely with the approval of all teachers of English. Examiners who organize English language examinations must take at least some of the blame. In every English language examination conducted in Great Britain that I know of—and I think I know them all—essay writing has a dominant role; it normally carries more marks than any other part of the examination, and often it is separated from the main body to become a little examination on its own. What can possibly be the purpose of this futile and time-wasting exercise? The other parts of the typical English language examination paper can perhaps be justified: obviously young people can rightly be expected to be able to read with understanding, to show some knowledge of how passages of prose are constructed, to know the elements of grammar, and to be able to understand the normal usages of civilized communication. But in preparing pupils to pass English language examinations teachers have to train them to write essays merely for the sake of writing essays, and to write a stipulated number of words or for a stipulated length of time, regardless of whether what the candidates have to say needs to be said at such a length, and regardless, too, of

whether the candidates have anything worth saying to say on the kinds of topics usually chosen, or whether indeed anything should be said on them at all. The process can only encourage the production of padding and verbal hot air, the "leisurely periphrasis" which Prof. Scorer so rightly objects to.

The assessment of such unmotivated writing as English language examination essays can only be formal, and the artificiality of such a procedure at once condemns it, for the formality derives, as I have said, from an old tradition which is inappropriate to the times in which we live. After all, the number of people who want to write essays must mercifully be very small, and those few who feel that they do really want to write them no doubt will do so; but for the rest of us there could well be the blessings of silence or of other more worth-while activities, and we shall write only when we have something to say which we think (deceiving ourselves, perhaps) is worthy of being said.

The skills, if that is what they are, which such examinations as the General Certificate of Education English Language Ordinary Level are supposed to test are those of writers who are separated from their subject-matter. But if one accepts, as scientists and technologists, I imagine, must accept, that pieces of writing exist to communicate their meaning and not just the author's acquaintance with sentence and paragraph structure, grammar and "style", then one must also accept that subject-matter influences form. The examples of so-called errors which Mr. Kirkman gives exhibit slack thinking about subject-matter more than they exhibit anything else. A statement like "The dimensions and weight of the vibrating part of the rod was measured" shows that the author had no clear idea in his mind of what was measured; and the "English" of "The diagram was set up as shown . . ." is as good as one might find anywhere—it is simply that what it says is presumably not true. These examples and many hundreds of others which I have met in my experience with students in further education indicate that our traditional school methods of teaching English fail to make clear the relationship between words and things or to demonstrate to students the importance of meaning.

The great writers of the past were great writers, whether in "pure" literature or science, whether men like Shakespeare or Dickens, or Bacon or Darwin, because they had something significant to say, and what they had to say decided the form in which they said it. Although the object of teaching English in schools is not to produce great writers but only competent ones, the same principles will apply, for it is only the great writers of English who can tell us what good English is.

(4) It ought to be possible to assimilate into English classes in the upper forms of secondary schools and in further education some of the knowledge that has been acquired in this century of linguistic analysis and semantics. There are three fundamental questions which can be asked about linguistic communication and which in our time have been pretty thoroughly answered at the post-graduate level for most practical purposes of training young people to think clearly about the problems of self-expression in writing. They are: (1) What are the uses of language ? (2) What is the meaning of meaning ? (3) How does, or does not, any particular use of language express the meaning its author intended to express ? If one leaves aside highly technical questions of modern linguistic philosophy, cybernetics, neurology and mathematical logic, there is nowadays a sufficient basis of fact about linguistic communication to form a popular account of how language works that could be taught in the upper forms of schools and in further education. A syllabus could easily be devised, and need be no harder in its content, at Ordinary and Advanced Levels of the General Certificate of Education examination, than the mathematics at present taught in schools.

The language itself of many English classes and English language examinations is full of what telecommunication engineers call "noise". A little less "noise" and a little more "information" would be an advantage to everyone concerned.

RAY PATHS IN A ROTATING SYSTEM

By Dr. R. C. JENNISON

University of Manchester, Nuffield Radio Astronomy Laboratories, Jodrell Bank, Cheshire

THE transverse Doppler effects associated with the rotation of a source and an absorber have been examined using the Mossbauer effect[1] and the principles are well understood[2]. The entire situation may be expressed in terms of an inertial frame where the light paths are straight, and the light paths through the rotating system have received little or no attention. It will be shown that a very beautiful situation is exhibited by the light path within the system and that this leads to some interesting interpretations of the phenomenon of rotation.

There is always difficulty in defining a rotating system or disk, and for this reason I shall use as my context a hypothetical synchrotron machine in which self-luminous particles are orbiting at velocities closely approaching c in an outer ring and at progressively slower speeds in a series of smaller concentric rings. The system may be very large and in the centre we may place a synchronized turn-table equipped with servo controls and sighting tubes through which an observer may confirm that the orbiting particles are maintained in synchronous rotation with a period $1/2\pi\omega$. The observer will have a variety of means for confirming that the instantaneous speed of a particle at distance r is given in his system by the product ωr.

I shall now use this rotating system as a frame of reference and in complex notation may define the position of one of the rotating particles by the elementary transforms:

$$Z = Z'e^{-i\omega t},\ Z' = Ze^{i\omega t}$$

The central observer would then associate the points sighted in synchronous rotation with the condition that Z' for each particle is independent of t.

The history of a light ray through the centre in system Z is simply:

$$Z = cte^{ia}$$

and in system Z':

$$Z' = ct\ e^{i(\omega t+a)}$$

This path is an Archimedean spiral and would have opposite curvature if either the rotation were reversed or the light were propagated in the opposite direction. The result is precisely that which would be obtained in Newtonian kinematics for a projectile moving with

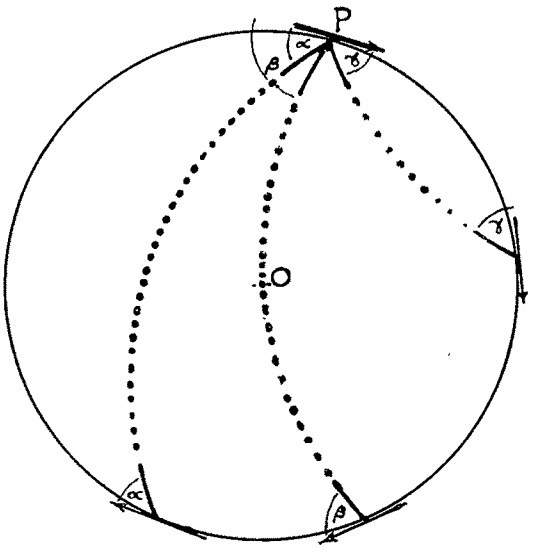

Fig. 1. The symmetry of ray angles for transmission from point P to various receiving points on the same ring. The angles may be obtained by Euclidean projection either directly or through an intermediate inertial frame

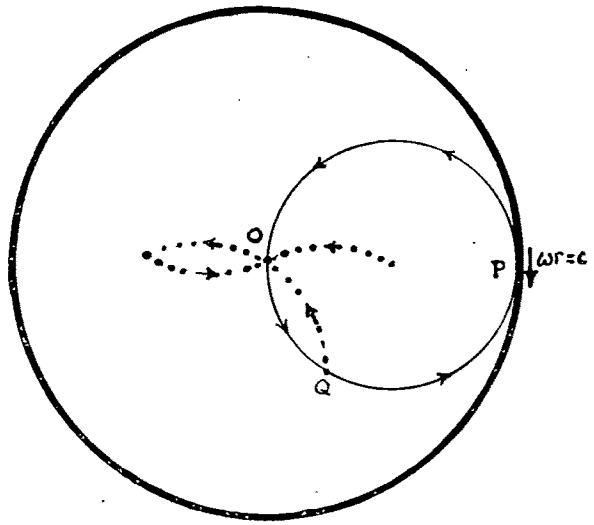

Fig. 2. Light pulse paths to and from the centre for the point P at $r = c/\omega$ and for Q at $r = c/2\omega$. The drawing also shows, dotted, a number of other paths to and from points in the ring at $r = c/2\omega$

velocity c. The Coriolis acceleration gives the Archimedean curve.

One may now query whether or not this really expresses the path within the disk for had I computed the situation in terms of t' where t' is the time applicable to an observer at the source I would have obtained an alternative result in his system. Though the two paths would be simple transformations neither could claim to apply generally and directly within the disk as a whole.

Consider now the more general situation where the path throughout is defined in terms of the various local systems Σ_0, Σ_1, Σ_2 . . . Σ_r through which it passes. In each of the annular systems we have associated local time-scales t_0, t_1, t_2 . . . t_r applicable to all experiences within the regions.

Consider the emission of light from a point in the system Σ_r. Let this light be seen through a sighting tube in the central region Σ_r. The time-scale t_r results in a reddening which one may compute from the Doppler shift:

$$\nu = \nu_r \frac{1 + \frac{\omega r}{c} \cos\theta_r}{\sqrt{1 - \frac{\omega^2 r^2}{c^2}}} \qquad (1)$$

and a corresponding aberration of the ray angles at the source in terms of the systems Σ_0 and Σ_r:

$$\cos\theta = \frac{\cos\theta_r + \frac{\omega r}{c}}{1 + \frac{\omega r}{c}\cos\theta_r} \qquad (2)$$

Neither of these expressions is affected by subsequent change in speed or direction of motion of the source during the transit of the light signal to the observer.

Simple geometrical considerations would suggest that only the transverse Doppler component is applicable and hence equation (1) reduces to:

$$\nu = \nu_r \sqrt{1 - \frac{\omega^2 r^2}{c^2}} \qquad (3)$$

and in particular in equation (2):

$$\theta = \frac{\pi}{2} \text{ and } \cos\theta_r = -\frac{\omega r}{c} \qquad (4)$$

These results are, of course, entirely consistent with the relative dilation in the two systems, and for source and observer in the same ring we find:

$$\nu_{r1} = \nu_{r2} \qquad (5)$$

and:

$$\theta_{r1} = \theta_{r2} \qquad (6)$$

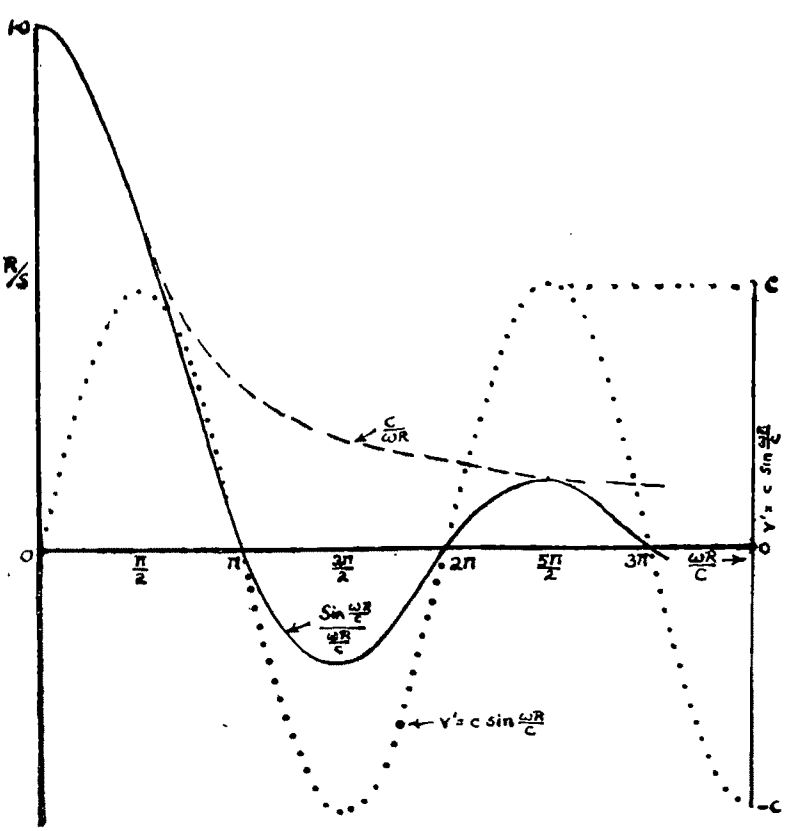

Fig. 3. The distance, relative to the optical path distances, from the centre to the apparent edge of a rotating system ($c/\omega R$), and to a particular ring at radius R, $\left(\frac{\sin \omega R/c}{\omega R/c}\right)$. The function $v' = c \sin \omega R/c$ is also plotted

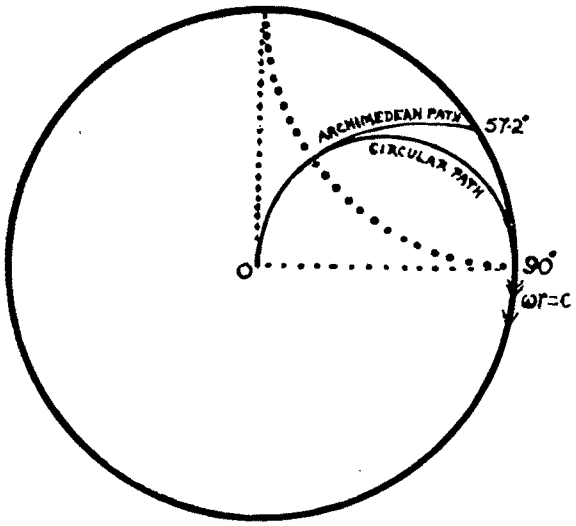

Fig. 4. The light paths to the centre corresponding to a circular arc and an Archimedean spiral; the curves are almost coalescent for $\omega r < 0{\cdot}4c$. The dotted lines are geodesics projected into a system at rest relative to O (after Møller, ref. 3)

The relationship (5) which is commensurate with the equal pseudogravitational potentials is now well known, whereas the associated condition (6), which may be used to fix the ray angles at the two points, has received little, if any, attention. The symmetry is illustrated in Fig. 1.

Equation (4) may be used to determine the complete path of the light ray within the system. It may be used to give precise instructions for the local excavations between the particles for a tunnel to be provided to allow the passage of light through the system. It is assumed for this purpose that the ray path of any given pulse of light is independent of the motion of the source. Equation (4) therefore gives a series of elementary rays which must join together to form a continuous light path, for the light from the outermost point may be seen through a single sighting tube in continuous conjunction with the light from other individual points in the systems Σ_0, Σ_1, Σ_2 . . . Σ_r as applicable. Hence we have for the ray: $\cos\theta_r = \frac{-r\omega}{c}$ which defines a circular arc for Euclidean projection.

The continuous ray constructed in the manner described has a constant curvature within the system and is in this sense a circular arc of radius $\rho = c/2\omega$ (Fig. 2). The curvature is therefore a function only of the angular velocity of the system. The ray path becomes a complete semi-circle for $\omega r = c$.

Some results of the analysis may be summarized as follows:

(1) The curvature of the ray is a function only of the spin or angular velocity ω.

(2) Different paths are taken by the light to and from any pair of points in the rotating system. Holes from a point on the equator to the centre of the Earth would deviate by 30 ft.

(3) It should be possible to determine absolute rotation by measuring the divergence of the paths in opposing directions.

(4) The time-independent or direct radius differs from the action or ray distance. The two are related as the chord is to the arc of a circle:

$$r = S\,\frac{\sin\frac{\omega r}{c}}{\frac{\omega r}{c}} \qquad (7)$$

This function may continue beyond the obviously meaningful region where $\omega r \leqslant c$ and then yields a quantized series of vanishing states (Fig. 3).

(5) The regular anisotropy could be expressed in terms of a spin dependent virtual refractive index within the system. The wave-fronts are not normal to the rays.

(6) Lorentz contraction of the individual segments in Σ_1, Σ_2 . . . Σ_r transforms the circular arc to an Archimedean spiral if expressed in a single frame. Both paths are shown on a hybrid diagram in Fig. 4.

I thank Profs. Bondi, W. H. McCrea, G. C. McVittie and J. L. Synge, and Mr. Howard Smith for criticisms of drafts of this article.

EFFECTS OF RADIATION ON TRANSISTORS IN THE FIRST *TELSTAR* SATELLITE

By D. S. PECK and E. R. SCHMID
Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania

THE *Telstar* communications satellite was planned as an experiment to investigate operating features of communications satellite systems, to obtain results of radiation effects in space and to examine, if necessary, the failure mode of the satellite. During the several months of successful operation it served effectively to carry out the communications experiments for which it had been designed. Following the initial failure of the satellite's command circuitry, it has performed additionally as an orbiting laboratory to supplement ground-based studies on the effects of ionizing radiation on transistors and semiconductor diodes. The response of the *Telstar* satellite to changing radiation conditions in its real orbiting environment and to changing circuit conditions in response to command has suggested further experiments to improve the understanding of the effect of ionizing radiation on transistor junction surfaces. Although these investigations have not fully clarified the details of the mechanism by which ionizing radiation causes degradation, they have at least provided a practical understanding of the effects of various pertinent factors.

Ionizing Radiation Effect

Considerable attention has been directed in the past to the effects of radiation on the bulk properties of semiconductor materials. These effects consist of: (*a*) hole-electron pair formation resulting from the collisions of charged particles with bound electrons in the material, resulting in the excitation of electrons to the conduction band and the production of holes in the valence band; (*b*) the generation of defects in the lattice structure resulting from collisions of energetic particles with nuclei of the lattice. The latter effect is that responsible for the degradation of solar cells.

In addition to investigations of these effects, recent work has been done on the sensitivity of transistor surfaces to ionizing radiation[1]. Degradation of surface-dependent characteristics appears to result from the combination of a fringing field at the semiconductor surface

(such as that provided by a reverse-biased collector unction) and the presence of ions and electrons produced by ionizing radiation in the gas of the encapsulation. Surface charges held by the fringing field tend to produce inversion layers, resulting in degradation of surface-dependent transistor characteristics. Fig. 1 shows the essential ingredients of this model of the mechanism for an *npn* diffused transistor structure. Since many semiconductor devices are encapsulated with a gas filling this phenomenon may affect the operation of some types of semiconductor devices in a radiation environment. Evacuated transistors, or those with oxide-protected surfaces, may also be affected, possibly due to ionization directly at the junction surface, but the effect is generally much reduced.

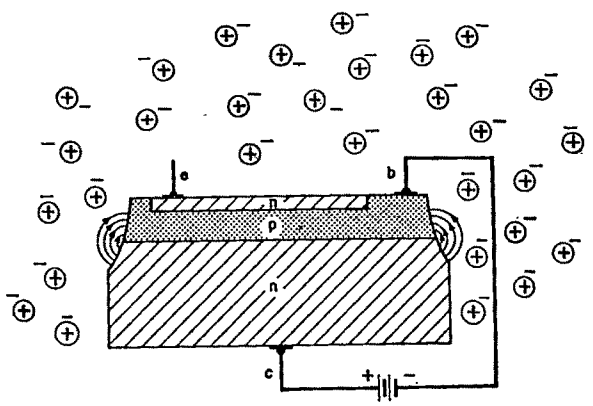

Fig. 1. Model of a reverse-biased transistor in a gas atmosphere ionized by radiation

This surface effect in transistors was recognized as a distinct phenomenon during the period of preparation of semiconductor devices for use in the *Telstar* satellite. The extent of the effect was examined for the various types involved by observing the reverse collector current and current gain characteristics during simultaneous exposure to ionizing radiation and electrical bias. (Depending on the dose rate, an ionization current will flow between leads, and measurement of very low currents may not be possible while in radiation. In this case, the characteristics are measured immediately after removal from radiation.) Some gas-filled silicon mesa transistors were found to have degraded seriously at a total dose of the order of 10^4 rads, corresponding to about 2,000 h in the 5 rads/h dose rate expected in the *Telstar* satellite orbit. Some diffused germanium transistors also showed similar effects but the degradation was less severe and more uniform within each transistor type. Transistors with relatively wide base regions, such as most alloy transistors, are subject to effects of bulk damage at a much lower dose than are diffused transistors and while the surface effect may be present, its seriousness may be masked by that of the bulk damage. Diffused silicon diodes show a reverse-current response similar to that of diffused silicon transistors, although they generally degrade at a higher dose.

Ionization in a transistor in orbit would be caused by high-energy protons and electrons which are not sufficiently shielded by the satellite structure or the transistor encapsulation. For laboratory tests, however, γ-rays may be used to simulate the ionization effect of space radiation. Tests using γ-rays from a cobalt-60 source have disclosed many interesting facets of the radiation effect. Three factors have particular pertinence to the impact of the radiation effect on the *Telstar* satellite circuits.

Effect of Collector Bias

Since the surface effects depend on the presence of both radiation and collector reverse bias we might expect to find that changing the bias will alter the effect. Studies have indeed shown that the degradation of collector reverse current with radiation is strongly dependent on collector bias. Fig. 2 shows the median collector current of a number of transistors, of one sensitive silicon type, exposed at each of several collector voltages.

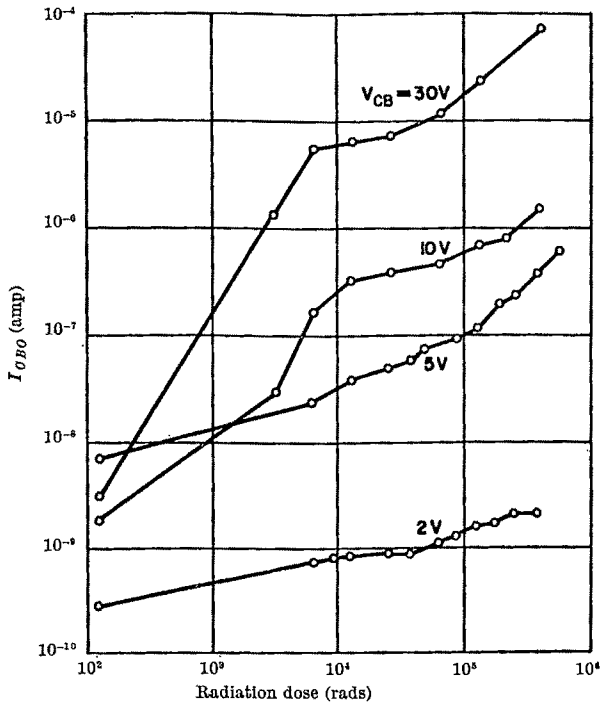

Fig. 2. Dependence of degradation in I_{CBO} on collector bias

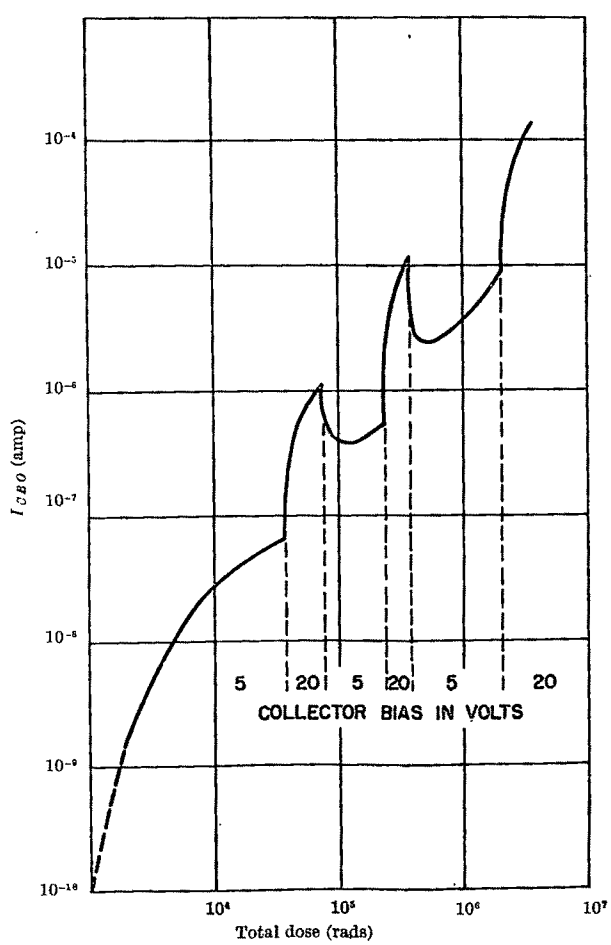

Fig. 3. Influence of collector bias cycling on I_{CBO} degradation

Fig. 3 shows, in addition, the effect on an individual transistor of cycling between two voltage-levels and indicates the manner in which the reverse current degradation is dependent on the bias-level. After cycling from an initial collector voltage to a different voltage and back, the collector current returns quickly to the pattern which might be expected had it remained at the original voltage throughout. This suggests that a surface condition is being developed at a rate relatively unaffected by the voltage value (at least over the range of 5–20 V for this transistor) but that the voltage does affect the resulting surface characteristics.

Effect of Dose and Dose Rate

Investigations of the dependence of collector junction characteristics on dose rate have shown varying results. In general, the degradation appears to be dependent on total dose rather than on dose rate; however, a change of a factor of 10^5 in dose rate can result in an immediate change in collector current by a factor of 10^2–10^3.

The complexity of the phenomenon is demonstrated by the results on devices which were exposed to a 30-sec dose of $8{\cdot}5 \times 10^5$ rads/h as a screening procedure for selecting the most stable devices for use in the *Telstar* satellite. They returned essentially to their initial characteristics when afterwards life-tested in a 5-rad/h dose rate. At a total life dose the same as that of the screening dose, however, approximately the same degradation had developed as in the screening dose. The radiation mechanism apparently allows the ionized surface states to recover to a reduced growth level consistent with the lower dose rate, yet causes eventual degradation corresponding to a specific total dose.

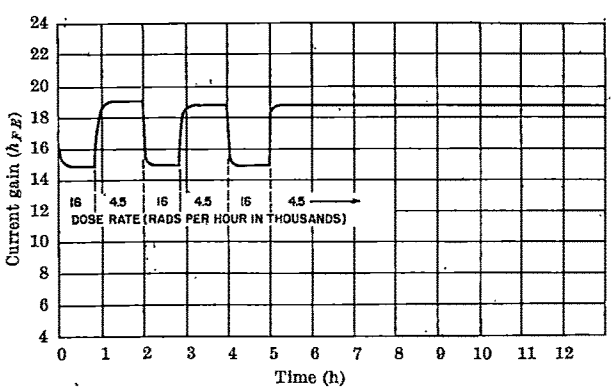

Fig. 4. Influence of radiation dose rate cycling on transistor current gain

More recent experiments by H. K. Gummel at Bell Telephone Laboratories have now shown a repeatable pattern of change in gain resulting from changes in the radiation intensity. Fig. 4 shows typical results of cycling a transistor between two dose rates, indicating a gain level corresponding to each radiation intensity. Over a longer period of time, however, either gain level shows the typical monotonic degradation with total dose.

It would appear that, in addition to the long-term dependence on total dose, a dependence on intensity can be expected in a radiation-sensitive transistor.

Recovery Effects

The surface changes resulting from ionizing radiation are not permanent and the characteristics will essentially recover within a few days at room temperature after removal from the radiation environment. Recovery out of radiation will be somewhat more rapid with the collector voltage removed, since this will allow the surface charges to move more rapidly than if they were held by the reverse-bias field. As might also be expected, recovery will be even more rapid without bias if the devices are left in the radiation environment so that the ionization of the gas can contribute to more rapid movement of the surface-charges. Present results are insufficient to indicate to what extent the recovery rate may be dependent on radiation intensity during recovery, extent of previous degradation or other such factors.

When a recovered transistor is again irradiated it returns to its previous degraded condition during a dose which may be much less than that of the previous exposure. The tests by H. K. Gummel show further that the rate of return to the degraded condition, as well as the degree of degradation, may vary as the cycle is repeated, even for an individual transistor. Predictions of these effects on a degraded transistor are therefore undependable.

Effect of Radiation on *Telstar* Performance

Although an appreciable percentage of the radiations sensitive transistor types in the *Telstar* satellite circuit had been screened by γ-ray exposure in order to select the most stable devices, the malfunctioning (November 19–23, 1962) of the command system showed a pattern of degradation, occasional recovery and recurring degradation which indicated a remaining sensitivity to radiation[2]. The decoders are situated at the outside edge of the electronics canister, receiving the least shielding from other components; they also contain some of the more critical circuitry with respect to allowance for device changes, and many of the decoder transistors are of a type most sensitive to radiation. At about the time of failure it also became clear from other results that the satellite had been exposed to a radiation intensity approximately two hundred times that which had been expected[3]. The total exposure at that time was apparently in the order of 3×10^6 rads, whereas the devices had been screened at about $1{\cdot}4 \times 10^4$ rads; the screening results could not have been extrapolated with any confidence to this unexpected exposure.

The decoder circuits are always under bias from the solar cells and, except for the operation of a specific command, also from the battery. It was recognized that this condition would accelerate degradation of transistor characteristics and that some recovery might be hoped for if voltage could be removed from these circuits for an appreciable length of time. Furthermore, many of the circuits include flip-flops which are left in one state or another depending on the last digit of the latest command signal. The degradation of the transistor left in the 'off' state, with full collector voltage of about 15 V, could be considerably greater than that of the transistor left in the 'on' state, with a resulting collector-base voltage of less than 1 V. Any commands which succeed in changing the states of transistors in the decoder circuits might, therefore, be expected to alter the degradation and recovery rates, hopefully in such fashion as to improve the marginal transistor or transistors. Variations in the response of the decoder circuits during the period of intermittent operation prior to total failure on November 23, 1962, were not correlatable, however, with the final command signal at the end of each pass.

Subsequent effort then concentrated on the development of modified commands which might be accepted by the decoder, taking into account the circuit effects of the possible degradation of various individual transistors. Such modified commands were eventually successful on December 20, 1962, following which the circuits appeared to improve further after periods of complete removal of circuit voltage by disconnection of the batteries and removal of solar cell voltage during eclipse periods. Normal performance was restored by January 2, 1963. During February 4–19, however, one decoder exhibited intermittent response to command, indicating no improvement in response to removal of circuit voltage during eclipse. Although additional modifications of the command signals resulted in improved operation for a short period, by February 21 these commands were no longer effective and the satellite would not respond further.

By that time it was becoming increasingly clear that the periods of loss of response of the command system corresponded to times at which the average radiation intensity was approaching its maximum value because of the changing satellite orbit. Precession of the orbit changes the percentage of time which the satellite spends in regions of accumulation of high-energy electrons in the Earth's magnetic field, resulting in cyclical changes in the average radiation intensity to which the satellite components are exposed. With the development of data indicating the location and intensity of such concentrations, estimates could be made of the average orbital exposure of the satellite, showing that the two failures occurred at periods approaching the maximum intensity, and the January 2, 1963, recovery occurred as the intensity approached the minimum of the cycle. The indication was thus that the transistor response was partly dependent on the dose rate. The confirmation of this dose-rate dependence in the laboratory, as indicated in Fig. 4, makes plausible such an explanation of the response of the satellite circuits.

The response of the satellite to its environment and to command experiments has, therefore, indicated the characteristic ionizing radiation effects on transistors, the variation of degradation with collector voltage, the recovery with removal of voltage, the sensitivity to dose rate and the eventual effect of total dose. Some of these effects were known sufficiently early to guide the efforts aimed at recovering usefulness of the satellite circuitry and others were deduced from the satellite response, to be confirmed on the ground. Toward this end the ability to compare results in the laboratory with those under actual orbiting conditions has been a significant factor in indicating the appropriate testing techniques and exposure-levels to be used in further studies.

The laboratory tests, however, indicate that, with transistor types of appreciable sensitivity to this phenomenon, the repeatability and predictability of response of individual units is certainly open to question and it becomes obvious that the emphasis in development of radiation-resistant circuits must be in the direction of reducing or eliminating the radiation sensitivity of transistor types.

Some of the early tests indicated the insensitivity of most evacuated types of silicon transistors and further work has confirmed that these types show relatively little degradation even beyond a dose of 10^7 rads. Similarly, many planar types, even gas-filled, suffer only limited degradation in the region of 10^6–10^7 rads dose. Hence the availability has been demonstrated of known production techniques for supplying transistors suitable for long life in satellites exposed to ionizing radiation and use was made of these techniques in supplying transistors for the critical decoder circuits for the second *Telstar* satellite. The different response from samples of various types, even of evacuated or planar processing, warns of the need for evaluation of each type for such environment and, perhaps, of each production lot or of each individual device. At least the recognition of the problem has led also to a recognition of solutions which are at hand.

NEWS and VIEWS

Physics at Sheffield : Prof. W. Sucksmith, F.R.S.

Prof. Sucksmith has now retired from the headship of the Physics Department at the University of Sheffield, after holding this post since 1940. In that year, he arrived from the University of Bristol, having been a reader in magnetism there, to find a small staff, depleted by National Service calls, and very modest experimental facilities. As a measure, albeit a very inadequate one, of his achievement in building up the Department, there are now more than twenty staff members, plus a post-graduate research school of twice this number, and the Department has recently moved into the new Hicks Building, with splendid facilities for research over a wide field.

Without question a brilliant experimentalist, Prof. Sucksmith has built up a research school in experimental magnetism at Sheffield with an international reputation. In the year of his appointment to the chair in Sheffield, he was elected a Fellow of the Royal Society, after successfully completing outstandingly novel and difficult experiments which led to the measurement of the gyromagnetic ratio for paramagnetic substances, and it is a tribute to the precision of these investigations that it is only now that physicists are requiring improved accuracy. His unique achievements in this field led to his visiting the United States in 1961 as a consultant on a project to measure the gyromagnetic ratio for a wide range of paramagnetic materials. His later research work centred primarily around the physical properties of ferromagnetics. In this work, the Sucksmith ring balance, invented initially to measure the susceptibilities of paramagnetic oxides, was developed as a suitable method for measuring the saturation magnetization of ferromagnetic metals and alloys at different temperatures. His outstanding contributions to experimental methods in the field of magnetism were suitably acknowledged in 1953, when he was chosen as Duddell Medallist of the Physical Society. His wider services to the University of Sheffield were recognized by the Council very recently by the conferment on him of the title of emeritus professor. His many friends in Sheffield are delighted that he and Mrs. Sucksmith will remain among them, and will all join in wishing them a long and happy retirement.

The University has decided to experiment with a system in which henceforth the headship of the Department of Physics will be held in turn for a period of three years by each of the two professors concerned. On the retirement of Prof. Sucksmith, Prof. G. E. Bacon becomes head of the Department for the first period (see *Nature*, 196, 1268; 1962).

Inorganic Chemistry at Bristol : Dr. F. G. A. Stone

Dr. F. G. A. Stone, reader in inorganic chemistry at Queen Mary College in the University of London, has been appointed to the new chair of inorganic chemistry in the University of Bristol. He will be in charge of a Department of Inorganic Chemistry formed by the division of the Department of Physical and Inorganic Chemistry for which Prof. D. H. Everett has hitherto been responsible. With Prof. Everett retaining charge of physical chemistry, the School of Chemistry will consist of three Departments, that is, Organic Chemistry (Prof. Wilson Baker), Physical Chemistry, and Inorganic Chemistry. This reorganization is part of a programme of expansion made possible by new buildings now under construction. A Cambridge graduate, whose interest in inorganic chemistry was stimulated by studies on the boron hydrides with Prof. H. J. Emeléus, Dr. Stone has

held fellowships at the University of Southern California with Prof. A. B. Burg and at Harvard University with Prof. E. G. Rochow. He then remained at Harvard, first as instructor and then as assistant professor, until he returned to England in 1962. He is widely known for his work on the synthesis of organometallic compounds, particularly in the field of the carbonyl complexes and fluorocarbon derivatives of the transition metals, and for his use of modern physical methods in the determination of molecular structure. He has published a monograph on "Hydrogen Compounds of the Group IV Elements", more than eighty research papers and numerous review articles, and has recently become co-editor, with Prof. R. West of Wisconsin, of *Advances in Organometallic Chemistry*, to be published annually by the Academic Press.

Theoretical Physics at Durham: Prof. B. H. Bransden

FOLLOWING the establishment of a chair of theoretical physics at the Durham Division of the University of Durham, Dr. Bransden, of the University of Glasgow, has been appointed the first holder as from October 1. Dr. Bransden graduated in 1945 from University College, London, with a first-class honours degree in mathematics and physics. After a short period in industry he entered the Department of Applied Mathematics of University College as a research student and obtained his Ph.D. in 1950. From 1951 until 1955 he was a lecturer in theoretical physics at Queen's University, Belfast, and since 1955 has been successively lecturer and then senior lecturer in natural philosophy at Glasgow. He was a research associate at CERN in the session 1960–61. Dr. Bransden's research interests have included light nuclear scattering, and, more recently, pion-nucleon, and pion-pion scattering, and the K^* resonance. He has published many scientific papers on these subjects and is the leader of an active research group.

British Scientific Instrument Research Association: Mr. S. S. Carlisle

MR. S. S. CARLISLE has been appointed director of the British Scientific Instrument Research Association (SIRA). The oldest of the co-operative research associations, SIRA has grown rapidly in recent times, having doubled its staff and income over the past seven years.

Mr. Carlisle, who takes up his appointment on November 1, has been with the British Iron and Steel Research Association since 1946. He became head of its South Wales Laboratories in 1954, returning to the London Laboratories four years later as head of the Physics Department. He became an assistant director of research in 1960. Mr. Carlisle's chief concern in recent years has been the development of the Physics Department's long-range research and development activities in such fields as strip handling by new techniques of fluid cushioning which resulted in development of the Hover Pulley, in-line product inspection technology for modern fast steel manufacturing processes, development of new composite materials such as fibre-reinforced steels and composite coatings. He has also been responsible for co-ordination of work on automation and its application in industry. Mr. Carlisle is a vice-president of the Society of Instrument Technology and has been recently elected to the Council of the Institution of Electrical Engineers.

U.S. Funds for Research and Development

A FINAL report on a survey of research and development funds and scientists and engineers in 1960, issued by the National Science Foundation as *NSF* 63–7 in the *Survey of Science Resources Series*, puts expenditure by industrial firms on research and development at 10,500 million dollars out of a total of 14,000 million dollars, an increase of 10 per cent on 1959, and nearly three times the total for 1953 (*Research and Development in Industry, 1960—Final Report on a Survey of R and D Funds and R and D Scientists and Engineers*. Pp. xii+118. Washington, D.C.: Government Printing Office, 1963. 65 cents). Of this 10,546 million dollars, 385 million dollars (4 per cent) was spent on basic research, 2,062 million dollars (20 per cent) on applied research, and 8,100 million dollars (76 per cent) on development; 4,359 million dollars derived from company sources and 6,117 million dollars from the Federal Government. More than 9,000 million dollars was expended by companies with 5,000 or more employees, and almost another 900 million dollars by firms of 1,000–4,999 employees. Federal funds for such research were 8 per cent higher than in 1959 and more than four times the comparable total in 1953. Company-financed research and development was 11 per cent higher than in 1959 and double that in 1953—chemicals and allied products (848 million dollars), electrical equipment and communication (816 million dollars), motor vehicles and other transport equipment (660 million dollars), and machinery (584 million dollars), accounting for 64 per cent of the 1960 total. The survey indicated that the number of companies with research and development programmes did not appreciably change between 1959 and 1960. The 300 firms with the largest programmes in terms of dollars accounted for 92 per cent of the funds for industrial research and development. About three-fifths of the basic research was in the physical and mathematical sciences, one-fifth in the engineering sciences and the remainder in the biological and other sciences. Guided missiles, communication equipment and electronic components and aircraft and parts accounted for 5,500 million dollars out of the 10,200 million dollars utilized for applied research and development. The full-time equivalent of 307,300 scientists and engineers employed in industrial firms on research and development in January 1961 was nearly two-fifths of the total employed in the industrial sector; 85,500 were employed on aircraft and missiles, 72,200 in electrical equipment and communications, 34,400 on chemicals and allied products, and 31,700 on machinery. Of the total, 79 per cent were employed by firms with 5,000 or more employees, and 10 per cent in companies with less than 1,000 employees. The average expenditure per scientist or engineer in research and development in 1960 was 35,000 dollars compared with 34,900 dollars in 1959, the average figure varying with the size of the firm, from 38,900 dollars in firms with 5,000 or more employees to 19,100 dollars in firms employing less than 1,000.

U.S. Federal Funds for Science

IN the note on *Federal Funds for Science* on p. 1144 of the June 22 issue of *Nature*, the figure of 12,300 million dollars represents the anticipated expenditure on research and development and on plant for that purpose (and not for plant only as stated), the 14,400 million dollars being the amount obligated for these purposes. The figure of 368 million dollars is the increase authorized by Congress over the amount originally in the budget for 1963 and not, as stated, the increase in the amount for the Department of Defence, which was 1,010 million dollars, the largest increase over 1962 reported being 2,000 million dollars for the space programme administered by the National Aeronautics and Space Administration.

Primary and Secondary Education in Britain

IN a written answer in the House of Commons on August 1, the Parliamentary Secretary to the Ministry of Education, Mr. C. Chataway, stated that, during the past year, the Curriculum Study Group had been assisting the Secondary School Examinations Council to establish the new Certificate of Secondary Education examinations. The Group was also collaborating with the Nuffield Foundation in their projects for improving science and mathematics teaching and helping to organize the pilot scheme for teaching foreign languages in the primary

schools, for which the Foundation is sponsoring the preparation of teaching materials, as well as planning an enquiry into the content of the secondary school curriculum. It is also concerned with the proposal now under discussion to form an advisory body concerned with schools' curriculum and examinations, and would be providing professional assistance to the reconstituted Central Advisory Council in their study of primary education under the chairmanship of Lady Plowden.

The Colonial Development Corporation

The annual report of the Colonial Development Corporation for the year ended December 31, 1962, records 110 approved projects at the end of the year, of which eight, totalling an investment of £1·63 million, were new (Pp. vi+95. London: H.M.S.O., 1963. 6*s*. 6*d*. net). These were: in the Far East, the Sarawak Electricity Supply Corporation and Fiji Agricultural Trials; in East Africa, the Chinja and the Metaara Tea Supply Co., Ltd., the Mauritius Housing Corporation, and the Nairobi City Water Supply; and in the High Commission Territories, the Basutoland Electricity Authority and Vuvulane Irrigated Farms. Additional investment of £1,882,000 in existing projects has been approved. Of the committed capital at the end of the year, £15·8 million was in the Caribbean, £20·6 million in the Far East, £23·6 million in East Africa, £22·6 million in Central Africa, £21·3 million in the High Commission Territories, and £13·3 million in West Africa. Of this total, 53·7 per cent was for basic development, 34·5 per cent for primary production and processing, and 11·8 per cent for commerce and industry; for 1961 the corresponding figures are 54·8 per cent, 34·4 per cent and 10·8 per cent, respectively.

The Macaulay Institute for Soil Research

As has been the case with many research institutes, the Macaulay Institute for Soil Research was first accommodated in a country house at Craigiebuckler on the outskirts of Aberdeen. As its activities increased, temporary buildings were erected in the grounds and eventually a completely new building was planned and erected. This was formally opened in September 1962 by Mr. D. L. Macaulay, a son of the founder, and is an excellent example of a modern research establishment, finished in a style compatible with the nature of the work being carried out. Every effort has been made to overcome troubles from chemical corrosion, noise and vibration, and air-conditioning is installed in certain sections.

The report for 1961–62 gives a brief description of the great variety of studies in progress (Pp. 55+1 plate. Craigiebuckler, Aberdeen: The Macaulay Institute for Soil Research, 1963). It is sufficient to mention that there are departments of pedology, soil survey, spectrochemistry, biochemistry, plant physiology, microbiology, soil fertility and statistics. But the research programme involves considerable collaboration between departments. For example, investigations on crop performance embrace field, pot and laboratory studies, major and micronutrients and statistical evaluation of the results. A few of the topics dealt with in recent publications concern principles of soil classification, direct-reading spectrochemical methods, natural chelating substances, cation-exchange of plant tissues, phosphate-dissolving micro-organisms, fractionation of organic phosphate, minerals in clays, weathering of basic igneous rock, the genetic soil groups of Scotland, response to fertilizers—all indicative of the rapid development of soil science in the past thirty years.

Disarmament and Arms Control

Disarmament and Arms Control, a new international quarterly journal, has been launched to provide a forum for the discussion of disarmament, arms control and related topics in the belief that well-informed discussion of such issues can reduce the present manifest dangers of mankind (1, No. 1; Summer 1963. Pp. v+1–110. Subscription rates: '*A*', £10 (30 dollars) applicable to libraries, Government departments and industrial establishments; '*B*', £2 (6 dollars) for individual subscribers, who certify to the publishers that the journal is for their personal use. London and New York: Pergamon Press, 1963). Its aim is to encourage the exchange of ideas and experience between workers in different countries, and it is hoped to include a regular section of comments by readers; the periodical is dedicated to the improvement of communication and understanding by seeking to formulate and clarify the new concepts required. For the present it is published in English only, with abstracts of each article in Russian, French and German, but a full translation of any article can be obtained on application to the publishers. The present issue is being distributed by the American Academy of Arts and Sciences to its Fellows and Foreign Members. The first number is admirably printed and produced and its quality is illustrated sufficiently by the titles and authors of its five main articles: "First Step—Sealed Records Caches ?", by J. C. Polanyi; "The Role of the Neutrals in the Geneva Negotiations", by M. Samir Ahmed; "Violations of Disarmament Agreements", by R. J. Barnet; "The International Control of Fissile Material Production"—being a shortened version of a paper contributed by the Atomic Energy Authority to the Disarmament Conference at Geneva in August 1962; "A Proposal for an African and Near-Eastern Zone Free from Certain Weapons", by D. H. Frisch. Besides book reviews, there is a section containing short abstracts of current literature and research. The first issue seems well designed for its purpose and should strengthen the efforts in this field which scientists are already making through the Pugwash movement and in other ways.

Atom

The June 1963 issue of *Atom* completes W. F. Wood's review of the reactors at Harwell commenced in the May issue. In the July issue is printed a lecture by J. F. Putman on economic aspects of the technical application of radioisotopes, which gives some impressive savings. Annual savings in the United Kingdom through the use of radioisotopes are estimated at £3·5 million, but potential savings at £14·5 million, including £2·75 million in the paper and board industries, £1·9 million in chemical industry, £1·05 million in iron and steel, and £1·775 million in electrical engineering. The number of British firms using radioisotopes has increased from 658 in 1957 to about 1,200.

Apartheid and the South African Library Association

The *Library Association Record* for June 1963 includes a note from more than thirty members of the staff of the Johannesburg Public Library giving the text of a resolution passed at a general meeting of the Southern Transvaal Branch of the South African Library Association deploring the decision taken by the South African Library Association Conference in resolving to enforce separate racial associations on the library profession (see *Nature*, 196, 1242; 1962). The resolution sets forth reasoned objections. It maintains that common professional ideals, aims, interests and problems form a bond which transcends differences of age, sex, religion, politics, language, race or colour, and therefore strongly objects to any of these fortuitous differences being utilized to build artificial barriers between colleagues. The Association is numerically small and fragmentation can only weaken the Association and produce separate and even impractically tiny bodies. Since the Government intends to enforce apartheid on profesional associations, it is urged that the action of the Conference was untimely and unnecessary.

Had it waited for the separation to be imposed from outside, no wedge need have been driven between its members, many of whom feel strongly and bitterly on the subject; the library profession would not have inflicted a gratuitous insult and slight on its non-white members and through them on their peoples; professional bodies such as the Library Association and the American Library Association, who would doubtless have offered support and sympathy when Government action enforces the establishment of separate associations, would not have been alienated and antagonized; librarians would not have set themselves apart from professional bodies in South Africa, several of whom have already expressed concern at the inevitable consequences of the Government's proposed legislation; and finally, the Association would not have played into the hands of South Africa's critics at the United Nations and elsewhere.

Documentation of Science Organization

An interesting paper by G. Rózsa on "Documentation of Science Organization as an Emerging New Branch of Scientific Information" has been issued as No. 32 in the *Bibliographical Publications of the Scientific Academy of Hungary* (Pp. 15. Budapest: Magyar Tudományos Akadémia Könyvtára, 1962). Directing attention to the prolific growth of scientific organizations, in size and number as well as in scope, Dr. Rózsa suggests that documentation of scientific organization involves covering the following fields: history, theory, philosophy and systematization of science; scientific policy and government administration of scientific work; international collaboration in scientific work; planning management and organization of scientific work; levels of research; methodology of research work; economic problems of scientific work; management of scientific manpower; scientific personnel; scientific agencies and organizations; and scientific information. The first nine of these divisions he regards as containing the concept, themes and systematization of the necessary documentation, but this, he maintains, does not fit into any of the developed and usual schemes of science systematization, or even library or documentary systematization; however, it is probable that not all his readers are likely to accept the contention that science organization, in consequence, appears as a new branch of science. It is quite clear, however, that Dr. Rózsa uses the term 'discipline' in a sense which differs considerably from that in which it is used in academic circles in Britain or in the United States. He is concerned to see that efficient means are developed of handling the problem of communication or of documentation of scientific organization, whether on a general basis or within a particular field of science.

Magnetic Recordings

A revised bibliography on *Magnetic Recordings*, compiled and edited by R. E. Hadady and published by Kinelogic Corporation, 29 South Pasadena Avenue, Pasadena, California, covers the years 1954–61 inclusive, and lists 775 papers and articles from some 120 technical journals. An author index is included and both the names and addresses of the journals cited are given. The numbers of items for the respective years 1954–61 are 95, 62, 67, 70, 55, 63, 159 and 204, and they show how the interest in the subject of magnetic recording has varied, with a considerable revival and growth in the more recent years. The bibliography will be of interest to those engaged in data recording, data storage and retrieval, recording design, automation, and sound and television recording.

Southern Variable Stars

Astronomy has for long suffered from the lack of observations of objects in the southern hemisphere, and the increased *tempo* of results which has followed the installation of the 74-in. telescopes at Pretoria and Canberra is most welcome. The latest issue of *Monthly Notices of the Royal Astronomical Society* (125, No. 5/6; 1963) contains two contributions on southern variable stars. M. W. Feast (pp. 367–415) describes very extensive observations of long-period variable stars made at the Radcliffe Observatory, Pretoria, during the years 1952–60, when 281 spectra of 114 stars were obtained. Radial velocities were obtained from this material; for only a very few of these stars had similar observations been made previously. The velocities were obtained from both absorption and emission lines. Combination with data for northern stars yielded a very homogeneous set of velocities for 405 long-period variables. These data were subjected to statistical analysis for systematic motions, velocity ellipsoids and galactic rotations. The variables cover a wide range of population types. The shortest period variables have anomalous motions and may perhaps be pulsating in the first overtone. A. W. Rodgers and R. A. Bell (pp. 487–527) report on an analysis made at the Mount Stromlo Observatory, Canberra, of high-dispersion spectra of the southern cepheid variable κ Pavonis. This is a relatively bright star and is probably a member of the disk population somewhat similar to W Virginis cepheids. Variations in the parameters describing the atmosphere of the star were obtained at various phases of the cycle, and the density fluctuations studied. The abundances of the chemical elements in the star were also obtained.

The Zone of Fracture, and the Wave Spectrum of Earthquakes

Dr. Hans Berckhemer has examined this question and written about it in a paper entitled "Die Ausdehnung der Bruchfläche im Erdbebenherd und ihr Einflub auf das Seismische Wellenspektrum" (*Gerl. Beitr. Z. Geophys.*, Bd. 71/1). The amplitude-period spectrum of a seismogram is determined by what happens in the focal zone as well as by the conditions of wave propagation and the characteristics of the seismograph. Dr. Berckhemer describes a method which admits the separation of the influence of the focal process from the others. His investigation covers 20 earthquakes of magnitude from 4·5 to 8. It can be seen immediately that long-period waves are favourably excited by strong earthquakes. The comparison of isoseismal maps suggests that differences in the wave spectrum are caused by the different sizes of the fractured zones at the hypocentre. A simplified theory for a focal process with an extended focus is given in order to explain the observations. The assumptions made concerning the rupturing velocity are based on the results of laboratory experiments. Dr. Berckhemer has found that the relationship $\log F = 0{\cdot}45 + 1{\cdot}7\ M$ between the earthquake magnitude, M, and the size of the fractured area in square centimetres, holds for values of M between 5·5 and 8. A corresponding expression in terms of earthquake energy instead of magnitude is $\log F = 0{\cdot}85 \log E - 5{\cdot}7$. By comparing the last formula with an expression for the elastostatic energy of the fractured area given by Keylis–Borok, it is possible to obtain information about the shape of the seismic fault and to determine the shearing strength of the crust in the focal area (2–5·10^7 dynes/cm^2). Deviations from laboratory measurements may be explained by stress concentration at geological scars within the Earth's crust.

Powder Technology

A course of instruction in "Powder Technology" will be held in the Faculty of Engineering, King's College, University of London, for one year commencing in October. The course is designed for students with a first degree in engineering, physics, chemistry or certain other approved branches of applied science, and its successful completion will lead to the award of a College postgraduate

diploma. Further information can be obtained from the Registrar, King's College, Strand, London, W.C.2. The fee for the course will be £87.

Solid-State Electronics

A POSTGRADUATE course in "Solid-state Electronics" will be held in the Electrical Engineering Department of the Manchester College of Science and Technology commencing in October. The course is available to those with a good honours degree in physics, electrical engineering or related subjects, and will lead to the degree of M.Sc.Tech. by examination and dissertation. The course will last for four terms, the first three being devoted to lectures, tutorials and laboratory work, and the fourth entirely to work on a research project. Further information can be obtained from the Registrar, Manchester College of Science and Technology, Manchester 1.

Methods of Chemical Analysis

A FULL-TIME residential course on "Modern Methods of Chemical Analysis", with specialization in either spectroscopic methods or electroanalytical methods, will be held at Loughborough College of Technology for one year, beginning on October 1. The course will consist of general studies and practical work, and satisfactory completion can lead to the award of the Associateship of Loughborough College. The course is intended as an immediate postgraduate course for those obtaining a degree or equivalent qualification.

The following symposia and courses in modern chemical analysis will be held at Loughborough College of Technology during 1963–64. *One-day lecture symposia:* automatic analysis and control (October 8); modern gas chromatography (October 15); modern infra-red spectroscopy (November 19); modern polarography (February 4); nuclear magnetic resonance and electron spin resonance (March 17). *One-week residential courses:* gas chromatography (October 14–21); infra-red spectroscopy (November 18–25); polarography (February 3–10); atomic spectroscopy (March 9–15); X-ray methods of analysis (April 26–May 2).

Further information can be obtained from the Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire.

University News: London

PROF. R. S. NYHOLM has been appointed to the headship of the Department of Chemistry, University College, in succession to the late Prof. E. D. Hughes.

Sheffield

DR. JOHN STEPHEN FLORRY has been appointed "Glass Manufacturers' Federation" Senior Research Fellow in the Department of Glass Technology at the University of Sheffield as from October 1. Dr. Florry graduated with honours in metallurgy at the University of Sheffield in 1957 and then undertook postgraduate research in the Refractories Technology Department. From October 1960 until the present time he has been a metallurgist at the Material Research Laboratory of the Mullard Radio Valve Co. He was awarded a Ph.D. in December 1962.

Announcements

PROF. C. L. OAKLEY, professor of bacteriology in the University of Leeds, has been appointed a member of the Agricultural Research Council in succession to Prof. J. W. Howie, who retires on September 30.

A MEETING of the German Society of Polar Research will be held in Karlsruhe during October 6–9. The subjects under discussion will be "The Antarctic" and "High Alpine Glaciers". Further information can be obtained from Deutsche Gesellschaft für Polarforschung, 23 Kiel, Eckernforder Strasse 1.

A THREE-DAY postgraduate course on "Electron Probe X-Ray Microanalysis" will be held at the Bristol College of Science and Technology during October 3–5. The fee for the course will be six guineas. Further information can be obtained from K. Humphreys, Bristol College of Science and Technology, Ashley Down, Bristol 7.

A SYMPOSIUM ON "Insect Reproduction", arranged by the Royal Entomological Society of London, will be held at the Imperial College of Science and Technology, University of London, during September 19–20. Further information can be obtained from the Registrar, Royal Entomological Society of London, 41 Queen's Gate, London, S.W.7.

A CONFERENCE on "Generation, Detection and Properties of Coherent Radiation of Wave-length Less than One Millimetre", arranged by the British Radio Spectroscopy Group, will be held in Bournemouth during September 24–25. Further information can be obtained from G. Phillips, Research Division, Signals Research and Development Establishment, Christchurch, Hants.

THE annual general meeting of the Photobiology Group will be held in the University of Cambridge during September 26–27. The programme will include a short symposium on "Woodland Light Climates", together with a number of papers on various other photobiological topics. Further information can be obtained from Dr. L. R. Fisher, National Institute for Research in Dairying, Shinfield, Reading.

A CONFERENCE on "The Physics of Optical Glass", arranged by the Optical Group of the Institute of Physics and the Physical Society, will be held at the Research Laboratories of Pilkington Bros., Ltd., Lathom, Lancashire, during October 3–4. Topics under discussion will include: special glasses; measurements of optical properties; working and testing of surfaces; physical studies of glass; instrumental requirements. Further information can be obtained from the Administration Assistant, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

A ONE-YEAR graduate course in "Solid State Electronics Engineering" will be held in the University of Birmingham, commencing October 1. The aim of the course will be to provide a broad and fundamental treatment of this sector of electronic engineering, and it will include groups of lectures on: quantum mechanics; structure of matter and physical properties of materials; theory and applications of solid-state and quantum devices; computers and digital systems; selected topics in engineering mathematics, as well as practical work and a three-month study or research project. Successful completion of the course will lead to the degree of M.Sc. (for degree students) or to the Diploma of Graduate Studies (for non-graduate students). Further information can be obtained from the Registrar, University of Birmingham, Birmingham 15.

THE following short evening courses will be held at Hendon College of Technology: digital computers and their industrial applications (twelve lectures, commencing September 23); a design course for electronic engineers (twelve meetings, commencing October 1); transistors and transistor circuit design (sixteen lectures, commencing October 16); an introduction to microwaves (twelve lectures, commencing September 26); global communications (nine lectures, commencing October 10); high-fidelity sound reproduction (nine lectures, commencing October 9); statistics (two consecutive courses, each of six lectures, commencing September 26 and November 7); electronics for engineers (sixteen meetings, commencing October 29); relativity and space (seven lectures, commencing October 9); introduction to plastics technology (six lectures, commencing October 8). Further information can be obtained from Hendon College of Technology, The Burroughs, Hendon, London, N.W.4.

PHYSICS IN AFRICA

PROBLEMS and opportunities facing physics departments in African universities were discussed at the Leverhulme Inter-Universities Conference held at Salisbury, Southern Rhodesia, during June 10–20. The delegates, drawn mainly from the region between the Sahara Desert and the Limpopo River (with two advisers from the United Kingdom) were of many nationalities—Indian, Norwegian, French and Belgian, as well as British, Nigerian and South African. The institutions which they represented included small and recent foundations (such as Roma, Basutoland, with 173 students) along with others of greater size and seniority.

Many African universities, having grown out of institutions established in Colonial days, retain close links with the mother countries. French influence is still strong at Dakar (Senegal) and Abidjan (Ivory Coast); the University of Lovanium, in Léopoldville, is run on characteristic ally Belgian lines. Several colleges in former British territories were originally in special relation with the University of London; only one (the University College of Rhodesia and Nyasaland) retains this status, the others having all taken steps to secure autonomy. New foundations in Ghana, Nigeria, Tanganyika and elsewhere will, it is expected, grant their own degrees from the outset.

The universities of mid-Africa present a rich diversity of constitution, tradition and academic outlook, but they have many problems in common. The formation of new universities—now proceeding at a rate unequalled even in the United Kingdom—is part of the movement towards independence. It would be an over-simplification to regard the universities in developing countries merely as symbols of national pride, but it must be accepted that the advancement of learning in many African territories is closely linked with the contemporary political ferment.

The first problem discussed at the conference was the role of the universities in an emerging country. The definition offered recently by an African politician ("factories for graduates") expresses one view of the situation. The repatriation of Colonial administrators and experts of all kinds creates serious problems in newly independent countries, where facilities for higher education have often been very limited. It is, however, not certain that university expansion should have first priority in the effort to build up the local supply of professionally trained people. Several universities are short of students, particularly in science, because of deficiencies in the provision of secondary education for African children. Many universities follow the present English practice by requiring candidates for admission to have at least two advanced-level passes in the General Certificate of Education. This is a higher standard than is now required in a number of advanced countries, including South Africa, India, Scotland and the United States. Its attainment in African conditions is extraordinarily difficult. In Southern Rhodesia, for example, 129,000 African children began their primary education in 1962 but fewer than 6,000 were enrolled in secondary schools and only 81 remained at school after taking the Ordinary-level examination for the General Certificate of Education. About half these students may eventually graduate and not all of them are likely to become teachers.

The Conference agreed that expansion of secondary education will be necessary before the universities can play their full part in the communities that they serve. Meanwhile, the universities are under pressure to organize (as some have already done) a preliminary year to bring students of limited academic attainment up to the standard required for entry to a degree course.

The shortage of African students is both the cause and the consequence of the shortage of teachers. Since few countries in the world have enough well-qualified teachers, it is becoming more difficult for African schools to recruit staff from abroad. An imaginative scheme sponsored by the United Nations, at a cost of more than £300,000, will attempt to deal with this situation by bringing several hundred recent graduates, from all over the English-speaking world, to Salisbury. They will study at the University College of Rhodesia and Nyasaland for the postgraduate certificate in education of the University of London and will then teach in various African countries.

The inter-dependence of school and university was discussed further when the conference passed to its second main topic, the teaching of physics to undergraduates. The African child, reared in a culture based on folk-lore and witchcraft (which the white man has disturbed without adequately replacing) does not take readily to the study of science. Having had no contact with modern technology, he finds difficulty in scientific and mechanical tasks which his contemporaries in Europe or North America would consider trivial (one delegate suggested the distribution of 'Meccano' in primary schools as a useful preparation for later scientific studies). The African teenager may even be suspicious of experimental science as an activity more akin to manual labour than to intellectual exercise.

Against this background it is unreasonable to plan for a large output of highly qualified honours graduates—particularly since the abler students can often obtain scholarships to support their undergraduate studies in foreign universities. It is judged that a considerably increased supply of physicists at the level of the general honours or the pass degree would best serve the short-term needs of most African countries.

Although the universities are not yet able to produce great numbers of physicists, there is much to be done in the teaching of physics as a subsidiary subject at undergraduate-level. Reference was also made to the physicist's role in the advancement of technical education. Training courses for technicians are not popular, even where the industries which need the products are already established. The educated African hopes to obtain a degree, which confers much improved status and earnings. Short of a degree, he will often prefer clerical employment to technical work, which is not yet esteemed as the foundation of a 'respectable' career.

The conduct of research was the third major theme of the conference. A physics department in Africa has, as elsewhere, three main tasks: (*a*) the teaching of students; (*b*) the advancement of knowledge; (*c*) the application of scientific ideas and methods to practical problems arising in industry, agriculture, defence and other public activities. An active research effort is, the Conference urged, essential for the fulfilment of all three of these responsibilities. The maintenance of such an effort is difficult. The most serious handicap reported by many delegates was the lack of research students. The output of honours graduates suited for further training is small, and most of them prefer to go abroad for their research experience. On the other hand, expatriate staff are not generally recruited below the lecturer-level. In these circumstances, many African universities are not able to offer the Ph.D. degree. It was agreed that a successful physics department must have some measure of continuity, through the postgraduate training and eventual absorption (as staff members) of its own students. Free movement of scientists is important, but every department should be able to recruit a proportion of its staff from among its own graduates.

Some of these problems will solve themselves as African universities grow in stature and resources. Meanwhile, the Conference recommended, two steps should be taken. First, the institution of an intermediate research degree,

at the M.Sc. level, would be a useful measure towards the growth of participation by African students in the research programmes of physics departments. Secondly, the help of the Department of Scientific and Industrial Research and of other research-sponsoring organizations should be sought in the recruitment of research students from overseas.

In the absence of research students, much of the experimental work in a project has to be done by the lecturers, or by the small number of full-time research fellows. Progress is further retarded by the shortage of technicians. The supply of assistance at this level depends on the provision of secondary education (up to Ordinary-level) in mathematics and physics and also on the development of full-time or part-time technical education to the level of the Ordinary National Certificate or the City and Guilds final examination in appropriate subjects.

Educational facilities of this kind are essential to the development of a healthy industrial economy and are, therefore, of great importance in many African countries. Their provision will be a slow process, and physics departments will have to rely on expatriate technicians—who can do valuable service in the training of indigenous staff.

Physics departments in Africa are isolated in the geographical sense, but they also face the danger of intellectual isolation. Many active areas of modern physics are closed to them, through lack of funds for equipment and staff. Contacts with other physicists are also very limited. Chemists and biologists can be found in most countries, going about their normal work in industry, agriculture or Government service. Physicists are needed mainly in industrialized communities; consequently teachers in African universities can seldom sharpen their wits by contact with practising physicists in the outside world. African universities in general make reasonable provision for overseas leave; the Conference emphasized the value of attendance at scientific conferences and of frequent discussion with visiting research workers.

Despite many obstacles and discouragements, a lively spirit of enquiry is evident in many physics departments. Good use is being made of the excellent local opportunities for research in geophysics (including seismic studies and palæomagnetism), meteorology, cosmic radiation and ionospheric investigation. The cost of this research is largely defrayed by European or American sources or by international organizations.

Physics departments in Africa face some of the difficulties which were known in English provincial universities forty years ago. Student numbers are small (one African university has 186 first-year students in history, but only 15 in physics), because physics is not yet seen to have any immediate relevance to the needs of the community. The teaching load is nevertheless heavy. Funds for equipment are meagre and research is a constant struggle. British physics advanced rapidly as a consequence of the Second World War; the political upheaval which is now transforming the African scene must, for its full consummation, be accompanied by an upsurge of science and technology. Physicists now working in African countries are fully alive to their responsibilities at this exciting time.

J. M. A. Lenihan

FREE RADICALS

The sixth International Symposium on Free Radicals was held in the Department of Physical Chemistry in the University of Cambridge during July 2–5. The meeting had an extensive scientific programme; but pre-printing of the papers made it possible to avoid parallel sessions. The delegates were accommodated in Trinity Hall, Sidney Sussex and Downing Colleges, and the social functions, which included a reception in the Guildhall and a guest night dinner held in St. John's and Downing Colleges, provided plenty of opportunity for discussions. The three hundred delegates included Dr. W. A. Noyes, jun. (president of the International Union of Pure and Applied Chemistry), Academician V. N. Kondratiev, Prof. S. Claesson, Prof. P. A. Giguère, Dr. G. Herzberg, Academician W. Kemula, Dr. Bernard Lewis, Dr. F. O. Rice and Prof. G. Semerano.

The inaugural lecture was given by Prof. R. G. W. Norrish, who discussed the many ways in which kinetic spectroscopy and flash photolysis have contributed to the understanding of the properties of free radicals.

As with previous symposia, the emphasis of the plenary lectures and contributed papers was primarily on free radicals in the liquid and solid states, although H. Schüler and G. Arnold (Göttingen) discussed the dissociation of *cyclo*hexane and *n*-butane into different radicals and diradicals by slow electrons in the positive column of a glow discharge. Electron bombardment in the gas phase was also used by R. Marx, S. Leach and M. Horani (Orsay, Paris) to produce free radicals from water. The radicals which could be condensed from an electric discharge through water vapour were also discussed by P. A. Giguère (Laval, Quebec). The closely related problem of using electron spin resonance to identify the radicals produced in the radiolysis of ice and hydrogen peroxide–water systems at low temperatures was discussed in a plenary lecture by R. Livingston (Oak Ridge, Tennessee) and in papers by D. Schulte-Frohlinde and K. Eiben (Karlsruhe), I. Safarik, B. C. Green and J. W. T. Spinks (Saskatoon) and S. J. Wyard and R. C. Smith (Guy's Hospital, London). The existence of hydrogen superoxide (H_2O_4) is not unequivocally established in these systems, but there is clear evidence for the trapping of OH and HO_2. The nature of the active species in the radiolysis of aqueous solutions was also discussed in a plenary lecture by J. Weiss (King's College, Newcastle upon Tyne).

Several papers were concerned with the identification and study of the electron spin resonance spectra of trapped radicals produced by irradiation of both organic and inorganic solids. It was significant that a high proportion of the work reported was carried out on single crystals. These papers were preceded by a plenary lecture on the interpretation of hyperfine coupling by D. H. Whiffen (National Physical Laboratory, Teddington), and the parent compounds studied included persulphates by P. W. Atkins, J. A. Brivati, A. Horsfield, M. C. R. Symons and P. A. Trevalion (Leicester); nitrates by J. Cunningham (Chicago) and R. M. Golding and M. Henchman (Cambridge); fluorinated organic compounds by J. K. Brown and D. S. Stiles (Birmingham); succinimide by N. M. Atherton (Sheffield); olefines and alkyl halides by P. B. Ayscough and H. E. Evans (Leeds); organic acids by R. J. Cook, J. R. Rowlands and D. H. Whiffen (National Physical Laboratory, Teddington); and acetylene by E. L. Cochran, V. A. Bowers and F. J. Adrian (Applied Physics Laboratory, Johns Hopkins).

Three contributions described the use of electron spin resonance to examine reactions of radicals produced by irradiating both hydrocarbon polymers (H. Fischer, K. H. Hellwege and P. Neudörfl (Darmstadt) and A. Charlesby, C. Graves, P. G. Garratt and P. M. Kopp (Royal Military College of Science, Shrivenham)) and polymethylsiloxane (H. Ormerod (Royal Military College of Science, Shrivenham)). Electron spin resonance was one of the many techniques mentioned by C. H. Bamford (Liverpool) in his plenary lecture on radical polymerization in the solid-state. The unusual reactivity and exceptional surface area of fluffs obtained by freeze-

drying polymer solutions were reported by R. B. Ingalls (North American Aviation) and L. A. Wall (National Bureau of Standards, Washington). Surface properties were also considered by V. B. Kazanskii and G. B. Pariiskii (Moscow), who were able to obtain electron spin resonance spectra of free radicals adsorbed on surfaces of insulators but not of semiconductors.

The electron spin resonance spectra of organic diradicals such as substituted methylenes were reported by W. A. Yager, K. W. Murray, G. Smolinsky, A. M. Trozzolo and E. Wasserman (Bell Telephone Laboratories).

Chemical reactions studied in the solid-state using electron spin resonance spectroscopy included the benzene photosensitized decomposition of hydrocarbons (N. V. Fock, B. N. Shelimov and V. V. Veovodskii (Moscow)), the reaction of ethylene or oxygen using an ingenious rotating cryostat (J. E. Bennett and A. Thomas (Shell, Thornton)), and the photolysis of methyl iodide at $\lambda = 2537$ Å, where the methyl radicals rapidly extract hydrogen from the methyl*cyclo*hexane cage (J. M. Flournoy, H. S. Judeikis (Aerojet, California)).

Chemical analysis was used by R. H. Duffett and G. J. Minkoff (British Petroleum, Sunbury) to examine the reaction of hydrogen and deuterium atoms with solid olefines. Fluorescence spectra of benzyl radicals in *cyclo*hexane glasses were studied by L. Grajcar and S. Leach (Orsay, Paris) to obtain information about the structure of the solid-state. For their studies oxygen in liquid and solid argon, A. M. Bass and H. P. Broida (National Bureau of Standards, Washington) used ultra-violet spectroscopy. The formation and decomposition of purple sulphur at low temperatures was illustrated with a colour film by F. O. Rice (Notre Dame, Indiana).

It is more difficult to maintain significant concentrations of reactive species in the liquid state than in the solid phase. Three of the papers, however, reported electron spin resonance investigations of short-lived radicals under liquid conditions. The use of a fast-flow system in which the reactants were mixed close to the sampling cell was reported by P. L. Kolker, T. J. Stone and W. A. Waters (Oxford), who produced aromatic radicals by oxidation of phenols, and by W. T. Dixon and R. O. C. Norman (Oxford), who formed various aliphatic radicals using titanous salt–peroxide systems. L. H. Piette (Varian, California) showed that both rapid response and good sensitivity would be obtained with an electron spin resonance spectrometer on a statistical basis. Electron spin resonance studies of radicals produced by the photolysis of electron-donor–acceptor system were reported by C. Lagercrantz (Göteborg) and the spectra of terphenyl anions by K. H. Hausser, L. Mongini and R. van Steenwinkel (Euratom, Ispra). The production and properties of ketyl radicals formed by polarographic reduction were described by Z. R. Grabowski and M. K. Kalinowski (Warsaw).

The importance of diffusion of radicals in solution was discussed in papers by J. E. Guillet and J. C. Gilmer (Tennessee Eastman) and A. D. Osborne and G. Porter (Sheffield) respectively. The former showed that solvent cages are important in the decomposition of diacyl peroxides and that the activation energies for radical escape from a cage and for diffusion are identical. The latter workers showed, by studying the decay of active species in solvents of different viscosity, that the Debye equation is valid when the reacting species do not differ greatly in size from the solvent molecules.

This stimulating meeting was assisted by the Royal Society, by many British industrial firms, and by the provision of transport for many North American Delegates by the United States Air Force. It is planned to hold the seventh Symposium in 1965 in Italy, probably in Venice.

B. A. Thrush

INSPECTION OF ALKALI AND CEMENT WORKS

THE ninety-ninth annual report on alkali, etc., works in England and Wales covering the year 1962 by the Chief Inspector * notes the extension by the responsibilities of the inspectorate by the Alkali, etc., Works Order, 1961, to cover control of emissions from calcination of black liquors from paper manufacture and from operations involving uranium, beryllium, selenium and their compounds. At the end of 1962, 2,077 works were registered under the Act, involving the operation of 3,247 separate processes, and 10,768 visits and inspections were made during the year, including 140 special visits by the Chief and Deputy Chief Inspectors. During the inspections, 4,331 quantitative analyses were made of gases evolved from processes, compared with 6,992 in 1961, but the latter total included 3,065 tests taken during a special investigation into emissions from the salt glazing of earthenware.

In addition, 647 special samples were taken and submitted for analysis to the Government Chemist. Specific complaints investigated during the year, largely at the request of local authorities, concerned 297 works, compared with 283 in 1961, 292 in 1960 and 354 in 1959, and of these 297 works 233 were registered under the Act, and the complaints were most numerous against gas and coke works (47), ceramic works (41), electricity works (33), iron and steel works (27), aluminium works (14) and cement works (13). The degree of justification for complaint varied, and once again was most bitter against some of the smaller works. There was also some general complaint against overall emission in particular areas rather than against any specified works, and of the 16 examples include the blue-brick making area of Staffordshire and The Thames and Medway cement-making areas. Listed infractions, numbering 10, were again confined to the pre-1958 processes and remedies were applied on formal notification by the inspector without institution of proceedings. The root cause of the trouble in the Thames cement-making area was the approaching exhaustion of available Eocene clay supplies in North Kent and the consequent use of ever-increasing proportions of estuarine clay from the Cliffe marshes, and the resulting increased dust burden in the kiln gases has in turn led to overloading and erratic operation, or even failure, of electrical precipitates. Planning consent was sought to win sufficient Eocene clay from Essex to replace all the Cliffe clay in use and at the end of the year only one of the four works on the south bank of the Thames was on Cliffe clay. The report includes an interesting historical review of the evaporation of lime in open pans, a process for common salt now practically out of use and there is also a brief discussion of the problem of emissions from the Trophas steel converter. Although the Inspectorate is still much preoccupied with grit, etc., emissions from the intermediate-sized coal-fired power stations, considerable progress can be recorded in modernization and replacement of grit and dust collection plant, and there are reasonable grounds to believe that such emissions will be reduced to a satisfactory level, but concern is still expressed over the minimization of emissions of acid-soot from oil-fired power stations.

The annual report for 1962 of the Chief Inspector for Scotland, published under the same cover, records a decrease in the number of registered premises from 297

* Ministry of Housing and Local Government; Scottish Development Department. Alkali, etc., Works Regulation Act, 1906, and Alkali, etc., Works Orders 1928–1961. Alkali, etc., Works Regulation (Scotland) Acts, 1906, 1951, and Alkali, etc., Works (Scotland) Orders, 1952 and 1958). Ninety-ninth Annual Report on Alkali, etc., Works by the Chief Inspectors, 1962. Pp. 75. (London: H.M.S.O., 1963.) 5s. net.

to 285, chiefly due to closure of gas works by extension of the grid system of distribution. The 575 visits of inspection included 36 by the Chief Inspector and there were 142 further miscellaneous visits and 64 visits not under the Acts. The dust-testing team from the Department of Scientific and Industrial Research completed during the year 20 months of its three-year contract period and made 28 tests of dust emission from registered premises. The work has shown that circumstances in field work may require substantial modification of procedures laid down in accepted standard methods for dust measurement. Maintenance of operation of plants to prevent discharges of noxious and offensive gases from registered premises was generally satisfactory.

THE BRITISH COKE RESEARCH ASSOCIATION

THE nineteenth annual report of the British Coke Research Association* is noteworthy for the record of continued expansion and progressive research undertaken during the year 1962. One immediate objective has been the direction of attention to the more practical aspects of the results of research. This has been stimulated by the Association's participation in the Special Assistance to Industry Scheme, sponsored by the Department of Scientific and Industrial Research. The use of films, a fully equipped mobile laboratory and an expansion of the technical liaison and advisory services are now additional means of 'putting over' the great amount of 'know-how' which has been learned during past years about the correct methods of sampling, sample-preparation, physical testing and analysis of coke.

Naturally, with the competitive challenge of alternative fuels and of alternative methods of metallurgical practice, the question of the supply and demand of fuels manufactured from coals must constantly be a matter for vigilance and close examination. In recent years there have been changes in the demand for blast-furnace coke, partly as a result of the reduction in the production of steel. The demand has also fallen for the technical reason that blast furnaces now use less coke per ton of pig iron produced, because of the extension and improvement of sinter practice and the successful application to blast-furnace operation of the injection of fuel oil and of powdered coal. Given, however, a reasonable level of expansion of the national economy, the demand should not change much in coming years. Moreover, it has been concluded that the blast furnace will remain the principal producer of iron in the foreseeable future. While the coke-oven process, with improvements, will continue to be used to meet the demand for blast-furnace coke, there is, however, a possibility of a new process being developed, using cheaper coal and giving a product of uniform shape and size, described as a 'formed coke' which might prove to be more economic in use than the conventional product. Depending on capital and running costs, such a process might be economically competitive with the coke-oven process. The development of a formed-coke process, involving the erection of costly prototypes, would undoubtedly prove to be enormously expensive and might possibly be best pursued by international co-operation. The Russians and the Poles, among others, have devoted much time and money in recent years to this question. It is very satisfactory to learn that the British Coke Research Association is well aware both of the possibilities and the difficulties of adopting such a process, which in the event may best be suited to localities of the world remote from supplies of good coking coal.

A formed-coke process should provide means for the supply of a solid fuel tailored to the future requirements of the blast furnace; but the Association in fact is mounting a two-headed attack on this difficult question of new types of fuel for the iron and steel industry. The other possibility which is being investigated is that of influencing the properties and more particularly the size of coke produced in the conventional coke-oven by controlling the fissuring process during carbonization. Undoubtedly news of developments in both these fields will be awaited with great interest.

Passing to the record of the research achievement, painstaking effort, not always rewarded with equivalent positive result and calling for much detailed experiment, has continued in the general study of additions to the coal blend for carbonization. Examples of the additions in question are coal-tar pitches, petroleum residues, breeze and heavy petroleum oil. Nevertheless, results have arisen that are worth all the effort. Thus in the case of the possible substitution of breeze for a Welsh coal it was found that 3 per cent of fine breeze could replace the most costly component of the blend while providing coke of similar characteristics. Again, in respect of the use of sodium carbonate, the addition of which is known to improve the reactivity of coke for domestic purposes, with a 0·75 per cent addition of this salt before coking not only was the reactivity improved but also the size of the coke and the resistance to impact increased, though the resistance to abrasion fell considerably. Other features of economic importance have been revealed, for example, the determination of the end-point of carbonization, at which the 'soaking' of the charge has reached its optimum in terms of the useful properties developed in the coke.

The provision of means for carrying out coking trials at various ranges of capacity, from a full scale involving a 10 tons charge to as small a quantity as 15 lb., has apparently paid off handsomely, for one reads of trials that are necessary in the large oven and others of equal importance being run in the small ones. Further trials of new blends may be run in the large oven, when it has been established in the small ovens that an improvement is likely and that there is no danger of coking pressures large enough to damage the oven.

Since the earliest use of coke for iron production, the demand for metallurgical coke of low sulphur content has persisted and with the progressive exhaustion of the best coking coals the problem of sulphur impurity has remained of growing importance. More particularly does the difficulty arise in respect of the behaviour of the organic sulphur constituents. The objective is, of course, to discover whether these reactions may ultimately be capable of being controlled. In a very complete examination of the sulphur–carbon complexes to be found in coke, involving the most modern techniques, electron-spin resonance measurements among others, it has been concluded tentatively that the surface sulphides make an important contribution to the organic sulphur content of coke and that dehydrogenation by sulphur, and the interaction of sulphur with free radicals present in the coke, contribute to the formation of these complexes during the coking process. Their preservation in the coke seems to depend on their being of stability greater than that of their carbon–oxygen counterparts.

The Applied Studies Laboratory at Chesterfield has been concerned particularly with problems bearing on the thermal behaviour and fissuring of coke, methods of analysis and measurement and the use of oven coke in domestic appliances. The housewife requires a coke of ready combustibility, that is to say, she wants a fuel that

* Nineteenth Annual Report of the British Coke Research Association, 1962. Chesterfield, Derbyshire.

lights easily and does not go out overnight; accordingly, the questions of coke reactivity and size become the pertinent issue and the metallurgical requirement is the direct contrary of the domestic need. There are, however, situations in which hard coke may suffice for the domestic boiler; they may be defined by suitable experiment.

Progress has been made in the Association's contribution to the provision of cheap and effective methods of liquid-effluent treatment and measures to be taken for the reduction of the emission of smoke, dust and grit at coke ovens. With regard to the former, the Association is supporting, both financially and technically, basic research at the University of Leeds into the biological treatment of gas liquors. Considerable strides have been made in the study of the activated sludge process as applied on a coke-oven plant and of the relative merits of percolating filter processes. It is most interesting to know that these microbiological processes can destroy such undesirable constituents of waste liquors as phenols, cyanides and thio-salts, including thiocyanates, substances which by their poisonous activity can persuade even the scientists to describe some of them as 'devil liquor'. Perhaps even more interesting to the layman is the fact that spoil heaps may be brought into service as percolating filters, and where they also have lagoons these may serve as means of aeration. To bring the rejected refuse of the mine back as an active agent in solving surface effluent problems is indeed to raise slumbering devils to serve mankind. The genus *Thiobacillus* would appear to give much scope for study, since preliminary results indicate that the organisms reported in the literature are only a fraction of those that exist in Nature. In the matter of atmospheric pollution much has been done in the mitigation of air pollution as the result of the training of coke-oven staff and operatives.

In the associated work of the Northern Coke Research Laboratory the tradition of the devotion to fundamental studies has been sustained. They involve methods of adsorption and microwave spectroscopy. The objectives include the unravelling of the mechanism of the adsorption on carbon of oxygen, carbon dioxide and nitrogen under controlled conditions. It is a problem which has challenged the scientific world since the earliest physical chemists applied the methods of chemical kinetics to the basic problems of combustion. The latest methods permit rapid determination of surface area, an essential parameter.

Coke science is not like nuclear science, a subject which makes popular news, but progress which is respected by that section of the scientific world able to appreciate the problems involved is just as worthy of recognition. The Council of the Association, its director, Mr. G. W. Lee, his colleagues and staff are therefore indeed to be congratulated on their achievements. R. J. SARJANT

GEOMETRICAL OPTICS

THE Optical Society of America, at its Rochester meeting in October 1962, awarded the Frederic Ives Medal for distinguished work in optics to Dr. M. J. Herzberger, the head of the geometrical optics department and senior research associate, Research Laboratories, Eastman Kodak Co. The Medal was presented on October 4 by D. L. MacAdam, the president of the Optical Society. A list of some 150 of Dr. Herzberger's publications is given in the June issue of the *Journal of the Optical Society of America* (53, 659; 1963) together with the text of his address entitled "Some Recent Ideas in the Field of Geometrical Optics". Dr. Herzberger discussed three particular optical problems on which he had worked—the analysis of optical images, the improvement of achromatic systems, and the algebraic method of designing optical systems. The use of spot diagrams to describe image formation in optical systems is illustrated by application to the analysis of the so-called 'rim-ray curves' and the four-element air-spaced compound triplet, an *f*/5, 300-mm 'Tessar'-type lens, is taken as a numerical example. The method will appeal to those who prefer to think in pictures rather than numerically. In 1959, Dr. Herzberger discovered that it was possible to design lenses, with or without fluorite, which were corrected for colour over a wide range of wave-lengths. The fundamental idea is to consider the refractive index n, and not its square, as a characteristic physical quantity, and to utilize the dispersion formula:

$$n = A + B\lambda + C/(\lambda^2 - \lambda_0^2) + D/(\lambda^2 - \lambda_0^2)^2$$

where λ_0 is a constant which for the wave-length range 365 mμ to 1·01μ and 176 glasses and other transparent substances used in optical design has the value 0·168μ. Four data are therefore required to fix the dispersion of an optical substance in the visible region. The data suggested are discussed, and it is shown that two glasses can be used to design an achromat, and if three lens elements made of different glasses are used a super-achromat can be designed which is corrected for four colours.

The basic mathematical problems associated with the algebraic design of optical systems, that is without ray tracing, have recently been solved by Dr. Herzberger, and the work remaining consists only of the elementary, but tedious, job of the algebraic solution of certain linear equations with algebraic coefficients and the same non-zero determinant for all orders. In his address Dr. Herzberger explained the meaning of the 'characteristic function' or 'eikonal' and posed the two questions, the answers to which would reduce the designing of lenses to pure mathematics. He then outlined the procedure adopted to determine the focal eikonal to any desired order for an image formation given by a single thick lens with two aspheric surfaces. Dr. Herzberger concluded by saying that he felt confident that it would not be long before the brain achieves a decisive advantage over the computer in the design of optical systems.

FLUOROCARBONS

THE origin of the organic fluorochemicals industry lay in the refrigeration industry wherein, following several fatal accidents, there arose an urgent demand for a non-inflammable, non-toxic, low boiling-point refrigerant. The pioneers working for General Motors were Drs. McNary, Midgley and Henne, who carried out research on compounds of carbon, fluorine and chlorine, particularly CCl_2F_2 made by the action of SbF_3 on carbon tetrachloride. Prof. M. Stacey of the University of Birmingham contributes an interesting article on this subject in the Spring 1963 issue of *Catalyst*, the excellently written and illustrated industrial journal of the Shell Chemical Co., London. "Success was immediate and dramatic", says the author, "and, in 1931, in collaboration with Du Pont, General Motors formed the corporation Kinetic Chemicals which began the commercial production of a range of colourless odourless non-toxic and non-inflammable fluorochlorocarbons which were named the Freons".

These compounds derive from the reaction of anhydrous hydrogen fluoride on carbon tetrachloride, chloroform or ethylene. There are five major ones, CCl_2F_2, CCl_3F, $CHClF_2$, $C_2Cl_3F_3$ and $C_2Cl_2F_4$; these together constitute 95 per cent of the fluorochlorocarbons at present being used in industry. To-day they are produced in fourteen different countries and are severally known by titles such as 'Freons', 'Arctons', 'Isecons', 'Genetrons', 'Foranes', 'Eskimons', etc. World annual production is now in the region of 150,000 tons.

Besides refrigerants, however, there are other important applications of and developments from these fluorocarbons. One example is found in certain pressure packaging 'aerosols'. "As aerosol propellants, their production has risen dramatically in ten years from about 40 million units (cans) to 500 million units, and world production is still growing". Another development is a remarkable plastic based on tetrafluoroethylene ($CF_2=CF_2$). In its polymerized form, $(CF_2)_n$, this plastic possesses quite exceptional properties; it is chemically inert to solvents, acids, alkalis, oxidizing agents, steam, lubricants, etc.; at temperatures up to 300° C only fluorine gas and molten alkali metals attack it. As polymerized tetrafluoroethylene is thermally stable up to 300° C and has a constant and low power factor, it is especially valuable for electrical uses also in highly corrosive environments.

Prof. Stacey states: ". . . a number of new oils and plastics are now made from trifluoro chloroethylene and co-polymers. Various fluoro alcohols are being developed as monomers for polymers, and the esters of these alcohols are being used as stable lubricants". On a practical laboratory scale, it is found that the life of ground glass joints can be prolonged by covering them with polymerized tetrafluoroethylene sleeves as a protection against action of corrosive liquids. The article also gives details of the biological developments of these compounds and concludes: "Thus it will be seen that potentialities for synthesis are even greater than in the vast area of coal tar chemistry. There are prospects for new dyestuffs . . . new drugs and medicinals, as well as new materials for the study of reaction mechanisms".

REDUCTION OF OXYGEN AT A CARBON ELECTRODE EMERGING FROM AN ELECTROLYTE

By SAM R. FARIS

Socony Mobil Oil Co., Inc., Field Research Laboratory, Dallas, Texas

P. HERSCH[1] has described an experiment in which the corrosion of a metal is facilitated by the presence of a three-phase boundary between metal, electrolyte and the atmosphere. Weber[2] investigated the transport of oxygen to metal cathodes. He found that metal cathodes afforded higher current densities when partially submerged. Will[3] examined the oxidation of hydrogen at platinum electrodes. He found that a large increase in current occurs when the electrode is partially immersed in the electrolyte. The entire electrode was wetted by the electrolyte and no three-phase boundary existed; the oxidation occurred almost exclusively in a narrow region at the upper edge of the electrolyte meniscus and the adjacent film close by.

The purpose of this article is to describe similar experiments in which oxygen reduction at porous carbon cathodes is enhanced by raising the electrodes in the electrolyte.

One of the factors which limits the capacity of a fuel cell is mass transport of oxygen to the cathode. It is generally believed that oxygen first dissolves in the electrolyte and then diffuses to the surface of the cathode for reaction. It is desirable to have an electrode of large surface covered with a thin film of electrolyte in which the dissolved oxygen reaches this surface by diffusion along a short path. Establishment of large extents of this electrolyte film of optimum thickness is one of the difficulties encountered in the preparation of fuel cell electrodes.

A porous carbon electrode partially submerged in an electrolyte which wets it should have on it a film of varying thickness. An electrode under these conditions should show a larger current capacity than when it is completely submerged. This increase in current has been observed for porous carbon cathodes at which oxygen is being reduced in an electrolyte of aqueous potassium hydroxide.

The electrolyses were carried out in an H-shaped glass vessel with separate electrode compartments. The electrode assemblies were held in place by rubber stoppers. The anode was a porous block, 2·5 × 2·5 × 7 cm, made of Stackpole No. 139 carbon. The cathodes were made of porous carbon rods, 6–7 cm long, with circular cross-sections. These cathodes were sealed in U-shaped holders of glass with either epoxy resin cement or Corning '*RTV*-731' silicone rubber. The cathode compartment of the electrolysis cell was provided with a tube for entry of oxygen into the catholyte via a fritted glass gas dispersion tube. Another tube permitted oxygen to enter only the vapour space above the electrolyte. A saturated calomel electrode was used as the reference electrode. The electrolyte was aqueous potassium hydroxide of density 1·302 g/cm³ at 25° C (a nominal 40 wt. per cent solution). The potassium hydroxide solutions were prepared with A.C.S. reagent grade potassium hydroxide pellets using water having a specific resistivity of 2·0 – 4·0 × 10^6 ohm cm. The oxygen was U.S.P. grade twice washed with water before use. Fig. 1 illustrates the principal parts of the electrolysis cell.

After assembly of the cell with the cathode in the submerged position, oxygen, saturated with water vapour, was bubbled through the potassium hydroxide solution for a period of 2–4 h. The oxygen was then arranged

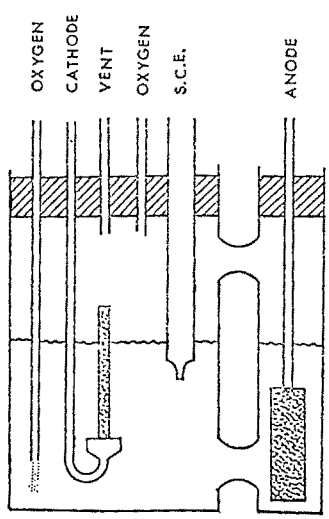

Fig. 1. Electrolysis cell

not to bubble through the electrolyte but to sweep continuously through the vapour space above the electrolyte.

The potential of the cathode was held at − 1·0 V versus the saturated calomel electrode with an electronic potentiostat. The current flowing through the electrolysis cell was continuously measured and recorded by a strip-chart recorder. To raise the cathode, electrolyte was pipetted from the cathode compartment or the glass electrode holder was raised. Both methods were used. The height of cathode raised above the free surface of the electrolyte was measured with an Ealing 11–550 cathetometer. At all times during the experiments the anode remained submerged. The temperature of the electrolysis cell was maintained constant to ± 0·1° C in a water bath.

Two kinds of carbon were used to make cathodes: Stackpole No. 139 with an apparent density of 1·35 g/cm³ and surface area of 0·72 m²/g; and Great Lakes carbon Type *HPL* with an apparent density of 1·73 g/cm³ and surface area of 0·18 m²/g. The surface areas were measured by the Brunauer–Emmett–Teller method using nitrogen as the adsorbate.

In Fig. 2 are shown the current versus height of emergence data for the two carbons used as cathodes in aqueous potassium hydroxide at 30° C. While the cathodes are submerged a small current of the order of 0·1 m.amp flows. As the cathode is raised in the electrolyte the current rises rapidly to a limiting value. The third curve shown in Fig. 2 was obtained for a Great Lakes carbon cathode after it had been made 'wet-proof' by painting it with a solution of paraffin in isooctane. After evaporation of the isooctane, a thin layer of paraffin coated the cathode. On emergence this treated cathode was not wetted by the electrolyte. These electrodes were rod-shaped, 6–7 cm long and with circular cross-sections of 0·62 cm diameter.

A cathode of Stackpole No. 139 carbon, 0·64 cm diameter and 6·0 cm long, was used in the electrolysis cell with air sweeping through the vapour space above the electrolyte. The air had been filtered and saturated with water vapour before it was introduced into the electrolysis cell. The results obtained at 30° C are shown in Fig. 3 and are there compared with the results for the same electrode with oxygen sweeping through the vapour space above the electrolyte.

Current versus height of emergence data were obtained for Stackpole No. 139 carbon cathodes at 10° C intervals over the temperature-range 10°–40° C. The currents increase as the temperature increases. Fig. 4 shows the

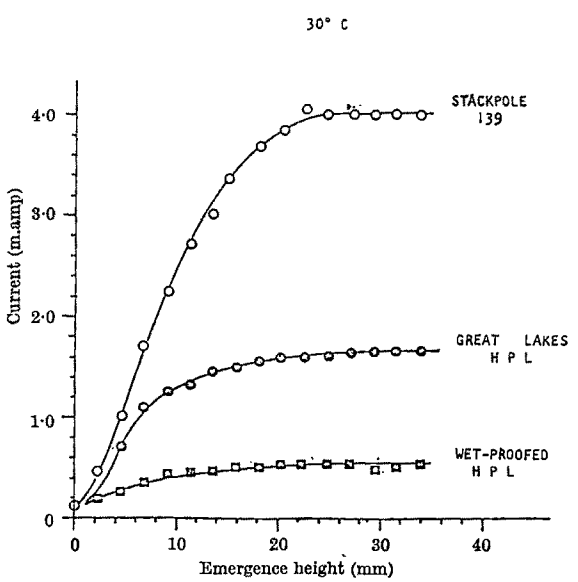

Fig. 2. Current versus emergence height for carbon cathodes

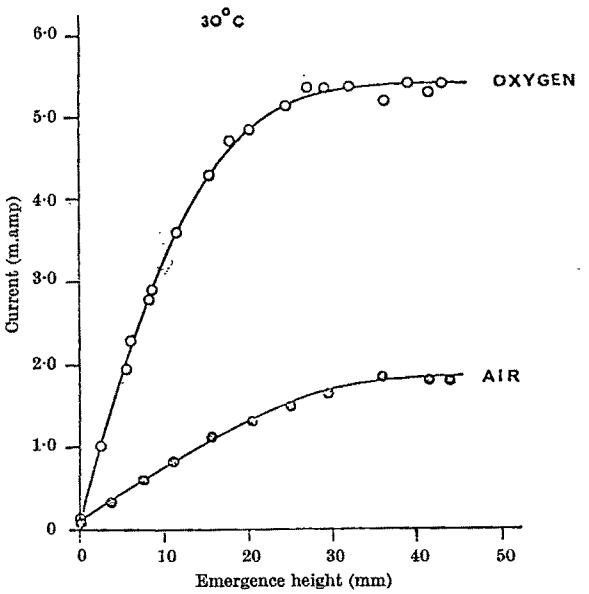

Fig. 3. Use of air in vapour space

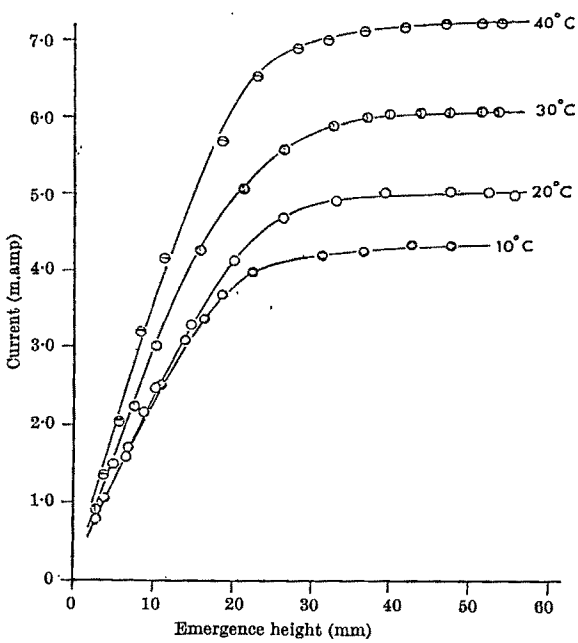

Fig. 4. Variation of current with temperature

variation of current with temperature for a cathode 7·0 cm long and 0·62 cm diameter. Additional results to illustrate the variation of current with temperature are given in Fig. 5, where the logarithm of the limiting current value at a constant value of height of emergence (46·6 mm in this case) are plotted against $1{,}000/T$ °K over a temperature-range of 10°–50° C. In the temperature-range 10°–35° C the variation of the logarithm of the limiting current with $1/T$ is approximately linear.

The slope of the linear portion of the curve in Fig. 5 corresponds to an activation energy of about 3·6 kcal/mol. This value is of the same order of magnitude expected for the energy of activation for diffusion of oxygen in the electrolyte.

Similar data for the variation of current with temperature for electrodes submerged in the electrolyte are difficult to obtain. These currents are erratic and not reproducible. A number of measurements of the current with the cathode submerged were made at 30° C and the current values varied from 0·12 to 0·40 m.amp.

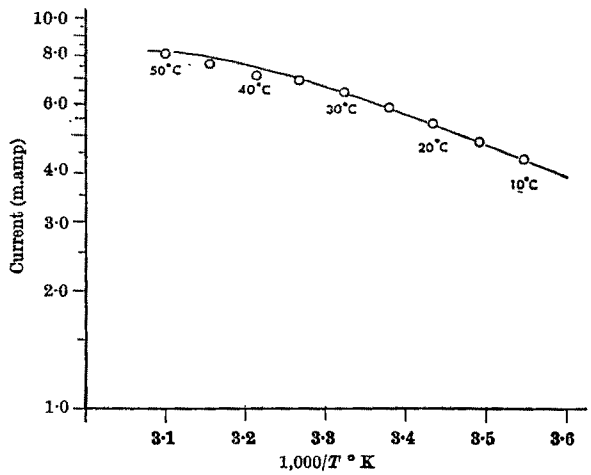

Fig. 5. Variation of current with temperature

The very small values of current for the submerged electrodes are very nearly the maximum to be expected from the diffusion of dissolved oxygen in the bulk electrolyte to the electrode surfaces. On raising the electrode a thin film of electrolyte is created through which oxygen transport by diffusion is considerably increased. As withdrawal continues the current increases to a limiting value. This indicates that the extent of optimum thickness electrolyte film is limited and does not increase with emergence beyond a certain value. Towards the top of the emergent electrode the electrolyte film is so thin that ionic mobility is hindered and the electrical resistance in the film has increased. In Fig. 6 the film of electrolyte above the point *A* on the emerged electrode is too thin to afford adequate ionic conduction. Consequently, this extent of electrolyte film above *A* contributes nothing to the current capacity of the electrode.

The electrolyte film located between points *A* and *B* on the emerged electrode is sufficiently thick to provide adequate ionic conduction but thin enough to allow rapid transport of oxygen by diffusion. When the electrolyte film between points *A* and *B* has been formed by raising the electrode, the limiting value of the current has been reached. Electrolyte situated below point *B* on the electrode is essentially the same as that encountered by the submerged electrode. According to Fig. 4, for example, the 'band' of optimum electrolyte film thickness between points *A* and *B* is formed at a height of emergence of about 3·0 cm for Stackpole No. 139 carbon cathodes. To raise these electrodes further only produces a film of electrolyte too thin to contribute to the current capacity of the electrodes.

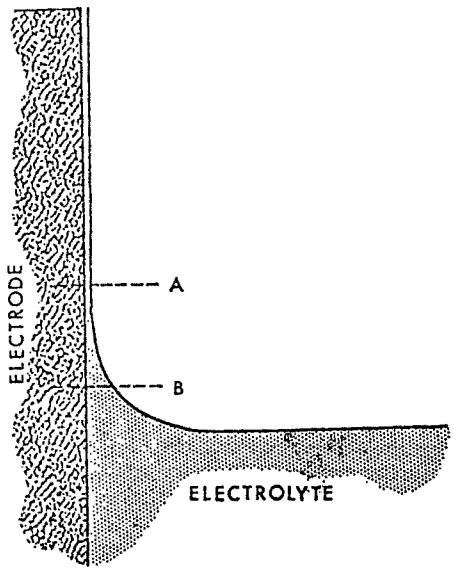

Fig. 6. Diagram of electrolyte meniscus and film

Unless the electrode is wetted by the electrolyte no film (or at best an insufficient film) is formed on emergence. This is clearly shown in Fig. 2 for the 'wet-proofed' cathode made of Great Lakes carbon. For the 'wet-proofed' cathode the limiting current was about 0·5 m.amp compared with a limiting current of about 1·7 m.amp for the untreated cathode. Both cathodes exhibited a current of about 0·1 m.amp when submerged. Even the small limiting current of 0·5 m.amp is probably the result of incompleteness of the 'wet-proofing' procedure. Presumably if the entire surface of the electrode were coated imperviously with paraffin the electrode would be a non-conductor so far as ionic conduction is concerned and an open circuit would result. For the Great Lakes carbon cathodes the *A* to *B* region of electrolyte film is formed at a height of emergence of about 2·0 cm. The Great Lakes carbon is a 'smoother' carbon than Stackpole No. 139 and has only about one-fourth the specific surface area.

The results of these experiments reinforce the belief that oxygen transport by diffusion through the electrolyte is the slow or current limiting step in the reduction of oxygen at porous carbon cathodes.

I thank the Socony Mobil Oil Co., Inc., for permission to publish this article.

FORMATION AND PROPERTIES OF THE BLACK FORM OF CARBON DISULPHIDE

By E. G. BUTCHER, M. ALSOP*, J. A. WESTON and H. A. GEBBIE

Basic Physics Division, National Physical Laboratory, Teddington, Middlesex

IN 1941, P. W. Bridgman[1] reported that carbon disulphide slowly changed its character when subjected to a pressure of 45,000 atmospheres and a temperature of 175° C. The new form was a black solid which for practical purposes was stable at room temperature and atmospheric pressure. Later, Whalley[2], in presenting results of infra-red investigations on this black material, gave as the conditions of formation 55,000 atmospheres and 185° C, while in 1962 Dachille and Roy[3] referred to it as a waxy polymer which was produced at 42 kbar at 100°–200° C.

This communication gives some results of further investigations of this material carried out here. Using the tetrahedral anvil apparatus[4] with a modified cell assembly (which will be described elsewhere) comparatively large samples (0·5 cm diam., 1·0 cm long, weighing 0·1 g or more) of the black high-pressure form of carbon disulphide have been produced, and it has been found

* Now at Windsor Technical College, Berkshire.

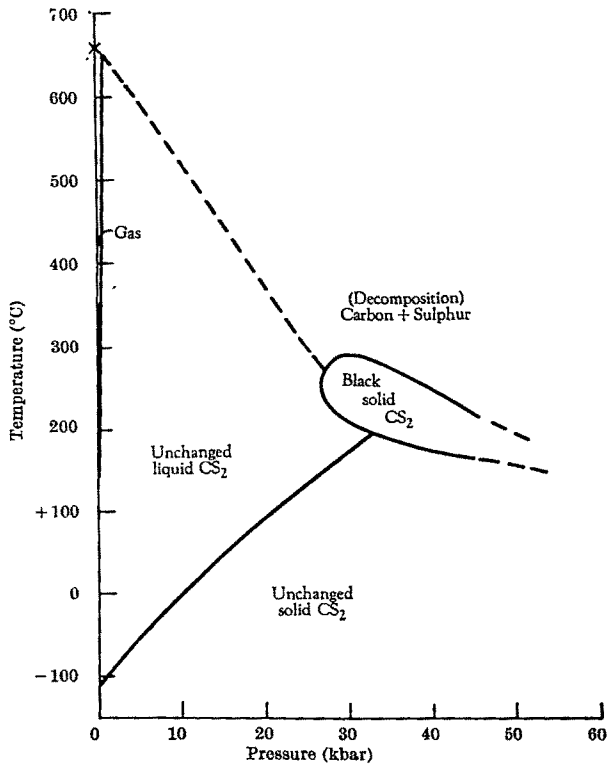

Fig. 1. Formation diagram of black carbon disulphide

that the formation of this black form occurs over a wide range of pressure but over a relatively narrow range of temperature. Fig. 1 shows a diagram of the formation conditions from which it will be seen that the black solid is formed at pressures as low as 27,000 atmospheres at temperatures of 220°–280° C. Above 280° C the material starts to decompose into carbon and sulphur. As the pressure is increased the formation temperature decreases so that at 45,000 atmospheres black carbon disulphide is formed over the temperature range of 165°–235° C, some decomposition into carbon and sulphur occurring at 240° C. The time taken for the change to occur in our apparatus is of the order of 10 min at the higher pressure (45,000 atmospheres) and somewhat longer at the low pressures. Under these conditions the yield approaches 100 per cent.

The black form of carbon disulphide is a solid at ordinary temperatures and pressures. It is stable for an indefinite period and no conditions have been found under which it reverts to the original liquid form. When heated it softens at about 70° C and decomposes into sulphur and carbon at 170° C. It is insoluble in all the normal laboratory solvents. Its density is found to be 1·89 g/ml. and this value compares with that for carbon 2·0–2·2 g/ml. (graphite) and 1·95–2·05 g/ml. for yellow sulphur. Our value does not agree, however, with the density value reported by Bridgman, who stated that the black solid had a density 4 per cent greater than a mechanical mixture of sulphur and carbon.

A determination of the stoichiometry of the black solid shows that the molecular composition is carbon disulphide. Measurements on three samples gave the proportions 82·8 per cent sulphur and 16·33 per cent carbon, compared with 84·22 per cent and 15·77 per cent of sulphur and carbon respectively which would be expected from the atomic weights.

X-ray powder photographs and electron diffraction measurements gave very little information, since in both a broad diffuse pattern was obtained indicating that there is little or no long-range order.

At room temperature the material has a very low electrical conductivity (approximately 10^{-15} ohm cm^{-1}), but this increases rapidly with temperature suggesting that the material is a semiconductor. In Fig. 2 the measured electrical conductivity is plotted against the reciprocal of the temperature and the slope of the resulting straight line indicates an energy gap of 1·15 eV. Some support for this value is obtained from near infra-red measurements. The material is black with high absorption in the visible region, but at a wave-length of approximately 8,000 cm^{-1} (1·2μ) the transmission increases and this locates roughly an optical absorption edge corresponding to an energy of 1 eV. The infra-red absorption spectrum in the frequency-range 2,000–1,000 cm^{-1} has been recorded using powdered samples and the potassium chloride disk technique. We confirm the results of Whalley in finding a strong absorption band at 1,063 cm^{-1}, which he assigns to C=S stretch. In addition, however, we find bands at 1,389 and 1,351 which at present we are unable to assign. Perhaps more revealing are some results of measurements in the far infra-red which are shown in Fig. 3. In this region liquid carbon disulphide and the solid made by freezing it show only weak absorption features, but with the black material there is strong absorption throughout the range 350–120 cm^{-1} with reproducible absorption

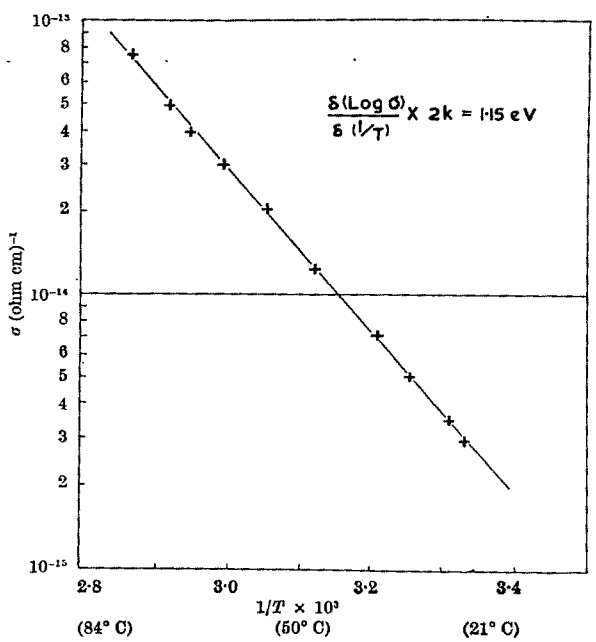

Fig. 2. Temperature dependence of electrical conductivity (σ)

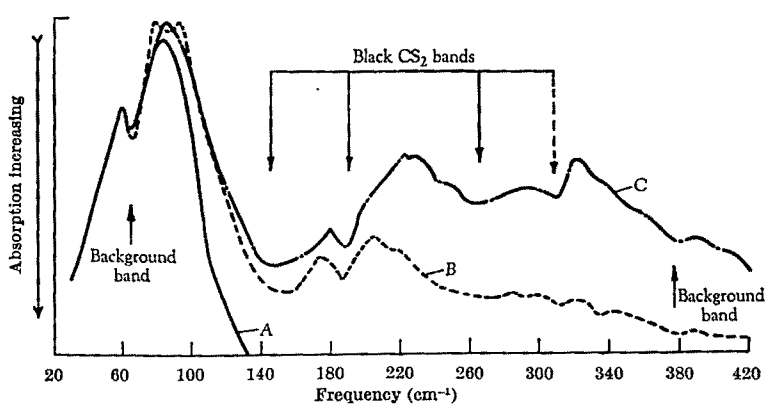

Fig. 3. Far infra-red absorption spectrum of black carbon disulphide with instrumental background spectrum superimposed. *A*, specimen 250μ thick; *B* and *C*, specimen ~100μ thick

maxima at 265 cm^{-1}, 190 cm^{-1} and 150 cm^{-1} and a less-definite feature at 310 cm^{-1}. No quantitative values of absorption coefficient in this region have been obtained so far, but that the absorption is high may be judged from the fact that transmission could be measured only when the sample thickness was reduced to be of the order of 100μ even when using an interferometer method where relatively large energy is available. The strong absorption in the region 350–120 cm^{-1} is in great contrast with the behaviour of liquid carbon disulphide and suggests the presence of polar groups in the black modification.

At frequencies less than 100 cm^{-1} the transmission increases and this has allowed us to make a rough measurement of refractive index for a frequency band at 30–40 cm^{-1} by an interferometric method[5]. A value of approximately 2·0 was found corresponding to a dielectric constant of 4·0. Measurement of dielectric constant at microwave frequencies (10^{10} c/s) and radio frequencies (10^{8} c/s) gave the values 4·2 and 4·0 respectively with negligible dielectric loss at both frequencies. The high values of dielectric constant of the black variety of carbon disulphide may also be contrasted with that of liquid carbon disulphide, which for low frequencies has the value 2·62.

It is evident from the foregoing that Bridgman's black carbon disulphide has a structure very different from ordinary carbon disulphide and that a polymeric structure formed by breaking the molecular double bonds is plausible, but it is also clear that more studies as well as refinement of the present measurements will be necessary before this structure can be described unambiguously.

We thank Mr. G. Mitchelmore for valuable help during the investigation of the formation conditions, Mr. R. Rushton of the Standards Division of this Laboratory for the measurements of dielectric constant, the National Chemical Laboratory for the microanalysis results, and the Warren Springs Laboratory for the density determination.

This work is published with the permission of the Director of the Laboratory.

A NEW APPROACH TO STUDYING THE PROTEIN-BINDING PROPERTIES OF PENICILLINS

By P. ACRED, D. M. BROWN, T. L. HARDY and K. R. L. MANSFORD
Beecham Research Laboratories, Ltd., Brockham Park, Betchworth

THE interaction of an antibiotic with serum is generally believed to result in a decrease in antibacterial activity. When the natural penicillins were originally examined, it was found that in the absence of serum, penicillin *K* was more active than penicillin *X*, and penicillin *X* was more active than penicillin *G*, but in the presence of serum, penicillin *G* was the most active. The reversal in activity was attributed to the fact that penicillin *G* was less bound to protein than penicillin *K* or *X*, and hence a greater concentration of free penicillin was available for antibacterial action[1].

The methods used to examine protein binding of penicillins have relied largely on *in vitro* static dialysis, but such methods, however, bear little relationship to the dynamic conditions in the body. We have, therefore, studied the phenomenon of protein binding with the view of determining more precisely its significance to antibacterial activity *in vivo*. Gel-filtration and both static and continuous dialysis methods have been used in this investigation.

The penicillins which were selected were penicillin *G*, 'Ampicillin' and '*BRL* 1071' (triphenylacetylpenicillin).

Static dialysis. To 5 ml. of human serum, 5 mg of the pencillin under examination were added. This was placed in a dialysis bag of 'Visking' tubing 0·75 in. diameter and suspended in 20 ml. normal saline and dialysed at 8° C for 24 h. Several dilutions of retentate and dialysate were prepared in M/20 phosphate buffer *p*H 7·0, and the amount of antibiotic was assayed by the cup-plate technique using *Sarcina lutea* as the test organism. The samples of each antibiotic were assayed against dilutions of known concentration of the same antibiotic.

Continuous dialysis. 5 mg of each antibiotic in 5 ml. serum were placed in 'Visking' tubing as described. The bags were suspended in a beaker through which water flowed continuously. The final concentration of the antibiotic was assayed in the serum at 24 h and the percentage obtained was calculated in terms of the concentration in serum at zero and 24 h.

Gel-filtration. 5 mg of each antibiotic were dissolved in 5 ml. serum and allowed to stand for 18 h at 10° C. 3 ml. of the serum were applied to a column jacketed at 10° C and containing 100 ml. 'Sephadex *G*25' gel equilibrated with water, the flow rate being 20–25 ml./h. Fractions (5 ml.) were collected and protein elution was followed by optical density measurements at 280 mμ on a 'Unicam' *S.P.* 500. The fractions were assayed for antibiotic content. Aqueous solutions containing 1 mg/ml. of the antibiotics were similarly treated.

Protein fractionation. Further examination of the bound fraction from the 'Sephadex *G*25' column was carried out using DEAE-'Sephadex *A*50'. After concentration by ultra-filtration the bound fraction was passed down a jacketed column kept at 10° C and containing 30 ml. of fully swollen DEAE-'Sephadex *A*50' equilibrated with 0·02 M phosphate buffer at *p*H 8·6. Stepwise elution was then carried out with 0·02 M phosphate buffer followed by saline of molarities 0·07, 0·12, 0·18 and 0·3 M, the change-over point being based on the optical densities of the fractions at 280 mμ.

Results

(*a*) *Dialysis.* The results obtained for the degree of protein binding are shown in Table 1. By static methods '*BRL* 1071' is bound 80–90 per cent to the serum proteins; penicillin *G* is much less bound, while 'Ampicillin' is only slightly bound. When examined by continuous dialysis, the final percentages bound were reduced but the reduction in the binding of '*BRL* 1071' was less than with the other penicillins (Table 1).

Table 1

Penicillin	Bound	
	Continuous	Static
Penicillin *G*	14·2 (5)	46·4 (21)
'*BRL* 1071'	41·4 (6)	91·6 (3)
'Ampicillin'	0·9 (3)	10·2 (6)

(*b*) '*Sephadex.*' Typical elution patterns from three penicillins of different binding properties obtained on 'Sephadex' columns are shown in Fig. 1. With the penicillin alone the antibiotic activity is confined to fractions 8–10. With serum alone the protein as determined by optical density at 280 mμ emerged in fractions 4–6. When the incubated penicillin serum mixture was passed down the 'Sephadex' column the protein again emerged in

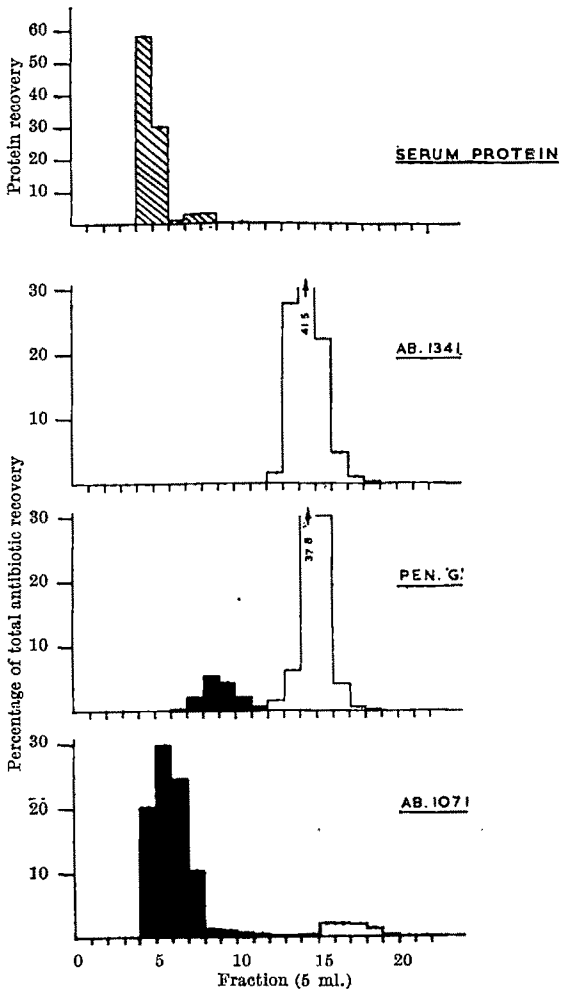

Fig. 1. Elution patterns from 'Sephadex' columns

fractions 4–6, whereas the antibiotic activity showed two peaks, if there was significant binding. One peak was associated with the protein and the other again emerged in the protein-free fractions 8, 9 and 10. The degree of protein binding was then calculated from the antibiotic content of the appropriate fractions. The 'Sephadex' method[2] offers considerable advantages over dialysis methods since the fractionation occurs in less than 2 h, and after a short wash with water the column is ready for further use. The dilution factor of both the bound and unbound material is small, and this aids the sensitivity of the method. The reduction in time needed for the separation of bound and unbound compound is also an advantage when dealing with labile materials.

'Sephadex *G25*' grade has a lower limit for complete exclusion of molecular weights of 3,500–4,500 and is the preferred grade for protein binding studies. With the '*G50*' and '*G75*' grades of different degrees of cross-linkage, the protein peak is flattened and tends to tail into the unbound antibiotic peak.

(*c*) *Protein fractionation.* The bound fraction from the 'Sephadex *G25*' column, on further examination on DEAE-'Sephadex *A50*', gave the bulk of the antibiotic activity in the 0·18 M saline fractions, whereas aqueous penicillin solutions gave a peak of antibiotic activity in the 0·07 M saline fractions with some tailing into the 0·12 M saline fractions. Starch-gel and cellulose acetate electrophoresis was then carried out on the protein fractions. The material eluted with 0·02 M phosphate was found to consist of pure γ-globulin. The other fractions were all multi-component, but the 0·02 M, 0·07 M and 0·12 M fractions contained no albumin and were made up of mixtures of α- and β-globulins. The material eluted with 0·18 M saline consisted almost entirely of albumin whereas the material eluted with 0·03 M saline contained some material of the same mobility as albumin together with a high electrophoretic 'pre'-albumin content. It is evident from this method that the bound penicillin is associated with the albumin fraction of the serum protein.

Discussion

From the results of the three methods described, it is evident that penicillins can differ in the degree and nature of their binding to serum proteins. Static dialysis shows that 'Ampicillin' is slightly bound, penicillin *G* is moderately bound while '*BRL* 1071' is considerably bound.

The nature of the binding of '*BRL* 1071' and penicillin *G* is evident from the results under the different conditions of continuous dialysis and gel-filtration. The binding of penicillin *G* is shown to be of a very loose nature and the binding of '*BRL* 1071' to be very firm. Such differences in binding can affect activity *in vivo*. If a compound is firmly bound to the serum proteins the concentration of free penicillin is reduced and hence its intrinsic activity is reduced. The *in vivo* activity, however, may not be significantly influenced if the binding is of such a loose character that the penicillin is readily available for antibacterial activity. This is the case with penicillin *G* which is bound to the extent of 46 per cent to serum protein yet its activity is apparently uninfluenced by the presence of serum in the same way as a compound, for example, 'Ampicillin' which is only slightly bound. On the other hand, '*BRL* 1071' is very firmly bound and its activity is much reduced in the presence of serum *in vitro* and *in vivo*. Therefore, before conclusions on *in vivo* activity can be drawn from *in vitro* results, information should be available on both the actual degree and nature of the binding to serum proteins.

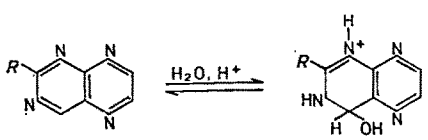
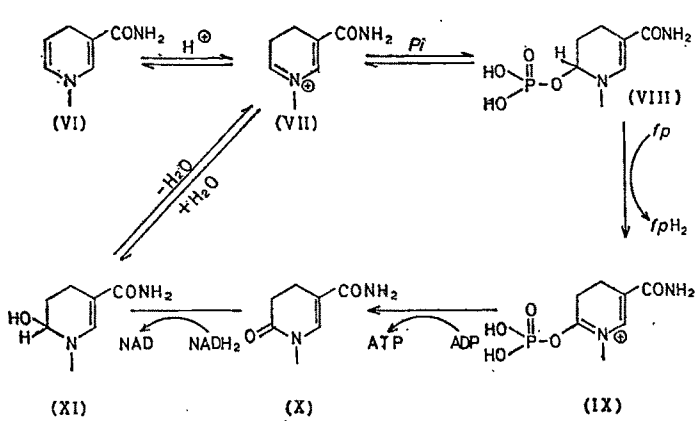
MECHANISMS FOR OXIDATIVE PHOSPHORYLATION AT THE PYRIDINE NUCLEOTIDE/FLAVOPROTEIN LEVEL



By Dr. J. A. BARLTROP, P. W. GRUBB and B. HESP
Dyson Perrins Laboratory, University of Oxford, England

IN respiratory chain oxidative phosphorylation, one molecule of adenosine triphosphate (ATP) is formed during the oxidation of reduced nicotinamide-adenine-dinucleotide ($NADH_2$) by flavoprotein[1]. This article presents chemical evidence for two mechanisms for this process, one involving the adenine ring of $NADH_2$ or of NAD and the other the dihydronicotinamide ring of $NADH_2$. In both mechanisms, it is postulated that part of the NAD ($NADH_2$) of mitochondria is involved in a nucleotide cycle of phosphate activation and transfer and is thus functionally distinct from the rest of the NAD ($NADH_2$) concerned in cellular redox reactions.

For participation of the adenine ring, the following cycle is proposed:



The adenine residue (I) is, in principle, susceptible to nucleophilic attack by phosphate (P_i) in either the 2- or the 8-position. The presence of certain metal ions (M^+) will assist, by chelation, the formation of the 2- or 8-phosphate adduct (for example, II). This step is analogous to the reversible formation of stable hydrates from 2-amino- and 2-hydroxy-pteridine[3,4]:

The oxidation of the phosphate adduct (II) by flavoprotein (*fp*) gives an adenylphosphate (III) which would be expected, by analogy with pyridyl phosphates[5], to be a high-energy phosphate capable of phosphorylating ADP to ATP. Such a reaction would yield the tautomeric 2-hydroxy-6-aminopurine derivative (IV*a*, IV*b*), which might be reduced by $NADH_2$ to the ψ-base (V) and hence to $NADH_2$. The sequence is therefore a cyclic process, one revolution of which generates one molecule of ATP while a pair of electrons is transported from $NADH_2$ to flavoprotein. This mechanism could equally well apply if the pyridinium ring of the molecule were in the oxidized form throughout, in which case (I) would represent NAD instead of $NADH_2$. A similar formulation can also be given for attack of P_i at the 8-position instead of at the 2-position, as shown.

An alternative mechanism, involving the dihydronicotinamide ring of $NADH_2$, is the following:

The acid-catalysed formation of the phosphate adduct (VIII) from $NADH_2$ (VI) via the ion (VII) has analogy in the chemistry of vinylamines. Oxidation of this adduct gives an imidoyl phosphate (IX), and these compounds are known to be high-energy phosphates capable of phosphorylating orthophosphates to pyrophosphates[2]. ATP is formed at this stage. The resulting amide (X) on reduction with $NADH_2$ should give the ψ-base (XI) and hence, by equilibration, (VI), (VII) and (VIII).

The thermodynamic and mechanistic feasibility of the early stages in these mechanisms (up to the phosphorylation step) was investigated using model systems in which compounds containing dihydronicotinamide or adenine rings were allowed to equilibrate with excess P_i and Mg^{2+}, then oxidized and warmed. The isolation of pyrophosphate (PP) was taken as indication that the system was potentially capable of producing the PP link of ATP.

In these experiments, mixtures containing two or more of the components (substrate, Mg^{2+}, and radioactive orthophosphate ($^{32}P_i$) were incubated with KBr_3 solution. Aliquots were applied to Whatman No. 4 paper moistened with 1 N acetic acid saturated with EDTA, then separated by electrophoresis at 20 V/cm for 2–2½ h. The P_i and PP areas were located by the Hanes–Isherwood reagent[6], excised, and the ^{32}P activity in each was counted with a Geiger–Müller tube.

For the first mechanism, adenosine was used as a model compound for NAD.

(i) PP from the Oxidation of Adenosine/P_i Mixtures

Omissions from incubation mixture*	Complete mixture	(−Mg^{2+})	(−Adenosine)	(−KBr_3)
PP/P_i ratio × 10^4	5·84	2·94	0·28	0·24
Yield of PP (per cent)†	2·9	1·5	—	0·12

* Incubation mixture: P_i, 50 μmoles (*p*H 7); Mg^{2+}, 20 μmoles; adenosine, 1 μmole; KBr_3, 50 μmoles. Total volume 320 μl. incubated at 50°–70° for 15 min.
† Calc. on adenosine present.

The experiment indicates that PP is formed in significant yields by the system adenosine/P_i/KBr_3, that omission of magnesium causes a severe drop in yield, and that omission of adenosine or of oxidant brings the yield of PP virtually to zero. The following experiment shows that the yield of PP formed is proportional to the concentration of adenosine present.

(ii) Effect of Adenosine Concentration

Adenosine in incubation mixture*	1 μmole	½ μmole	¼ μmole	0
PP formed in μmoles	0·033	0·017	0·0072	0·00072
Yield of PP (per cent)†	3·3	3·4	2·9	—

* Incubation mixture: P_i, 50 μmoles (*p*H 7); Mg^{2+}, 20 μmoles; KBr_3, 50 μmoles. Total volume 320 μl. Incubated at 65° for 10 min.
† Calc. on adenosine present.

In the experiments so far described, the PP might have been formed not by the mechanism proposed but by some oxidative reaction involving the sugar side-chain. This has been shown not to be the case by the failure to isolate PP when D-ribose is incubated with P_i, Mg^{2+} and KBr_3, and by the demonstration, in the next experiment, that adenine itself gives rise to considerable amounts of PP.

(iii) PP from Adenine

Omissions from incubation mixture*	Complete mixture	(−Mg^{2+})	(−Adenine)	(−KBr_3)
PP/P_i ratio × 10^4	13·4	6·15	0·43	0·009
Yield of PP (per cent)†	6·7	3·1	—	0·0045

* Incubation mixture: P_i, 50 μmoles (*p*H 4·6); Mg^{2+}, 20 μmoles; adenine, 1 μmole; KBr_3, 100 μmoles. Total volume 320 μl. Incubated at 64° for 2½ h.
† Calc. on adenine present.

The following experiment, conducted on 1,4-dihydro-*N*-methylnicotinamide (DHMN) as a model for $NADH_2$, shows that pyrophosphate links are produced by oxidizing the dihydro-compound in the presence of P_i.

(iv) PP FROM OXIDATION OF DHMN/P_i MIXTURES

Omissions from incubation mixture*	Complete mixture	(−Mg^{2+})	(−DHMN)	(−KBr_3)
PP/P_i ratio × 10^4	3·73	3·05	0·54	1·45
Yield of P_i (per cent)†	2·5	2·0	—	0·97

* Incubation mixture: P_i, 50 μmoles (*p*H 4·6); Mg^{2+}, 20 μmoles; KBr_3, 100 μmoles; DHMN, 0·75 μmoles. Total volume, 330 μl. Incubated at 60°–65° for 1 h.
† Calc. on DHMN present.

This experiment shows that significant yields of PP are formed by the complete system, that the yield is reduced slightly by omission of Mg^{2+} and greatly by omission of the other components. The relatively high yield of PP produced in the absence of added oxidant is presumably due to aerial oxidation.

It thus appears that ATP could, in principle, be formed by phosphate addition to, and subsequent oxidation of, the adenine ring of $NADH_2$ or NAD, and also by a similar process involving the dihydronicotinamide ring of $NADH_2$. Both mechanisms are chemically feasible, and that involving the pyridine ring is particularly attractive in view of the work of Griffiths and Chaplain[7], who have isolated from mitochondria a compound which appears to be a phosphorylated derivative of NAD reduced in the pyridine ring and capable of converting ADP to ATP.

Biochemical experiments are in progress to determine which (if either) of these mechanisms is the correct one.

REACTION OF PHENOXY RADICALS WITH METHYL RADICALS IN THE GASEOUS PHASE

By M. F. R. MULCAHY and D. J. WILLIAMS

C.S.I.R.O., Division of Coal Research, Sydney

REACTION of phenoxy radicals with other free radicals can be expected to occur mainly at the 'free electron positions' of the main canonical type-structures:

I II III

but theory is not yet able to predict the relative reactivities of the three positions. We have investigated the relative reactivities towards methyl radicals experimentally by examining the products of the reaction with methyl radicals in the gaseous phase.

Methyl radicals were generated by thermal decomposition of di*tert*-butyl peroxide:

$$[(CH_3)_3CO]_2 \rightarrow 2(CH_3)_3CO\cdot \rightarrow 2CH_3\cdot + 2(CH_3)_2CO$$

and phenoxy and methylphenoxy radicals by hydrogen abstraction from phenol, *o*-cresol and *p*-cresol:

$$(CH_3)_3CO\cdot + RC_6H_4OH \rightarrow RC_6H_4O\cdot + (CH_3)_3\,COH$$
$$CH_3\cdot + RC_6H_4OH \rightarrow RC_6H_4O\cdot + CH_4$$

The reactions were carried out in the temperature-range 445°–547° K at total pressures of 0·35–3·2 cm mercury in the stirred-flow reactor described elsewhere[1]. The liquid products were analysed by vapour-phase chromatography. About 50 per cent of the peroxide was decomposed and an excess of the unreacted phenol was always recovered.

With phenol itself the main liquid products found (apart from acetone and *tert*-butanol) were *o*- and *p*-cresol together with smaller amounts of anisole and 2,4- and 2,6-dimethyl phenol. No *m*-cresol, or mono- or di-hydroxy diphenyls or other phenolic substances could be detected, the detection limits for *m*-cresol and hydroxy diphenyls being respectively 5 and 0·5 per cent of the total cresols. The chief aromatic product from *p*-cresol was 2,4-dimethyl phenol. *o*-Cresol produced mainly 2,4- and 2,6-dimethyl phenol. Both cresols gave smaller amounts of 2,4,6-trimethyl phenol and of the methyl anisole corresponding to the original cresol. Neither produced a significant amount of any compound with methyl substituted *meta* to the hydroxy group: of the total dimethyl phenols produced in each case, *p*-cresol gave less than 0·2 per cent 3,4-dimethyl phenol.

Direct substitution by methyl radicals in the aromatic ring of the phenol molecule is evidently inappreciable under these conditions. This follows, first from the absence of *meta* substitution considered in the light of the nucleophilic character[2] of methyl radicals, and secondly, from the fact[3] that replacement of the hydroxylic hydrogen of phenol by methyl reduces the rate of reaction of the molecule with methyl radicals by an order of magnitude. We therefore conclude that methyl substitution in the ring occurs by combination of a methyl radical with the phenoxy radical at the *ortho* or *para* position (structure II or III), and that this is followed by hydrogen migration to give the *ortho*- or *para*-substituted phenol. Anisoles are formed directly by combination at the oxygen atom (structure I).

Since cresols react much faster than anisole with methyl radicals the relative rates of efflux of anisole and total cresols from the reactor (n_{an}/n_{cr}) must be corrected for secondary methyl attack to obtain the relative rates of formation. It can be shown that:

$$\frac{n_{an}}{n_{cr}} \simeq \frac{k_{ox}}{(k_o + k_p)}\left(1 + \frac{K[CH_3]}{v}\right)$$

where k_{ox}, k_o and k_p are the bimolecular rate constants for methyl addition to the oxygen atom and the *ortho* and *para* positions of the phenoxy radicals, v is the total volumetric rate of flow from the reactor and K is a con-

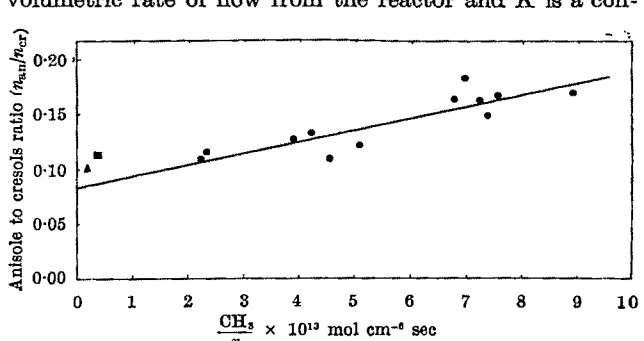

Fig. 1. Variation with $[CH_3]/v$ of relative rates of efflux of anisole (n_{an}) and cresols (n_{cr}) from the reactor. (Line drawn through points at 482° K by method of least squares.) ●, 482° K; ■, 516° K; ▲, 547° K

Table 1. Relative Reactivities towards Methyl Radicals and Relative Free Spin Densities of Reactive Positions of Phenoxy and o-Methyl Phenoxy Radicals

	Phenoxy			o-Methyl phenoxy		
	ortho	*para*	Oxygen	*ortho*	*para*	Oxygen
Relative rate constants	1·1 ± 0·1	1·0	0·17 ± 0·05	0·4 ± 0·1	1·0	0·11 ± 0·09
Relative reactivities of positions	0·55 ± 0·05	1·0	0·17 ± 0·05	0·4 ± 0·1	1·0	0·11 ± 0·09
ESR proton coupling constants (ref. 4) (a_i)	6·6 ± 0·3	10·4 ± 0·5	—	6·0 ± 0·3	11·5 ± 0·3	—
Relative spin densities (Q = 22·5) (ρ_i)	0·63 ± 0·06	1·0	> 0·26	0·52 ± 0·5	1·0	> 0·23

stant. $[CH_3]$ is obtained from the rate of formation of ethane, which is assumed to occur by combination of methyl radicals. Values of n_{an}/n_{cr} obtained from experiments with phenol, in which $[CH_3]$ ranged from 3×10^{-13} to 2×10^{-12} and $[C_6H_5OH]$ ranged from 1×10^{-8} to 6×10^{-7} mole cm^{-3}, are shown as a function of $[CH_3]/v$ in Fig. 1. Extrapolation to $[CH_3]/v = 0$ yields the value 0·08 ± 0·02 for $k_{ox}/(k_o + k_p)$. Values of similar magnitude were obtained from smaller numbers of experiments with the cresols, namely, 0·08 ± 0·06 for the *o*-methyl phenoxy and 0·14 ± 0·045 for the *p*-methyl phenoxy radical.

The relative rates of production of *o*- and *p*-cresol from phenol (n_{oc}/n_{pc}) do not vary significantly with changes in $[CH_3]/v$ (or other conditions). This accords with the relatively small difference in reactivity between *o*- and *p*-cresol[3]. The mean result from twenty-five experiments at four temperatures in the range stated here is:

$$\frac{k_o}{k_p} \simeq \frac{n_{oc}}{n_{pc}} = 1{\cdot}1 \pm 0{\cdot}1$$

The corresponding ratio for the *o*-methyl phenoxy radical obtained from five determinations of the relative rates of production of 2,6- and 2,4-dimethyl phenol from *o*-cresol is, as expected, about half this value, namely, 0·4 ± 0·1.

Taking into account the two *ortho* positions, the relative reactivities of the three distinguishable reactive positions of the phenoxy radical are in the proportion $\frac{1}{2}k_o : k_p : k_{ox}$. The relative values, together with the corresponding (less accurate) result for the *o*-methyl phenoxy radical, are given in Table 1.

It is interesting to compare the reactivities with the free spin densities (ρ_i) at the three positions. Relative values of ρ_i estimated from electron spin resonance measurements made by Stone and Waters[4] are also given in Table 1. The spin densities at the *ortho* and *para* positions were obtained from the relationship $\rho_i = \alpha_i/Q$ where α_i is the proton coupling constant at position i and Q = 22·5 (refs. 5 and 6). The lower limit for the spin density on the oxygen atom was estimated by subtracting the algebraic sum of the densities on the carbon atoms from unity, the values for the *meta* carbon atoms[4] and the (unknown) value for the carbon adjacent to the oxygen atom being taken as negative[7]. There is a clear correlation between reactivity and spin density at the *ortho* and *para* positions. However, it seems that, unless the value chosen for Q is too high, the oxygen position is less reactive than its spin density would indicate. This effect, to which a parallel may be found in the low reactivity of the ('saturated') carbonyl bond towards alkyl radicals, is presumably associated with the electro-negative character of the oxygen atom.

We thank Mr. J. W. Sweeting and Mr. J. Wilmshurst for carrying out the gas-chromatographic analyses.

STABILITY OF THYMIDINE LABELLED WITH TRITIUM OR CARBON-14

By Dr. E. ANTHONY EVANS and F. G. STANFORD

Radiochemical Centre, Amersham, Buckinghamshire

In view of the considerable interest in our recent paper on the decomposition of organic compounds labelled with tritium[1], we now publish a more detailed account of the stability of the important deoxyribonucleoside thymidine, labelled with tritium or carbon-14. Labelled thymidine is one of the most important tracer compounds at present used by research workers throughout the world. The compound is used for labelling the deoxyribonucleic acid (DNA) of proliferating cells and many papers on its use have been published[2]. A knowledge of the stability of the label in such a compound, under both chemical and biochemical environments, is obviously of great importance.

A detailed examination of the decomposition products of tritium labelled thymidine in aqueous solution by self-irradiation is being undertaken in another laboratory[3]. We have therefore confined ourselves mainly to a study of the gross effects of radiation decomposition of tritiated thymidine labelled generally, in the 6-position (predominantly) and in the 5-methyl group (exclusively), and thymidine labelled in the 2-position with carbon-14. As in our previous paper[1], various storage conditions were examined. For comparison, the effect of γ-radiation on solutions of tritiated and carbon-14 thymidine and on freeze-dried tritiated thymidine were also investigated.

Preparation of labelled thymidine. Thymidine-2-^{14}C, -6-T and -5-methyl-T were prepared by enzymatic coupling of the correspondingly labelled pyrimidine base, namely, thymine-2-^{14}C, -6-T or -5-methyl-T respectively, with 2-deoxy-D-ribose[4]. Generally labelled tritiated thymidine was prepared by an isotope exchange reaction between thymidine and tritiated water or tritiated acetic acid in the presence of a platinum catalyst[5]. Such exchange labelling procedures do not give exclusive tritium labelling in the pyrimidine base portion of nucleosides, as has been claimed in earlier papers[6].

Self-decomposition of labelled thymidine. The various ways by which radio-isotopically labelled compounds can undergo decomposition by self-irradiation are now well described[1,7]. In the case of thymidine-2-^{14}C we can neglect the decomposition due to primary (internal) decay of carbon-14 to nitrogen over the period of time we have investigated, due to the very long half-life of carbon-14 (5,680 years). The actual decomposition due to this primary (internal) decay is less than 0·01 per cent per annum. Decomposition products of thymidine-2-^{14}C will

therefore arise through primary (external), secondary or chemical effects. Decomposition products of tritiated thymidine can arise by all the modes of self-irradiation effects[1].

Observations with thymidine-2-^{14}C. Thymidine labelled with carbon-14 specifically in the 2-position of the pyrimidine ring at a specific activity of 18·3 mc./millimole, had a decomposition rate of only 0·9 per cent per annum. This rate of decomposition, examined over a period of almost three years, was found to be the same whether the compound was stored in aqueous solution or as a freeze-dried solid at +2° C or at −40° C. Identical results were also obtained by storage on paper (cf. ref. 7) under the same temperature conditions. At room temperature stored in aqueous solution the thymidine-2-^{14}C gave 1–2 per cent thymine-2-^{14}C per annum. For comparison we kept a sample of thymidine-2-^{14}C in tap water exposed to air and occasional sunlight for 5 months in the laboratory. At the end of this period analysis showed that the radiochemical purity was still 92 per cent and 5 per cent thymine-2-^{14}C was found. This remarkable stability of the carbon-14 labelled thymidine contrasts markedly with the stability of the tritiated compound. A comparison of the decomposition of thymidine-2-^{14}C and thymidine-T(G) (G = generally labelled with tritium in non-labile positions but the labelling is not necessarily uniform) in the freeze-dried state is shown in Table 1.

Table 1. DECOMPOSITION OF FREEZE-DRIED THYMIDINE-2-^{14}C AND THYMIDINE-T(G)

Compound	Specific activity (mc./m.mole)	Activity in ampoule (mc.)	Wt. of thymidine (mg)	Temp. of storage (°C)	Age months	Radiochemical purity (%)
Thymidine-2-^{14}C	18·3	0·1	2·4	−40	33	98
Thymidine-2-^{14}C	18·3	0·01	0·24	−40	33	98
Thymidine-2-^{14}C	16·0	0·01	0·15	0	25	100
Thymidine-T(G)	98	2	4·9	−40	38	60
Thymidine-T(G)	82	2	5·9	−40	36	50
Thymidine-T(G)	82	2	5·9	−40	36	70
Thymidine-T(G)	82	1	2·95	0	36	70
Thymidine-T(G)	261	2	1·83	0	39	65

Observations with tritiated thymidine. The decomposition of thymidine generally labelled with tritium, in aqueous solution, has been previously studied by Murray and Petersen[8]. They found that after 10 months' storage in aqueous solution at +4° C, thymidine-T(G) at a specific activity of 0·55 curies per millimole gave rise to only two decomposition products which were identified as thymine-T(G) and 2-deoxy-D-ribose-T(G). We have confirmed these results by storing thymidine-T(G) in aqueous solution for 39 months at −40° C. Analysis showed that the radiochemical purity of the thymidine-T(G), having a specific activity of 0·26 curies per millimole, at the end of this period was 35 per cent as thymidine-T(G) with 55 per cent of the remaining activity as thymine-T(G) and approximately 10 per cent 2-deoxy-D-ribose-T(G). These results were different from those we obtained on storing thymidine-6-T or thymidine-5-methyl-T in aqueous solution. These specifically labelled thymidines gave relatively small amounts of thymine-T (less than 5 per cent per annum) and mainly a radiation decomposition product(s) of R_F 0·0 on paper chromatography of the specifically labelled thymidine samples in ethyl acetate saturated with phosphate buffer at *p*H 6·0 (ref. 9) as solvent.

The radiation decomposition product(s) exhibited an ultra-violet light absorption spectrum in aqueous solution at *p*H 7·0 similar to thymidine, having a maximum at 267–268 mμ and a minimum at 242 mμ. This compares with the maximum at 267 mμ and minimum at 235 mμ for thymidine under the same *p*H conditions. The spectrum was unchanged in acid solution, but in alkaline solution the spectrum was entirely different from that of thymidine[20]; both the maximum and minimum disappeared and only an inflexion at 275 mμ was observed. However, re-acidification of the solution caused the re-appearance of the maximum at 267 and the minimum at 242 mμ, demonstrating that the decomposition product(s) is not decomposed in alkaline solution. The decomposition product(s) proved quite stable on keeping in aqueous solution at room temperature and remained unchanged after 7 months storage under these conditions. We did not investigate this product(s) further. The decomposition of thymidine-methyl-T and thymidine-6-T at a number of different specific activities, in aqueous solution, are shown in Tables 2 and 5 respectively. We have repeatedly made the observation that thymidine-T appears to undergo more rapid decomposition in the frozen state (0° C and below) than at +2° C and above[1]. Thymine as well as its nucleoside and nucleotide are reported[10] to be much more sensitive to decomposition under ultra-violet irradiation in the frozen state than in solution.

A similar phenomenon seems to apply to decomposition of thymidine-T by self-irradiation. Insufficient decomposition occurred in the case of the thymidine-2-^{14}C to enable similar conclusions to be drawn. The decomposition of freeze-dried thymidine-6-T at a specific activity of 9·5 curies per millimole is shown in Table 3. We were unable to detect any thymine-T formed as a decomposition product in this case, only the radiation decomposition product(s) having R_F 0·0 on paper chromatography in the ethyl acetate–phosphate solvent described here was detected.

Effect of γ-irradiation on labelled thymidine. The decomposition of thymidine labelled with carbon-14 or tritium in aqueous solution on γ-irradiation (2·5 megarads) was as to be expected. Virtually all the thymidine was destroyed during the 30-min irradiation and paper chromatography of the products in ethyl acetate–phosphate as here, gave mainly the radiation decomposition product(s) of R_F 0·0. This product(s) exhibited the same ultra-violet light absorption characteristics as the product(s) isolated from the self-decomposition of thymidine-T or carbon-14. A good correlation between the products formed from self-decomposition and those formed by the radiolysis of inactive thymidine in aqueous solution by X-rays at 0° C have previously been reported[3,11]. We have found that appreciable quantities of thymidine-T survive the γ-irradiation if a free radical scavenger, in this case benzyl alcohol, is present. Some results are recorded in Table 4.

Chemical stability of the label. Chemically, thymidine is a relatively stable substance, and it can be heated in neutral or alkaline solution up to 120° C for at least 1 h without decomposition[5]. This can be used as a method for sterilizing aqueous solutions of tritiated or carbon-14 labelled thymidine. On keeping for long periods in aqueous solution, hydrolytic cleavage of the *N*-glycoside linkage occurs at a rate which increases with increasing temperature of storage. Thymidine is hydrolysed by mineral acids giving thymine and 2-deoxy-D-ribose[17]. The carbon-14 label at carbon-2 is lost only by complete disruption of the thymidine molecule. In contrast, tritium atoms in organic molecules are sometimes lost by exchange with the hydrogen atoms of the solvent in which the compound may be dissolved[14]. This exchange, of course, occurs without changing the chemical form of the compound. However, the tritium atoms in the 6-position and the 5-methyl group of thymidine are firmly bound to the molecule and are not exchanged for hydrogen when the compound is heated in acid or alkaline solution. Only in the presence of a hydrogen transfer catalyst, for example, platinum metal, is the tritium label likely to be exchanged, and then only at elevated temperatures, to any appreciable extent.

Biological stability of the label. Provided the thymidine is not metabolized, the carbon-14 label at C-2 remains intact. Chemically stable tritium atoms may become labile under biological conditions[14,21]. There is at present, however, no evidence to suggest that the tritium label at C-6 or in the 5-methyl group becomes labile and hence

lost by exchange in biological systems. In the presence of thymine oxidase the tritium label at carbon-6 is lost[12], due to the formation of methyl barbituric acid, and in systems where demethylation of the 5-position occurs the tritium label in this position is also obviously lost[13]. Some thought is therefore necessary when selecting the correct position of isotopic labelling for specific investigations.

Conclusions. Thymidine-2-^{14}C is stable for a number of years when stored in aqueous solution below +2° C. The rate of decomposition by self-irradiation under these conditions is less than 1 per cent per annum, but there is no evidence that this state of storage is superior to keeping the compound in the freeze-dried state or on paper[7,16,18]. As no thymine-2-^{14}C could be detected at this storage temperature, the small amount of thymine-2-^{14}C which is formed on keeping the solution of thymidine-2-^{14}C at room temperature is probably produced by slow hydrolysis of the thymidine rather than by radiolytic fission of the *N*-glycoside bond. Table 1 shows that thymidine labelled with carbon-14 is much more stable than the tritiated compound of comparable specific activity, allowing for the difference in the energy of the carbon-14 β-radiation (max. 0·155 MeV) and the tritium β-radiation (max. 0·018 MeV).

In the solid state the self-absorbed energy per unit time for the tritiated thymidine will be greater than for the carbon-14 labelled material, due to the low range and penetrating power of the tritium betas. Primary (external) effects would thus be expected to cause more rapid decomposition in the case of the tritiated thymidine, in agreement with the experimental observations. Thymidine-6-T at high specific activity (9·5 curies/m.mole) stored as a freeze-dried solid, kept better than we had expected. The rate of decomposition in this condition, even at room temperature, is only 20–30 per cent per annum. The freeze-dried compound is less stable when stored at low temperatures, for example, −80° C. We are unable to explain this sensitivity to radiation at low temperatures at the present time.

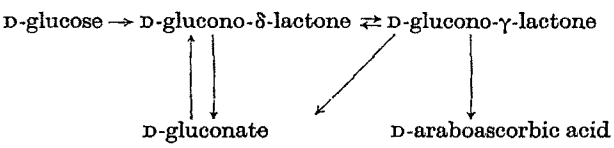
In general, the presence of air in the ampoules did not affect the rate of decomposition.

Even more surprising is the stability of freeze-dried thymidine-6-T to γ-irradiation[15]. Only a few per cent decomposition was recorded, as can be seen from Table 4. No thymine-T or carbon-14 labelled thymine was detected in the decomposition of freeze-dried thymidine-T or carbon-14 respectively, indicating that no appreciable breaking of the *N*-glycoside bond occurs by primary (external) decomposition. Solutions containing thymidine labelled with tritium or carbon-14 cannot be sterilized by γ-irradiation without decomposition of the thymidine, even in the presence of a free radical scavenger. However, in the latter circumstances a high proportion of the compound may survive as is seen from Table 4. The γ-irradiation of thymidine solutions produces at least six different products and the main product(s) has R_F 0·0 in ethyl acetate–phosphate buffer on paper chromatography. This product(s) is similar to the product(s) produced by self-irradiation of labelled thymidine[19]. Weiss and collaborators[19] have shown that pyrimidine ring structures remain intact on irradiation and do not break down into smaller molecules. The ultraviolet light absorption spectrum of our radiation decomposition product(s) would also suggest this although we did not further investigate the product.

The decomposition rates for thymidine-5-methyl-T and thymidine-6-T at comparable specific activities are respectively 0·5–1 per cent per month and 1–2 per cent per month. This rate of decomposition increases when the solutions are stored below 0° C. Thymine-T is formed as a decomposition product even at low temperatures and probably arises by radiolytic fission of the *N*-glycoside bond and not by hydrolytic fission. Analysis of a number of samples of thymidine-6-T kept in aqueous solution by distillation of the solvent showed that less than 5 per cent tritium is 'exchanged' into the aqueous phase on keeping samples for 1 year. This result again supports the view that practically no degradation of the pyrimidine ring occurs forming smaller molecules which may be volatile or 'leak' their tritium into solution by exchange.

Decomposition products will vary to some extent depending on the position of the label within the molecule, which further complicates the interpretation and comparison of such data. The analytical methods used for our radiochemical purity determinations were as previously described[1]. Inactive thymidine was detected on paper

chromatograms with the ultra-violet light from a 'Chromatolite' Engehard Hanovia lamp (ultra-violet-range 250–280 mμ).



We thank Dr. John R. Catch and Mr. D. A. Lambie for their interest and the U.K. Atomic Energy Authority for permission to publish these results.

TRANSFORMATION AND HYDROLYSIS OF D-GLUCONO-γ AND δ-LACTONE

By T. TAKAHASHI and M. MITSUMOTO
Department of Agricultural Chemistry, Tokyo University of Agriculture and Technology, Fuchu

WE[1,2] have proposed the following scheme for the pathway of D-araboascorbic acid synthesis by *Penicillium*:

The theory[6] of the transformation of D-gluconolactones was as follows:

D-glucono-γ-lactone ⇄ D-gluconate ⇄ D-glucone-δ-lactone;

but M. A. Jermyn[3] has reported that lactones transform directly without involving gluconate. We have observed by other methods the direct transformation of these lactones and consider that this reaction would occur during the D-araboascorbic acid synthesis. For the purpose of perfecting this pathway, experiments on transformation and hydrolysis of D-gluconolactones were carried out. As a result, a new scheme is proposed.

D-glucono-δ-lactone (δ-lactone) was given by Fujisawa Pharm. Ind. Co., Ltd. D-Glucono-γ-lactone (γ-lactone) was prepared from δ-lactone by the method of Isbell and Frush[4]. For quantitative analysis of lactones, Hestrin's method[5], slightly modified, was used. The identification of γ- and δ-lactones were carried out by paper chromatography. The following solvent was used: acetonitrile/acetone/water/acetic acid = 80 : 5 : 15 : 1. Hydroxylamine and ferric chloride were used for colour reaction.

(1) *Paper chromatography of lactones.* About 1 mg lactone was added at room temperature in 0·2 ml. of water and N/10 *tris*-maleate buffer solutions of various *p*H. The solution was spotted on the filter paper (Toyo Roshi, Co., No. 51) as soon as δ-lactone was dissolved. The paper chromatograms (Fig. 1) show that γ-lactone (R_F value 0·55) is produced from δ-lactone (R_F 0·35) in *p*H 4·6 or higher and its concentration becomes higher still with *p*H of buffer solutions. In N/10 phthalate–disodium phosphate buffer, which was used for the examination on the pathway of D-araboascorbic acid synthesis by dried cells of *Penicillium*, the same results were obtained. Lactones were not produced from gluconate under the same conditions. Therefore, it is clear that γ-lactone is formed from δ-lactone and not by way of gluconate. This reaction proceeds spontaneously and very rapidly at room temperature. The *p*H of D-araboascorbic acid synthesis from glucose and the lactones coincide roughly with that of this reaction. On the other hand, the formation of δ-lactone from γ-lactone is slight, under the same conditions (Fig. 2). The concentration ratios of both lactones were not seen to change with time.

From these results, the existence of γ-lactone in the broth resulting from gluconic acid fermentation was expected. Fig. 3 shows the paper chromatograms of γ- and δ-lactones in the broth of *Aspergillus niger*, *Penicillium notatum* and *Acetobacter roseum*. The cultural conditions are shown in Table 1. γ-Lactone was not found in the broth of *Pseudomonas fluorescens*. It seems

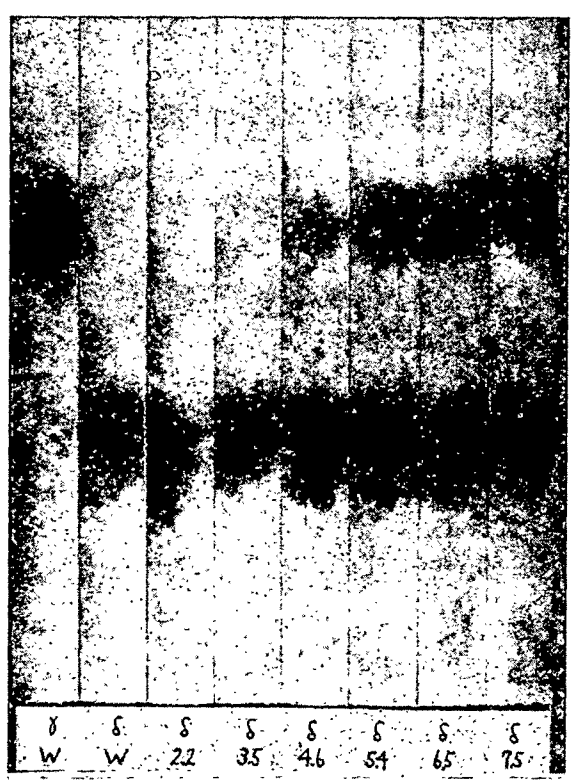

Fig. 1. Paper chromatograms of D-glucono-γ-lactone formation from δ-lactone in various *p*H buffer solutions

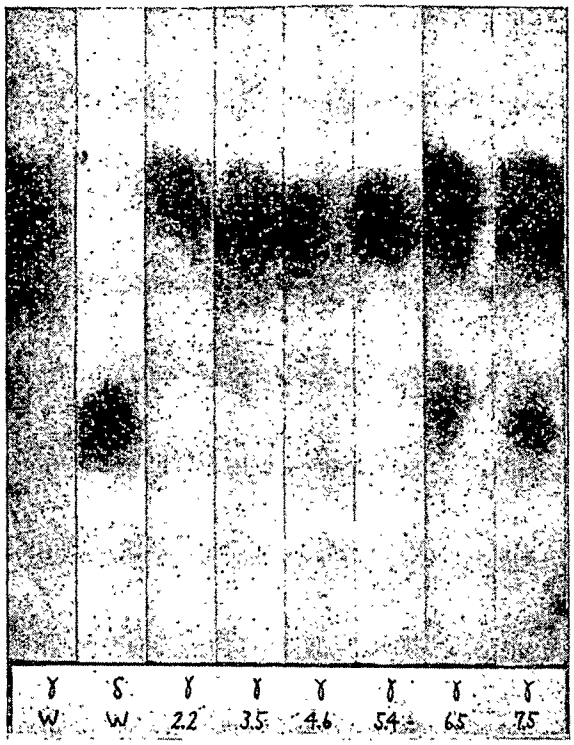

Fig. 2. Paper chromatograms of D-glucono-δ-lactone formation from γ-lactone in various *p*H buffer solutions

γ, D-Glucono-γ-lactone; δ, D-glucono-δ-lactone; *w*, water. Numbers, *p*H of N/10 *tris*-maleate buffer solution

that it was hydrolysed owing to a comparative high end *p*H (*p*H 4·5) of broth.

(2) *Hydrolysis of lactones.* About 10 mg of lactones were dissolved in 10 ml. N/3 *tris*-maleate buffer solution at various *p*H's. All experiments were carried out at 30°. Figs. 4 and 5 are spontaneous hydrolysis curves of γ- and δ-lactones. They show roughly straight lines with slight deviation and no lag period, so both hydrolysis reactions follow a first-order reaction. The deviations do not depend on the accumulation of gluconate or decrease in *p*H of the buffer solution.

Our results coincide with Jermyn's at the point of direct transformation of lactones; but did not at the hydrolysis pathway. Paper chromatograms show that the equilibrium of the transformation between both lactones inclines to γ-lactone and does not to δ-lactone, and that the velocity of transformation is very rapid. During all conditions tested, γ-lactone is more stable than δ-lactone. Therefore, we do not consider that at any *p*H large amounts of δ-lactone accumulate as an intermediate during the hydrolysis of γ-lactone. This opinion is supported by hydrolysis curves.

We propose a new scheme of spontaneous transformation and hydrolysis of D-gluconolactones. The scheme would be applicable in a wide range of *p*H.

‡ Gluconic and 5-ketogluconic acid producer isolated by Dr. T. Asai.

New scheme γ-lactone ⇄ δ-lactone
↖↘ ↙↗
gluconate

Jermyn (below *p*H 7) γ-lactone ⇄ δ-lactone ⇄ gluconate
Accepted γ-lactone ⇄ gluconate ⇄ δ-lactone

This is a scheme in which direct hydrolysis of γ-lactone is added to Jermyn's theory; that is to say, a consolidation of the accepted and Jermyn's theory. According to this

Fig. 3. Paper chromatograms of D-glucono-γ- and δ-lactones in cultural broth of micro-organisms

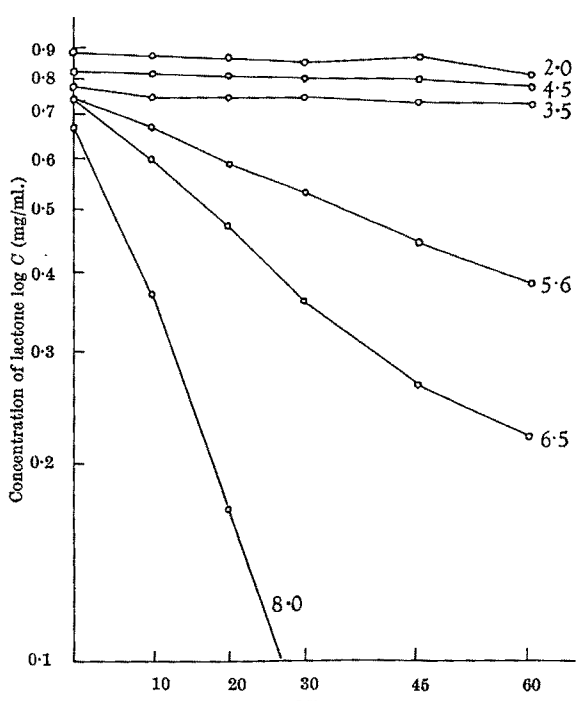

Fig. 4. Hydrolysis curves of D-glucono-γ-lactone in N/3 *tris*-maleate buffer solution of various *p*H, 30° C

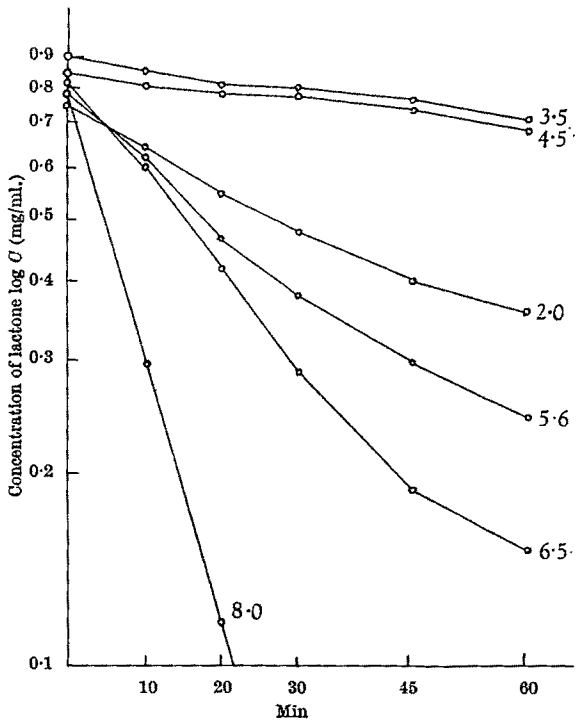

Fig. 5. Hydrolysis curves of D-glucono-δ-lactone in N/3 *tris*-maleate buffer solution of various *p*H, 30° C

scheme, we can reasonably explain the results of paper chromatographs and hydrolysis curves of gluconolactones.

For example, when δ-lactone is added in buffer solution, a part of it transforms to γ-lactone as soon as it is dissolved.

The concentration ratios of γ- and δ-lactone in buffer solution depend on *p*H of solution and initial concentration of δ-lactone. The velocity of transformation is very rapid, so their ratios do not depend on time. Both lactones in solution would be hydrolysed to gluconate, respectively, in first-order reaction. When γ-lactone is added, the formation of δ-lactone is slight at any *p*H. The hydrolysis of gluconolactones, especially δ-lactone in higher *p*H buffer solution, is always accompanied by their transformation (Figs. 1 and 2), and it is difficult to show true hydrolysis curves and their kinetic analysis.

This phenomenon shows that the transformation of lactones in D-araboascorbic acid synthesis is spontaneous and not enzymatic. Of course, we are not able to deny the existence of an enzyme catalysing this transformation. This has yet to be proved.

We thank Prof. B. Maruo and Prof. M. Matsui, University of Tokyo, and members of Takamine Research Institute, Sankyo Co., Ltd., and Tokyo Research Laboratory Fujisawa Pharm. Co., Ltd., for their kind advice.

EVOLUTION OF ETHYLENE BY SUB-CELLULAR PARTICLES FROM TOMATOES AS INFLUENCED BY COMPONENTS OF THE SYSTEM

By DR. G. RAM CHANDRA, PROF. MARY SPENCER and M. MEHERIUK
Departments of Plant Science and Biochemistry, University of Alberta, Edmonton

APART from evidence that energy is required for ethylene production, little is conclusively known about the biogenesis of this gas[1]. Recently we demonstrated that subcellular particles from tomatoes, *Penicillium digitatum*, rat liver and rat intestinal mucosa produce ethylene, and that evolution of the gas *in vitro* is related to the structural integrity of these particles[2–4]. In these investigations the particulate fractions were tested for ethylene production in a reaction mixture containing sucrose, potassium dihydrogen phosphate, magnesium sulphate, manganese sulphate, L-malic acid, adenosine triphosphate (ATP), and diphosphopyridine nucleotide (DNP). In this article, we have evaluated the contribution of this reaction mixture, chosen empirically on the basis of known biochemical properties of mitochondria, towards the production of ethylene by particulate fractions. The effect of temperature on ethylene evolution will be discussed in a later report.

Details of our preparative and analytical procedures have already been described[4,5]. The sub-cellular particles (separated by centrifugation at 35,000*g* for 15 min) were suspended in a reaction mixture and sonicated for 4 min in a Raytheon sonic oscillator (10 kc/s) operated at 1·1 amp and 0° C. When ATP and DPN (both obtained from the Sigma Chemical Co.) were used they were added after sonication. The mixture containing the suspended particles was divided equally and two 25-ml. portions prepared, one being used as a control. All reactions were conducted at room temperature.

The evolution of ethylene by sub-cellular particles from tomatoes as a result of free radical formation during sonication was suggested by Meigh[6]. While artefacts are, of course, a possibility, it should be noted that our preparations of sub-cellular particles produce ethylene not only when they are sonicated but also when instead of being sonicated they are aged *in vitro* or are disrupted mechanically by suspension in a 'Servall Omnimixer' or 'Virtis' homogenizer[4]. Treatment with phospholipase *A* or cholic acid, which affects the permeability and structural properties of mitochondria, also activates the ethylene-producing system[7]. Liberation of fatty acids, which have been implicated in the control of ethane production by sub-cellular particles from apples and tomatoes[6,8], could be expected to occur with the latter treatments as well as during ageing.

In addition to our use of a mercuric perchlorate collection system, whereas Meigh analyses the gases directly,

Table 1. COMPARISON OF ETHYLENE PRODUCTION BY TWO HALVES FROM A SINGLE PREPARATION OF SUB-CELLULAR PARTICLES FROM TOMATOES

Run	Halves	Ethylene, mμl./mg N (total mμl. C_2H_4 evolved, in brackets) 0–1	1–2	2–3	3–20 h
1	*A*	18·2 (153)	1·3 (11)	3·2 (28)	9·0 (76)

Reaction mixture: 0·5 M sucrose, 0·125 M potassium dihydrogen phosphate, *p*H 7·0. *N*, not detectable.

Table 3. Effect of DPN ($3·3 \times 10^{-4}$ M) on Production of Ethylene by Sonicated Sub-cellular Particles from Tomatoes

Ethylene mμl./mg N (total mμl. in brackets)

Time (h)	Run No. 1 +DPN	1 −DPN	2 +DPN	2 −DPN	3 +DPN	3 −DPN	4 +DPN	4 −DPN
0–2	21·7	77·1	36·6	90·0	24·6	50·4	(38)	(106)
2–20	18·6	97·1	40·6	93·7	5·9	33·4	(82)	(11·1)

	5 +DPN	5 −DPN	6 +DPN	6 −DPN	7 +DPN	7 −DPN
0–2	23·5 (141)	15 (90)	42·5 (281)	59·5 (478)	19·2 (251)	11 (143)
2–4	10·5 (63)	*N*	22·6 (150)	*N*	0·5 (7)	0·1 (1·6)
4–16	↓	↓	—	—	6·5 (85)	—
16–17	*N*	*N*	—	—	0·5 (6·3)	1·3 (17·3)

Reaction mixture: runs 1–3, as in Table 1; run 4, as in Table 2, plus ATP ($1·98 \times 10^{-3}$ M); runs 5, 6, 7, as in Table 2. *N*, not detectable.

there are several other important differences in procedure. Meigh[6] adds ATP and DPN before sonication, rather than after, as we do. He uses a 2-h incubation period, whereas we make several consecutive collections extended over a much longer period of time. Meigh also uses an enclosed system for incubation of the sub-cellular particles, whereas we pass a continuous stream of purified air over the particles.

Meigh[6] detected 'measurable quantities' of ethylene when a solution of sucrose (0·5 M) and ATP ($1·98 \times 10^{-3}$ M) was sonically treated. For identification and determination of ethylene he used a gas chromatographic apparatus capable of detecting 0·004 μl. of ethylene per litre of air, in a 1-ml. gas sample. This amount of ethylene can be expected to be present as an air contaminant[5] and under Meigh's experimental conditions about 9 ml. of room air are inadvertently trapped inside the closed reaction vessel. In our collection system we pass a moving stream of purified air over the particulate suspension, and in addition routinely run blanks on room air, purified air and the mercuric perchlorate. Under such conditions we could detect no ethylene production by the reaction mixture in the absence of sub-cellular particles. It should perhaps be noted that Meigh, who can determine 0·004 mμl. C_2H_4/ml. gas sample in comparison with our 0·01 μl./ml., analyses gas from about one-eighth the amount of particles we use, and at such levels possible minor contributions from the sonication process, air contamination, etc., may assume greater importance.

In view of the fact that many steps in the preparation of sub-cellular particles cannot be performed quantitatively, in all our experiments conclusions have been drawn only from comparisons made within the same experimental run. When both halves of a reaction mixture containing sonicated particles from one preparation are treated identically, reasonably comparable amounts of ethylene are obtained during the early periods of production (Table 1 and Table 2, runs 1, 2).

An additional reason for variation in the rates of ethylene production among different experimental runs could be variations in an 'endogenous' production (enzymatic and/or non-enzymatic) of ethylene, independent of the presence of added substrate and co-factors. That this is indeed the case is clear from the fact that ethylene was produced when the particles were suspended only in sucrose–phosphate buffer (Table 2).

Results of experiments evaluating the effects of DPN on ethylene evolution by the sonicated sub-cellular particles are summarized in Table 3. Addition of DPN to mixtures containing ATP (runs 1–4) resulted in a considerable lowering of ethylene production, both during the first 2 h and the subsequent 18-h collection periods. Possibly the presence of DPN promotes the utilization in other reactions of intermediates involved in ethylene production or even the further metabolism of ethylene itself. When DPN was added to particles suspended only in sucrose–phosphate, no consistent effect on the initial evolution of ethylene was observed (Table 3, runs 5–7) as if, in fact, the endogenous production was uninfluenced by the DPN supply.

Results assembled in Table 4 show that ATP enhanced production of ethylene, particularly during *in vitro* ageing. (While the stability of ATP during the entire ageing period may be questionable, other substances formed by virtue of its presence may continue to exert their effects over long periods of time.) These results, illustrating the stimulatory effects of ATP on ethylene production, are consistent with conclusions reached from investigations of the effect of dinitrophenol on ethylene production by whole tomatoes[9] and tissue slices[10].

Table 4. Effect of ATP ($1·98 \times 10^{-3}$ M) on Production of Ethylene by Sonicated Sub-cellular Particles from Tomatoes

Ethylene, mμl./mg N

Reaction mixture	Time (h)	Run No. 1 +ATP	1 −ATP	2 +ATP	2 −ATP
0·5 M sucrose, 0·125 M KH_2PO_4, *p*H 7	0–2	59·2	21·6	34·6	27·7
	2–20	81·6	21·6	59·5	11·9

		4 +ATP	4 −ATP	4 +ATP	4 −ATP
As above, + $MgSO_4$ (10^{-3} M)	0–1	9·3	9·3	59·8	48·2
	1–2	18·6	18·6	↓	↓
	2–20	22·6	*T*	66·4	25·0

		5 +ATP	5 −ATP	6 +ATP	6 −ATP
As above, + $MgSO_4$, (10^{-3} M), $MnSO_4$ (10^{-3} M) and L-malic acid (0·05 M)	0–2	36·0	28·8	35·8	25·8
	2–20	48·0	6·0	53·5	1·3

Reference to results in Table 5 shows that magnesium in the concentrations used in our experiments appears to assist in ethylene evolution, while ethylenediamine tetraacetate inhibited it. Since manganese was precipitated in the sucrose-buffer solution, its effect on ethylene evolution could not be satisfactorily tested.

Table 5. Effect of Mg^{++} and EDTA on Production of Ethylene by Sonicated Sub-cellular Particles from Tomatoes

C_2H_4, mμl./mg N

Time (h)	Run No. 1 +Mg	1 −Mg	2 +Mg	2 −Mg
0–1	58·6	36·5	56·0	39·4
1–2	↓	↓	2·1	2·1
2–20	40·5	24·3	—	—

	3 +EDTA	3 −EDTA	4 +EDTA	4 −EDTA
0–2	24·9	29·6	27·0	36·0
2–20	12·2	26·0	25·0	45·0

Reaction mixtures: Runs 1, 2, 3, as in Table 2, + $MgSO_4$ (10^{-3} M) or EDTA (0·008 M). Run 4, as in Table 1, + EDTA, sodium salt (0·008 M).

These investigations indicate the existence of a complex situation governing the evolution of ethylene by sonicated sub-cellular particles from tomatoes. Initial evolution of the gas on fragmentation of the particles occurs whether they are suspended in sucrose phosphate buffer or in the complete reaction mixture. Certain substrate components do, however, influence the level of ethylene evolution. During ageing, further disintegration of the particles undoubtedly takes place, with possible liberation or production of enzymes, precursors or co-factors necessary for ethylene production.

We thank Mr. T. A. Tribe for assistance.

INHIBITION OF 6-MERCAPTOPURINE-RESISTANT CANCER CELLS IN CULTURE BY *BIS*(THIOINOSINE)-5′,5‴-PHOSPHATE

By JOHN A. MONTGOMERY, GLEN J. DIXON, ELIZABETH A. DULMAGE, H. JEANETTE THOMAS, R. WALLACE BROCKMAN and HOWARD E. SKIPPER

Kettering-Meyer Laboratory, Southern Research Institute, Birmingham, Alabama

ONE of the stumbling-blocks to major advancement of the status of clinical cancer chemotherapy, particularly with respect to the leukæmias and lymphomas, appears to be the development of drug resistance *in vivo*; that is, chemical selection and overgrowth of specific drug-resistant mutant cells from large, originally heterogeneous populations of neoplastic cells.

An effort has been made to gain knowledge at the molecular level regarding the nature of the altered metabolism within specific drug-resistant cells which makes possible their uninhibited growth in the presence of levels of drug which are lethal to the parent, drug-sensitive cells from which they arose. It might be hoped that such basic knowledge would eventually allow for more rational drug design and synthesis aimed at circumventing the specific metabolic mechanisms responsible for, or associated with, resistance to particular classes of chemotherapeutic agents.

It has been demonstrated in a convincing manner that associated with development of cellular resistance to purine antagonists, such as 6-mercaptopurine, 8-azaguanine, 6-thioguanine, 8-azaadenine, 8-azahypoxanthine, 8-azaxanthine, 2-fluoroadenine, and 2,6-diaminopurine, there is often a marked decrease or a loss of the pyrophosphorylase activity responsible for converting the specific purine antagonist to its respective ribonucleotide, presumably the inhibitory form of this class of metabolite antagonists[1–4].

Loss of specific purine ribonucleotide pyrophosphorylase activities represents only one mechanism of resistance to purine antagonists. It cannot be said that such loss of enzymatic activity is the cause of resistance since these biochemical alterations could be only fortuitously associated with resistance to purine antagonists. However, the consistency of the metabolic evidence provided a logical basis for a rational hypothesis. A demonstration that 6-mercaptopurine ribonucleotide is indeed an effective inhibitor of cells resistant to 6-mercaptopurine that lack inosinic acid pyrophosphorylase activity* would strengthen the view that there exists a causal relationship between the loss of this enzymatic activity and resistance to 6-mercaptopurine. Evidence of this nature cannot be obtained readily because purine ribonucleotides, which can be biosynthesized intracellularly or in appropriate cell-free systems, apparently do not gain entry into many types of intact cells[5]. Presumably for this reason 6-mercaptopurine ribonucleotide fails to inhibit cells resistant to 6-mercaptopurine[6,7] even though it does inhibit cells sensitive to 6-mercaptopurine†.

Although the general problem of cell permeability is complex and poorly understood‡, the observations discussed here led to the preparation of a number of derivatives of 6-mercaptopurine ribonucleotide[9,10] in the hope that some of them might be able to penetrate cancer cells and there be split by phosphodiesterase action to 6-mercaptopurine ribonucleotide, thus circumventing the loss of inosinic acid pyrophosphorylase activity in 6-mercaptopurine-resistant cells. Such a result would provide strong evidence for the mechanism of resistance to purine antagonists which has been proposed; such a compound might be an effective inhibitor of neoplasms resistant to this class of compounds provided it was not extensively degraded *en route* to such resistant neoplastic cells.

The cells used in these studies were *H.Ep* No. 2 (Toolan[11]), which are quite sensitive to 6-mercaptopurine and are designated *H.Ep* No. 2/*S*, and a subline of the parent sensitive line, which is approximately 1,000 times more resistant to 6-mercaptopurine than the *H.Ep* No. 2/*S*. The development and characteristics of this resistant line, designated *H.Ep* No. 2/*MP*, have been described previously[12].

Inhibition investigations were carried out following the procedure of Eagle and Foley[13] as modified by the Cancer Chemotherapy National Service Center for cytotoxicity screening in cell culture[14]. Cell growth was measured by the protein determination procedure of Oyama and Eagle[15]. After preliminary studies using serial one-log dilutions of compound, subsequent experiments were carried out using 0·3-log dilutions in order to obtain a more exact ED_{50}. The ED_{50} is defined as that concentration of drug in μg/ml. or μmoles/ml. which will inhibit the growth of cells to 50 per cent of cell control growth.

Simultaneous experiments were carried out with the *H.Ep* No. 2/*S* and *H.Ep* No. 2/*MP* cells and were termin-

* In all experience to date, loss of inosinic acid pyrophosphorylase activity has been accompanied by the loss of capacity to convert 6-mercaptopurine to 6-mercaptopurine ribonucleotide; presumably the same enzyme is responsible for both reactions.

† In this case inhibition is undoubtedly due to cleavage of the ribonucleotide to the ribonucleoside and to the base, which can enter the cells and there be converted to the ribonucleotide.

‡ It is perhaps pertinent to the present work that, whereas sodium D-glucuronate is not metabolized by human beings, the non-ionized glucuronic acid lactone is metabolized. This difference may be due to the ability of the lactone to penetrate the cell membrane and then be hydrolysed to the acid, which can be metabolized intracellularly[8].

ated when cell controls showed an increase in protein of seven- to ten-fold over the initial base line controls. The two cell-lines grow at essentially the same rate (22–24-h generation time) so that it was possible to terminate the experiments at the same time. Experiments were terminated after either 72 h or 96 h. Since 72 h is the minimum length of time for a seven- to eight-fold increase in growth it was sometimes necessary to continue an experiment an extra day in order to achieve the desired growth increase. When it was necessary to continue an experiment the cultures were re-fed with fresh medium containing the proper concentrations of compound.

The syntheses of the compounds used in these investigations, 6-mercaptopurine ribonucleoside[16], 6-mercaptopurine ribonucleotide[17], 2′-deoxy-5-fluorouridylyl (5′→5′) thioinosine, 2′-deoxy-5-fluorouridylyl (3′→5′) thioinosine, and *bis*(thioinosine)5′,5‴-phosphate[10], have all been reported.

Although none of a series of simple ester derivatives of 6-mercaptopurine ribonucleotide[9] showed more than minimal ability to inhibit *H.Ep* No. 2/*MP* cells in culture (G. G. Kelley, unpublished results), three dinucleoside phosphates, 2′-deoxy-5-fluorouridylyl (5′→5′) thioinosine, 2′-deoxy-5-fluorouridylyl (3′→5′) thioinosine, and *bis*-(thioinosine)5′,5‴-phosphate, have proved to be quite effective inhibitors of both *H.Ep* No. 2/*S* and *H.Ep* No. 2/*MP* cells. The inhibitory action of the 5-fluorouracil derivatives could be due simply to their breakdown to 5-fluorouracil, itself an effective inhibitor of *H.Ep* No. 2/*MP* cells. The action of the third compound, *bis*(thioinosine)5′,5‴-phosphate, obviously cannot be explained on a similar basis. Since 6-mercaptopurine, 6-mercaptopurine ribonucleoside, and 6-mercaptopurine ribonucleotide are all ineffective inhibitors of *H.Ep* No. 2/*MP* cells except at high levels, inhibition by *bis*(thioinosine)5′,5‴-phosphate can only occur if this molecule penetrates these cells intact. Inside the cell this compound itself might be an effective inhibitor or its inhibitory activity might result from phosphodiesterase cleavage to 6-mercaptopurine ribonucleotide (Fig. 1), probably the metabolic product of 6-mercaptopurine that inhibits the growth of cells sensitive to 6-mercaptopurine.

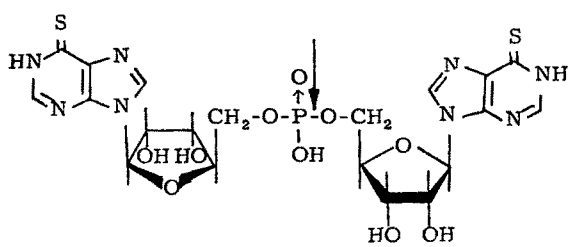

Fig. 1. Possible phosphodiesterase cleavage point of *bis*(thioinosine)-5′,5‴-phosphate

Since in a preliminary experiment at one concentration *bis*(thioinosine)5′,5‴-phosphate showed only minimal activity against *H.Ep* No. 2/*MP* cells[7], repetitive experiments at several concentrations were carried out on two different preparations of this compound. The ED_{50} values determined from these seven individual experiments, given in Table 1, show the reproducibility of this inhibitory effect. In each experiment 6-mercaptopurine was also evaluated to check the degree of resistance of this cell line. *Bis*(thioinosine)5′,5‴-phosphate and 6-mercaptopurine were tested against *H.Ep* No. 2/*S* cells in concurrent experiments, and these results are also given in Table 1. The data from these individual experiments were plotted on semilog paper to obtain the average ED_{50} values for 6-mercaptopurine and *bis*(thioinosine)-5′,5‴-phosphate against *H.Ep* No. 2/*S* and H.*Ep* No. 2/*MP* (Fig. 2 shows the plot for the *H.Ep* No. 2/*MP* cell line). These average values are compared in Table 2 with the ED_{50} values for 6-mercaptopurine ribonucleoside, 6-mercaptopurine ribonucleotide, and the two 5-fluorouracil derivatives. These results indicate that, whereas *bis*(thioinosine)5′,5‴-phosphate is of the same order of effectiveness as 6-mercaptopurine in the inhibition of *H.Ep* No. 2/*S* cells, it is 240 times as effective as 6-mercaptopurine in the inhibition of *H.Ep* No. 2/*MP* cells. (These comparisons are on a molar basis. Since the *H.Ep* No. 2/*S* cells are inhibited by 6-mercaptopurine, 1 mole of *bis*(thioinosine)5′,5‴-phosphate is equivalent to 2 moles of 6-mercaptopurine for the inhibition of this cell line, but not for the *H.Ep* No. 2/*MP* cell line.)

Table 1. Inhibition of Growth of *H.Ep* No. 2/*S* and *H.Ep* No. 2/*MP* Cells in Culture by 6-Mercaptopurine and *Bis*(Thioinosine)5′,5‴-Phosphate: ED_{50} Values from Individual Experiments

* Average of seven experiments (see Fig. 2).
† Non-inhibitory at this, the highest dose tested.

LePage *et al.*[18] have shown that azaserine-induced accumulation of formylglycinamide ribonucleotide (FGAR) was inhibited by purine analogues such as 6-mercaptopurine and 6-thioguanine, presumably by pseudo-feedback inhibition of 5-phosphoribosylamine synthesis. Using this same technique it was found that 6-mercaptopurine and 6-thioguanine inhibited formylglycinamide ribonucleotide formation in sensitive *H.Ep* No. 2 cells in culture but not in sublines resistant to these purine analogues[19]. It was demonstrated previously[20] that the 6-mercaptopurine-resistant cells lacked inosinic and guanylic acid pyrophosphorylase activities and thus lacked the enzymatic capacity to form ribonucleotides from the base analogues. McCollister *et al.*[21] have shown recently that the ribonucleotides of mercaptopurine and thioguanine inhibited the enzymatic synthesis of 5-phosphoribosylamine, the first irreversible reaction unique to purine biosynthesis, and that the free bases and the corresponding ribonucleosides were inactive as inhibitors of this reaction. In view of the observed inhibition of the growth of *H.Ep* No. 2/*MP* cells by *bis*(thioinosine)5′,5‴-phosphate, we were led to examine this compound for its effect on formylglycinamide ribonucleotide formation.

Table 3. Effect of Nucleotide Derivatives of 6-Mercaptopurine on Azaserine-Induced Formylglycinamide Ribonucleotide (FGAR) Accumulation in *H.Ep* No. 2/*MP* Cells in Culture

Inhibitor	FGAR-^{14}C accumulation in the soluble fraction (% of azaserine control)
Azaserine control	100*
+ 6-Mercaptopurine ribonucleotide 0·29 μmoles/ml.†	77
+ *Bis*(thioinosine) 5′,5‴-phosphate 0·14 μmoles/ml.‡	9
0·014 μmoles/ml.	56

* Activity of FGAR-^{14}C = 73,146 counts per minute/10^7 cells.
† Concentration = 131 μg/ml.
‡ Concentration = 93 μg/ml.

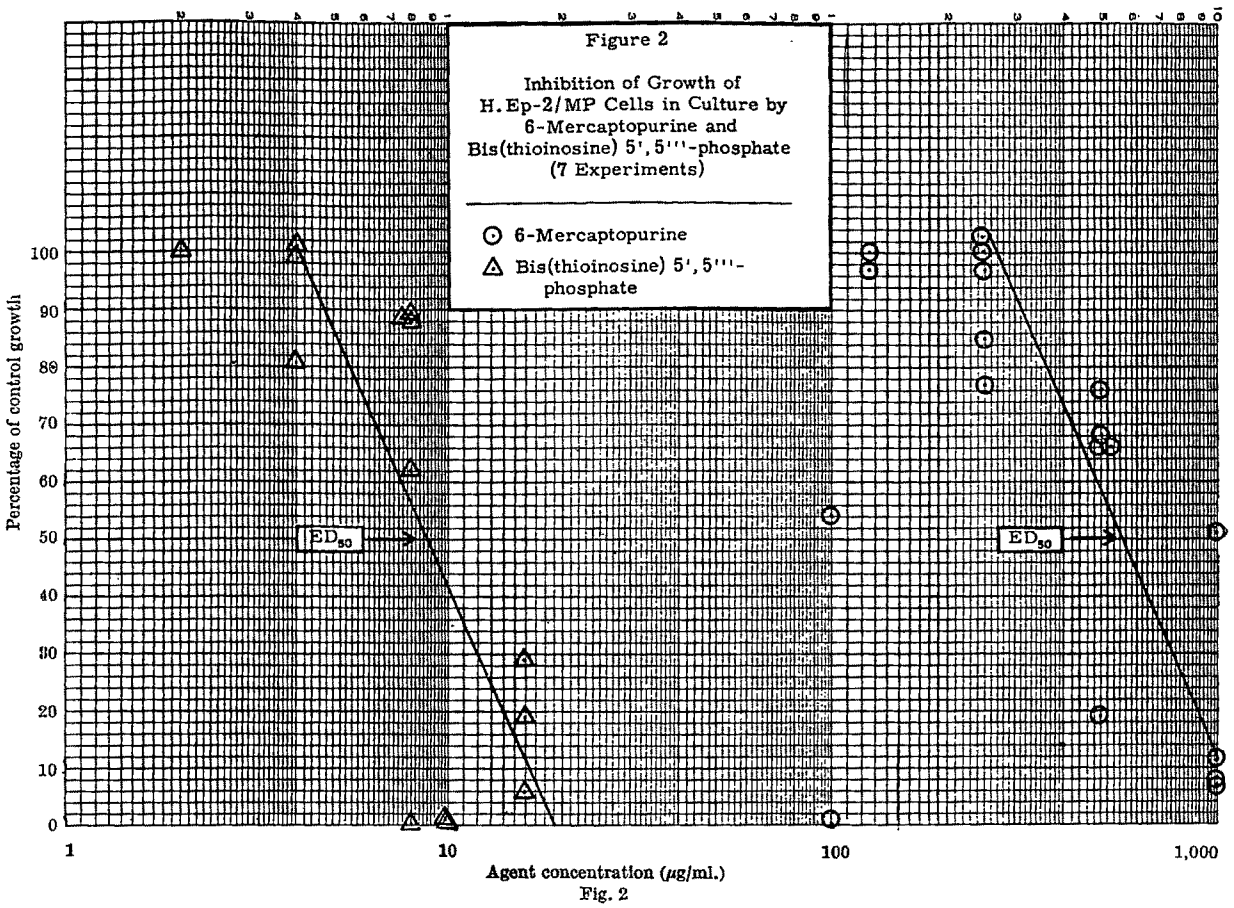

Fig. 2

H.Ep No. 2/*MP* cells in suspension culture were treated with azaserine (10 μc./ml.) followed 1 h later by sodium formate-^{14}C (25 μg/100 ml. culture medium containing approximately 4 × 10^7 cells). 2 h after addition of the radioactive substrate *H.Ep* No. 2/*MP* cells were collected by centrifugation and soluble extracts of the cells were prepared for analysis by two-dimensional chromatography-autoradiography as described previously[20]. The purine nucleotide analogues were added to suspensions of *H.Ep* No. 2/*MP* cells at the indicated concentrations (Table 3) 30 min after the addition of azaserine; 30 min later sodium formate-^{14}C was added, followed 2 h later by collection of cells, as described for the azaserine control culture.

Radioactive FGAR was located on the paper chromatograms by exposure of the paper to 14 in. × 17 in. sheets of X-ray film (Eastman Kodak, single emulsion, blue sensitive) for one week. Quantitative determinations of radioactivity were made by counting disks cut from paper chromatograms in a Packard Instrument Co. liquid scintillation spectrometer by modification of procedures previously described[22].

The azaserine pretreatment of *H.Ep* No. 2/*MP* cells caused significant accumulation of formate-labelled FGAR (Table 3). Addition of a relatively high concentration of 6-mercaptopurine ribonucleotide, 131 μg/ml., resulted in only 23 per cent inhibition of FGAR accumulation whereas *bis*(thioinosine)5′,5‴-phosphate at a molar concentration one-half that of 6-mercaptopurine ribonucleotide caused 91 per cent inhibition of accumulation of FGAR. Even at a molar concentration one-twentieth that of 6-mercaptopurine ribonucleotide the diester phosphate produced 44 per cent inhibition of FGAR accumulation. It might be postulated that *bis*(thioinosine)5′,5‴-phosphate gained entry into the resistant cells where it was afterwards cleaved intracellularly to yield 6-mercaptopurine ribonucleotide. The relative inactivity of 6-mercaptopurine ribonucleotide may be a consequence of extracellular cleavage to the ribonucleoside and the purine base.

Razzell and Khorana[23] found that venom phosphodiesterase hydrolysed thymidylyl(5′→5′)thymidine in addition to cleavage of simple esters of nucleoside-5′-phosphates and certain oligonucleotides. Preliminary results obtained in this laboratory have indicated that venom phosphodiesterase readily cleaved *bis*(thioinosine)5′,5‴-phosphate and, furthermore, that the soluble supernatant fraction prepared by high-speed centrifugation of disrupted *H.Ep* No. 2 cells also brought about hydrolysis of this compound (R. W. Brockman, Sue Chumley and Frank Hays, unpublished observations). In view of previous observations in this laboratory that simple esters of 6-mercaptopurine ribonucleotide were not inhibitory to *H.Ep* No. 2/*MP* cells, it is significant that Anderson and Heppel[24] found that a partially purified leukæmia cell phosphodiesterase was inactive in hydrolysing simple esters of nucleoside-5′-phosphates and that the presence of a nucleoside group on each side of the phosphodiester bond seemed requisite for cleavage by this enzyme.

The results obtained in this work provide good evidence in support of the mechanism of resistance discussed and have encouraged us to pursue the synthesis of a sufficient quantity of *bis*(thioinosine)5′,5‴-phosphate to evaluate this compound against neoplasms resistant to 6-mercaptopurine in experimental animals. Furthermore, in view of the repeatedly observed decrease in the capacity of cells that are resistant to pyrimidine antagonists to form pyrimidine ribonucleotides[25], it will be of interest to evaluate the effectiveness of the *bis*(ribonucleoside)5′,5‴-phosphates of bases such as 5-fluorouracil, 5-bromouracil and 5-iodouracil, and the azapyrimidines against appropriate drug-resistant cells.

CAPACITATION OF RAM SPERMATOZOA AND PENETRATION OF THE OVINE EGG

By P. E. MATTNER

C.S.I.R.O., Division of Animal Physiology, Ian Clunies Ross Animal Research Laboratory, Prospect, New South Wales

THE need for rat and rabbit spermatozoa to spend a "capacitation" period of 2 h and 4–6 h, respectively, in the female genital tract before attaining full fertilizing ability was first demonstrated by Austin[1] and Chang[2]. Capacitation of spermatozoa probably occupies 2–4 h in the hamster[3] but may be developed in less than 1 h in the mouse[4]. The observation by Dauzier and Thibault[5] that fertilization of sheep ova can be achieved *in vitro* with spermatozoa recovered from the genital tract of mated ewes, but not with freshly ejaculated semen, indicates that ram spermatozoa may also undergo capacitation in the genital tract of the ewe. The following observations made at this laboratory on the penetration of the ovine egg *in vivo* support this conclusion.

Laparotomy was performed in multiparous Merino ewes 18–30 h after the observed onset of œstrus. If ovulation had occurred, approximately 0·02 ml. of freshly ejaculated ram semen was deposited in the ampulla of the appropriate Fallopian tube(s). Ewes were killed by intra-cardiac injection of pentobarbitone solution at various intervals after insemination. Eggs were recovered from the Fallopian tubes within 10 min after death and mounted in saline[6].

During preliminary examination by phase-contrast microscopy (× 200 – × 500), eggs were rolled on the slide by slight movement of the coverslip. The tail of a penetrating spermatozoon lying free within the perivitelline space was clearly discernible in unfixed eggs but, until the eggs were fixed and cleared, it was impossible to determine whether or not the head of the spermatozoon had entered the vitellus or was merely attached to the vitelline membrane. Each egg was flooded with 5 per cent formol saline for 2–5 min, washed with saline and fixed and cleared in acetic-alcohol[7] for 2–5 h. Treatment of the eggs with formol saline delayed the breakdown of the zona pellucida and enabled the exact location of the head of the penetrating spermatozoon to be determined in the partially cleared egg while the zona remained intact. When completely cleared of yolk, the eggs were stained for 2–15 h with 1 per cent aceto-orcein prepared according to Ferguson[7]. Excess stain was removed with 45 per cent acetic acid before the eggs were re-examined using bright-field microscopy (× 200 – × 800).

The results of the examination of 44 eggs are shown in Table 1. Spermatozoa were attached to the zona pellucida in every egg recovered. Nevertheless, penetration of the zona pellucida was not found to have occurred until 1·5 h after insemination. It would appear, therefore, that the lower limit of the time required for capacitation of ram spermatozoa in the Fallopian tube of the ewe is approximately 1·5 h.

In all eggs recently penetrated, the entire spermatozoon was contained within the perivitelline space and the head was attached to the vitelline membrane. Active flagellation of the tail of the spermatozoon within the perivitelline space, resulting in oscillatory movements of the vitellus within the zona pellucida, was observed in 3 of the 4 penetrated eggs recovered at 1·5 h and in 2 of the 3 penetrated eggs recovered at 1·75 h after insemination. Movement of the tail of the penetrating spermazotoon was not seen in any of the eggs recovered at longer intervals. As the presence of the head of the penetrating spermatozoon within the vitellus was not observed until

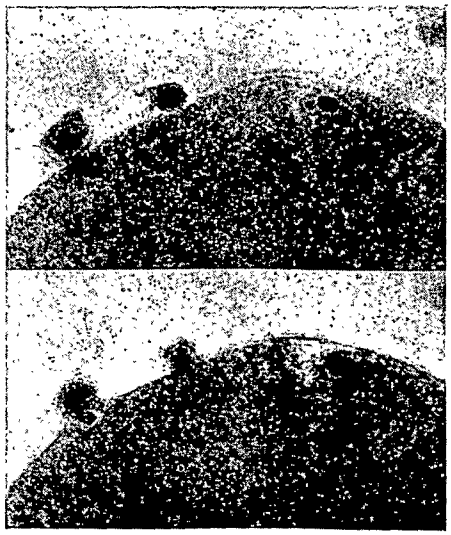

Fig. 1. A fertilized sheep ovum 3·25 h after tubal insemination showing entire spermatozoon within vitellus at the time of abstriction of the second polar body

Top, spermatozoon head deeply stained but showing only slight change in shape and volume; bottom, same ovum: chromosomes aggregated near periphery of vitellus at completion of second maturation division of ovum

Table 1. Examination of Eggs recovered From The Fallopian Tubes of Ewes at Different Times after Tubal Insemination

Time after tubal insemination (h)	No. of eggs				
	Examined	With zona pellucida penetrated	With sperm head within vitellus	With two polar bodies	With two pronuclei
½	3				
1	3				
1¼	4				
1½	5	4			
1¾	3	3			
2	4	4			
2¼	3	3	1		
2¾	4	4	2		
3	3	3	3		
3¼	4	4	4	1*	
3½	4	4	1*	4	3
4	4	4		4	4

* Second polar body abstricted but individual chromosomes in vitellus still distinguishable.

2·5 h after insemination, it is likely that 1–1·5 h is required for the absorption of the spermatozoon head into the vitellus of the ovine egg compared with approximately 30 min in the rat[8] and mouse egg[4].

Spermatozoon heads which were attached to the zona pellucida or were in the perivitelline space did not stain readily, but those that had entered the vitellus exhibited a strong affinity for the orcein stain. However, little change was seen in the size or shape of the spermatozoon head within the vitellus before the second polar body had been abstricted at the completion of the second maturation division of the egg nucleus (Fig. 1). This appeared to take place approximately 0·5 h after the spermatozoon head was absorbed into the vitellus. Thereafter, development of the male and female pronuclei appeared to be rapid. Small but discrete male and female pronuclei were observed in 3 of 4 eggs recovered 3·5 h after insemination and two large pronuclei were present in each of the 4 eggs recovered 4 h after insemination.

VARIATION IN THE SENSITIVITY TO GAMMA-AMINO-BUTYRIC ACID OF DIFFERENT REGIONS OF THE MAUTHNER NEURONE

By Dr. J. DIAMOND

Department of Pharmacology, Harvard Medical School, Boston, Mass.*

Mauthner cells occur paired in the medulla of most teleost fishes and certain amphibia. The cell has attracted the attention of biologists because of its large size, its unusual shape, and the distinctive grouping and morphology of the nerve endings which make synaptic connexions on it (Fig. 1, taken from ref. 1). Furshpan and Furukawa[2] have established a basis for the placing of a microelectrode tip at various predetermined regions of the cell, which lies 1–2 mm below the surface. Their findings thus made it possible to devise experiments to demonstrate regional differences in chemical sensitivity of the Mauthner cell. In this article such differences are described, and tentatively correlated with known morphological and functional features.

Substances were tested by applying them ionophoretically to the cell membrane from micropipettes (tip diameters of 0·5–1·5μ) while recording the internal potential of the resting and excited cell. Attention has been directed, in particular, to γ-amino-butyric acid (GABA) and L-glutamic acid. GABA was passed as a cation from a 4 M solution of *p*H 2·5, glutamic acid as an anion from a 2 M solution, *p*H 7·3 or 8·6. Intracellular electrodes were micropipettes, tip diameters of 0·5–1·5μ, filled with either 3 M potassium chloride or 0·6 M potassium sulphate. Goldfish, initially anæsthetized in 2 per cent urethane, were perfused through the mouth with 0·3 per cent urethane in water, and prepared similarly to those of Furshpan and Furukawa[2]. The head was clamped, the brain exposed and the cerebellum displaced to reveal the dorsal surface of the medulla. Wire electrodes inserted alongside the vertebral column in the tail excited the Mauthner cells antidromically via their large low-threshold axons in the cord. Similar electrodes were inserted through the skull for orthodromic activation of the cells via the VIII nerves in the region of the vestibular apparatus. Initial intramuscular injections of *d*-tubocurarine prevented movements caused by Mauthner cell excitation.

* Present address: Department of Physiology, University College, London.

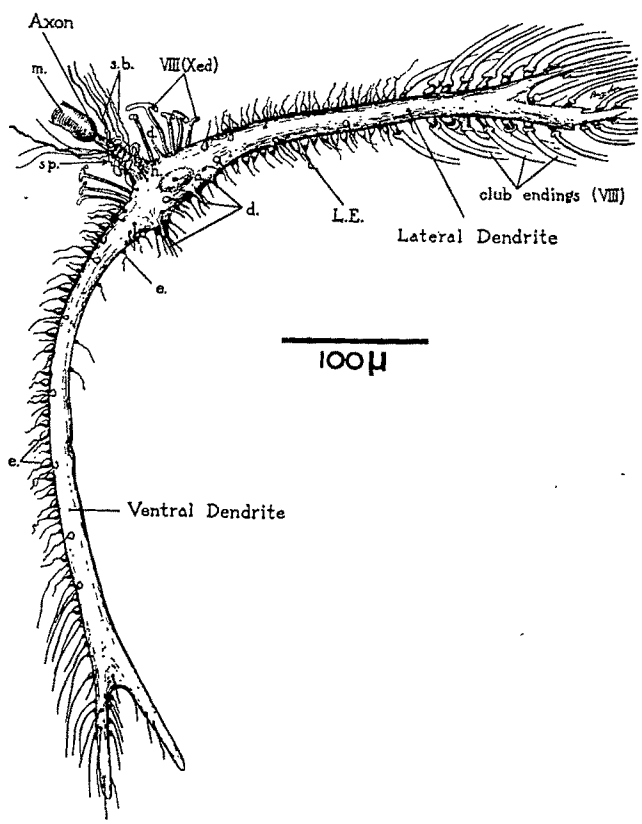

Fig. 1. Semi-schematic representation of the right Mauthner cell and associated nerve endings in the goldfish (reproduced ref. 1). VIII (*Xed*), and *LE*, refer to endings of fibres of the contralateral VIII nerve, though the large end-bulbs (*LE*) may include endings of secondary vestibular fibres (ref. 1). Club endings (VIII) are ipsilateral in origin. *h* = axon-hillock

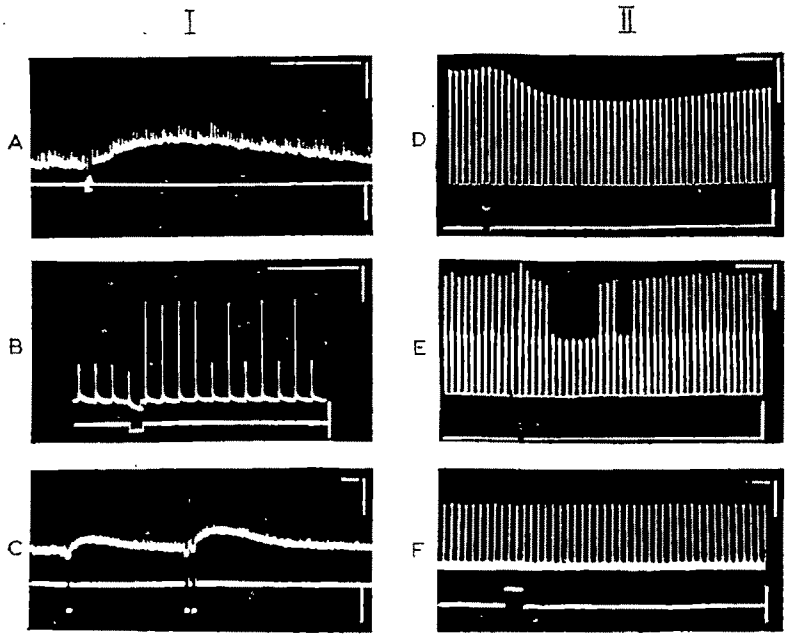

Fig. 2. (I) Effects of L-glutamic acid: (*A*) glutamate pipette at cell body. − current pulse causes downward deflexion on lower trace; (*B*) glutamate applied during sub-threshold ipsilateral VIII nerve stimulation at 10/sec; (*C*) glutamate pulses applied through pipette on lateral dendrite, 550μ lateral to axon-hillock. (II) Effects of GABA: internal recordings with potassium sulphate electrode. (*D*) GABA pipette at cell body. + current pulse (upward deflexion on lower trace) applied during antidromic excitation at 10/sec; (*E*) GABA pulse applied to cell body during orthodromic excitation at 10/sec; (*F*) GABA pulse applied through pipette on lateral dendrite, 400μ lateral to axon-hillock. Vertical bar in *A* = 2 mV; in *C* = 5 mV; in all other records = 20 mV. Horizontal bars = 500 msec in all records. Vertical bar at end of current trace = 10^{-6} amp in *A* and *B*, and 10^{-7} amp in *C*, *D*, *E*, *F*

Micropipette tip positioning was determined as follows. First the axon hillock of the Mauthner cell (which served as a reference point) was located in the medulla as described by Furshpan and Furukawa. The electrode tip lies within a few μ of this point when it records, some 0·5 msec after a spinal cord stimulus, the characteristic highly localized negative spike of 20–50 mV. The electrode, or drug pipette, could then be withdrawn from the brain and moved laterally and posteriorly along the approximate line of the cell body and lateral dendrite for a measured distance, and re-inserted near the desired spot. Re-insertions along an antero-posterior line were continued until the shape and size of the extracellular potential indicated a close positioning to a chosen cell region. The recording electrode was usually inserted into the cell body, while the position of the drug electrode was frequently varied during the course of the experiment. An appropriate 'braking' voltage was applied to this pipette, just adequate to prevent the effects of drug diffusing from the tip[3]. Fig 2*A* shows the effect of glutamate applied just outside the cell body. The addition of sub-threshold EPSP's (evoked orthodromically) to such a sub-threshold response caused the cell to fire (Fig. 2*B*). The effects of GABA applied at the same place are shown in Fig. 2*D* and 2*E*. It diminishes the amplitude of the intracellularly recorded spike (Fig. 2*D*), and can prevent orthodromically evoked firing (Fig. 2*E*, which shows the (reduced) EPSP's remaining when the spikes are blocked). During the effects of GABA there was often no change in resting membrane potential when a potassium sulphate electrode was used, but with a potassium chloride electrode GABA frequently caused a depolarization. It seems, therefore, that GABA acts principally by increasing the membrane conductance to chloride and possibly other ions. In all these respects, GABA closely mimics the effects, described by Furshpan and Furukawa, of the natural inhibitory transmitter. Controls using pipettes filled with hydrochloric acid or sodium chloride plus hydrochloric acid (*p*H 2·0) have shown that these effects of GABA are clearly distinguishable from any due to concomitantly released H^+ ions.

Figs. 2*C* and 2*F* show corresponding records made with the drug pipettes at the distal part of the lateral dendrite. This region of the cell shows a striking difference from the cell body in its sensitivity to GABA, but not to glutamate. That this difference was not due to difficulty in placing the GABA pipette tip close to the membrane was shown by the results obtained with double-barrelled pipettes (tips totalling 1–4μ), having GABA in one barrel and glutamate in the other. The response to glutamate was a critical indicator of the proximity of the tip to the membrane, and was a convenient one to use, since it was followed by little or no desensitization. It was always possible to find a 'critical' pipette position, which gave responses to glutamate like those of Fig. 2*A* and *C*. This position must have been fairly close to the membrane, for small movements often resulted in penetration of the cell, and the response to glutamate was very sensitive to electrode shifts of only a few μ. In regions sensitive to GABA, the position for optimum GABA response coincided with this position for optimum response to glutamate. Using this method for positioning double-barrelled pipettes at the cell surface, systematic surveys were made of the distribution of sensitivity to the two substances. The results of the most complete mapping experiment are shown in Fig. 3 in which the 'threshold charge' (that required for a just-detectable response), for glutamate and GABA applied successively, is plotted for various distances along the cell up to 400μ from the axon-hillock. Each point represents a critical located position as described above. Large current pulses introduce errors due to local *p*H changes, and to diffusion of drug to adjacent regions; therefore the sensitivity to GABA of the distal region is likely to be over-estimated. An internal electrode within 75μ of the distally located drug pipette

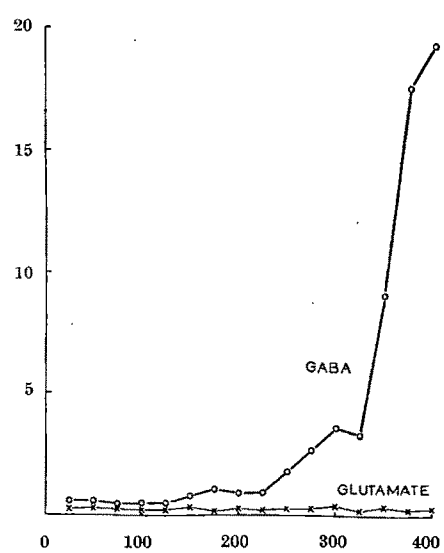

Fig. 3. Sensitivity of cell body-lateral dendrite regions of Mauthner cell to GABA and to L-glutamic acid. See text for explanation. Ordinate, threshold charge (coulombs × 10^{-8}), Abscissa, distance (μ) lateral to axon-hillock, which is at the origin

also failed to detect a significant response to GABA, that to glutamate being normal. The threshold charge for glutamate was remarkably constant, not only from one region to another (Fig. 3), but even from cell to cell.

The conclusion from these results is that while the Mauthner cell membrane is uniformly sensitive to glutamate there is a regional variation in sensitivity to GABA, the action of which mimics that of the natural inhibitory transmitter. This variation may be correlated with other known features of the cell. The GABA-insensitive region corresponds with that which receives the large-club endings of the ipsilateral VIII nerve (Fig. 1, which was not corrected for shrinkage; this must have been in the region of 30 per cent (Bodian, personal communication)). These endings are almost certainly excitatory[2]. On the other hand, the axon-hillock, cell body, and probably the proximal part of the lateral dendrite—the regions where GABA has an inhibitory effect—receive fibres from the contralateral VIII nerve[1]; stimulation of this nerve inhibits the Mauthner cell, probably directly[3].

This work was carried out while I was a Fellow of the U.S. National Multiple Sclerosis Society. Travel to and from the United States was supported by the Wellcome Trust, with a Wellcome research travel grant.

SINGLE-CELL ISOLATION AND PRESERVATION OF BACTERIAL CULTURES

By Prof. J. E. DeVAY and W. C. SCHNATHORST
Department of Plant Pathology, University of California, Davis, and U.S. Department of Agriculture, Agricultural Experimental Station, Davis

CULTURES originating from single cells are usually recognized as a minimum precaution to ensure culture purity in studies on bacterial variation and transformations; moreover, derivatives of these clones isolated as single cells often increase the confidence in the results of such investigations. Frequently the difficulties encountered with direct methods, where single cells are seen before isolation, have encouraged the use of simpler indirect methods where single colonies used for isolations are assumed to arise from single cells.

The poured-plate technique, an indirect method, is probably used most commonly because of its speed and simplicity. McNew[1] has presented evidence to support the assumption that, with the poured-plate technique, colonies can be selected that have single cells as their origin. However, several authors[2-6] have pointed out or demonstrated the inadequacy of this method for single-cell isolations. In a comparison of the poured-plate method with a direct method involving mechanical manipulation, Riker *et al.*[7] found they could not separate the cells of *Agrobacterium tumefaciens* (Smith and Townsend) Conn. and *Agrobacterium rhizogenes* (Riker *et al.*) Conn., from a mixed culture using poured plates whereas the bacteria were separable by the direct or mechanical method.

Hildebrand[4,5] has classified the direct methods for isolating single cells into two categories, semi-mechanical and mechanical. The semi-mechanical procedures, although not considered as precise as the mechanical methods, have been used effectively[4,5]; they usually involve the use of a microscope to locate a single cell or a gelatin or agar surface. The location of the cell is marked and when a small colony has developed a transfer is made to an appropriate medium, or the cell may be transferred immediately along with a small amount of medium on which it is resting. The mechanical method commonly utilized is essentially the same as that introduded by Barber[8]. A micromanipulator equipped with a needle or micropipette is used to handle directly an individual cell and to effect its isolation usually into a microculture chamber. The special equipment and skill that are required to use such a method effectively have minimized its use. Thus the need for a method of handling a bacterium directly with the precision of a micromanipulator and the simplicity of a semi-mechanical method has been apparent.

In 1954, Lederberg[9] described a modification of the de Fonbrune oil-chamber technique, a method the features of which approach the desired simplicity and ease of use. The surface of a ruled glass slide is layered with mineral oil and, by means of a capillary pipette, microdroplets containing bacterial cells are deposited under the thin layer of oil. The drops, which spread to a diameter of 0·1–0·2 mm, are examined microscopically. Those that contain a single bacterium are either recovered immediately by flushing them repeatedly in and out of a capillary pipette with subsequent transfer to a suitable medium, or they are left to incubate until a large bacterial clone develops.

Frequent use of Lederberg's[9] technique in examination of plant pathogenic bacteria has resulted in further modifications reported here that have improved its ease of use and effectiveness without the loss of its simplicity. Additional data are presented on the preservation of bacterial clones in distilled water, adapted from the method of Kelman[10,11], in which long-term storage is accomplished with preservation of desired traits such as pathogenicity.

Isolation of single bacterial cells. A major difficulty often encountered in the method described by Lederberg[9] was the spreading of the droplets under the oil on clean glass slides until their definition was lost and recovery of single cells was impossible. On occasion when the droplets were found that contained single bacterial cells, only small amounts of them could be aspirated into capillary pipettes because they adhered to the surface of the glass slides, often resulting in the loss of the bacterial cell; better results were achieved when the slides were first coated with silicone. Later it was found that 'Plexiglass' (acrylate and methacrylate resin) slides provided an ideal surface without the use of silicone on which the droplets retained a desired form under the oil and could be examined critically with the microscope.

Moreover, the use of spherical droplets rather than spreading or flattened droplets enabled the operator to work with droplets 50–70μ in diameter that could be viewed in their entirety in each plane during search of the droplet with low-aperture objectives. Flattened droplets 0·1–0·2 mm in diameter, although allowing use of phase or dark-field microscopy, required a shift in gaze to search different quadrants in each plane of the droplet and increased the possibility of overlooking one or more additional bacterial cells. It was also found that heat sterilization of the mineral oil gave assurance of an aseptic system and did not affect the viability of single cells of *Agrobacterium tumefaciens*, *Pseudomonas syringae*, van Hall, or *Xanthomonas malvacearum* (Erw. Smith) Dowson.

Materials. (*a*) Bacterial cell dilutions are prepared from cultures 10–12 h old grown in 5 ml. of nutrient broth and seeded with a loop of cells from an agar slant. Dilutions are made in nutrient broth beginning with a sample withdrawn from the centre of the broth culture until a dilution is obtained that yields 1 or 2 cells per microdrop.

(*b*) Microscope slides 7·5 × 2·5 cm are cut from 'Plexiglass' stock, 3 mm thick. A grid of 5 mm squares is scratched on the top of the slides leaving a margin of approximately 5 mm. The slides can be used repeatedly and are sterilized in 70 per cent ethanol, then dried in sterile Petri dishes at 45° C.

(*c*) A heavy mineral oil, non-medicated, is dispensed into a 125-ml. Erlenmeyer flask and sterilized by heating on a hot plate for 2 h at approximately 300° C. A glass rod inserted in a cork makes a convenient applicator.

(*d*) Capillary pipettes are drawn from glass tubing (2 mm inside and 3·5 mm outside diam.). Pieces approximately 6 in. are fire polished on both ends then heated in the centre and drawn to give a capillary 4–5 in. long and about 0·5 mm in diameter. The pipettes are cut apart and then the capillaries are heated about 0·5 in. from the larger diameter section and drawn to a smaller size. The fine capillary can best be drawn after heating the larger capillary in a flame about 1/8 in. long. An eye-dropper with a small tip makes a convenient burner. The fine capillary should be about 1 in. long and have a bore about 50μ in diameter for making droplets of approximately the same diameter. Frequently capillaries are drawn with a bore of about 100μ; these pipettes are useful for recovering the droplets containing a single bacterium. The pipettes are plugged with cotton and sterilized by autoclaving them at 121° C for 15 min.

(*e*) Rubber tubing 2 ft. long (3 mm inside and 4 mm outside diam.) is used to control the deposition of droplets on to the slides and also for their recovery.

(*f*) A microscope equipped with a 5-power objective and an eyepiece micrometer is used when depositing the droplets with bacteria on the 'Plexiglass' slides (Fig. 1). The microscope stage should be level to prevent movement of the oil layer and the droplets.

(*g*) A level surface on which to rest the 'Plexiglass' slides is used when the thin layer of oil is applied to the area over the grids. Drawing a line with a wax pencil around the margin of the slide's surface will prevent the oil from flowing over the edge of the slide if it is not level.

(*h*) Also needed are nutrient agar slants or other substrates that are best for culturing the single cells.

Method. Approximately 1 ml. of mineral oil is placed on the surface of a 'Plexiglass' slide and spread over the area above the grid scratched on top of the slide. The slide is then positioned on a level mechanical stage. A small sample (50 μl.) of the dilute bacterial suspension is taken up in a capillary pipette the delivery of which is controlled using a length of rubber tubing extending to the operator's mouth.

Holding the pipette in a stationary lateral position with the hand resting on the corner of the stage, the tip of the pipette is then positioned just above the oil layer and over a square on the slide's grid (Fig. 1). A high aperture objective (× 5) allows ample working distance and sufficient resolution so that the pipette can be manipulated and the tip dipped into the oil. With slight air pressure a microdroplet is delivered into the oil layer and the tip of the pipette is then raised just out of the oil. Without moving the pipette further, another square is positioned under the pipette's tip by means of the mechanical stage and the process is repeated until several droplets have been deposited under the oil. The droplets, about 50μ in diameter, will settle to the surface of the slide and retain a spherical shape. Under bright field, the droplets are then examined for the presence of bacteria using a low aperture objective (× 43). By focusing through the droplet, each plane is seen in its entirety and the bacterial population is determined. If more than one cell is present

Fig. 1. Deposition of broth microdroplets on a 'Plexiglass' slide. A capillary pipette is attached to a rubber tube extending to the operator's mouth. The high-aperture objective (× 5) is useful during this manipulation. After the droplets are deposited under the layer of oil on the slide they are examined for single cells with a low-aperture (× 43) objective

per droplet, the dilution of the bacterial suspension is adjusted to give 1 cell per droplet, and a new series of droplets are deposited under the oil.

When droplets are found that contain a single cell they are immediately recovered and transferred to a nutrient agar surface or other substrate favourable for their growth. For recovery, a capillary pipette the tip of which was too large (approximately 100μ) for delivering the original droplet, is charged with about 50 μl. of sterile broth. With the same procedure used in delivering the droplet, the tip of the pipette is brought up to the droplet and the droplet is gently aspirated into the pipette. The contents of the pipette are then transferred on to an agar surface as a series of small droplets. Within 3–4 days a microcolony should be evident.

Preservation of single-celled clones. A simple procedure for preserving the resulting single-celled clones consists of allowing the colonies to develop until a loop (2 mm diam.) of the cells can be transferred to 5 ml. of sterile glass-distilled water in a screw-cap tube. The cells are then dispersed in the water and the tubes are stored at 10° C. When subsequent transfers are needed, a loop of cells from the water suspension is streaked on nutrient agar and the tube re-stored. Hundreds of transfers are thus possible from the tube in which the initial population of cells was stored. So far this method of storage has been found suitable for *Corynebacterium insidiosum* (McColloch) Jensen, *Agrobacterium tumefaciens* and *Pseudomonas* sp.

One hundred single-celled isolates of *P. syringae* originally obtained from soil and diseased plants were stored in this manner in March 1961. At the time of storage and following at 6-month and 20-month intervals, populations of the viable cells were determined. The results of these tests on 15 representative isolates are given in Table 1. The pathogenicity of the isolates on peach seedlings and their production of a wide-spectrum antibiotic was not lessened after 20 months in storage.

In an earlier investigation 1 culture of *A. tumefaciens* and 9 cultures of *P. syringae* were stored in 5 ml. of sterile distilled water at room temperature that varied from 22° to 32° C. After 40 and 30 months, the cultures of *A. tumefaciens* and *P. syringae*, respectively, showed no marked decrease in cell viability or change in pathogenicity.

Discussion

It is generally accepted that the poured-plate method of isolating single cells is frequently unsatisfactory because: (1) bacterial cells tend to clump naturally; (2) cells often occur in pairs; (3) agar has an agglutinating effect on the cells; (4) single cells of some bacterial species will not grow in agar. With this method, it is assumed that certain individual colonies have developed from single cells. Thus it is a gamble and never gives the assurance of single-cell origin that is obtained with mechanical methods where the single cell is observed before isolation. Although the disadvantages of the poured-plate method are apparent, the method is still widely used because of its simplicity and speed when compared with other methods requiring more equipment and skill.

The method described in this report most closely approaches the simplicity and accuracy required of a technique for isolating viable single cells. It overcomes the disadvantages of manipulations encountered with the method described by Lederberg[9] and gives better assurance of single-cell isolation.

Other advantages and checks on accuracy absent in other methods include, first, the use of droplets that retain a spherical shape and are about 50μ in diameter. Such droplets enable the operator, during microscopic examination, to scan them vertically without shifting the eyes to search a droplet in different areas of each horizontal plane. Secondly, the entire droplet can be easily recovered immediately after it is found to contain a single cell. Thirdly, by delivering the recovered droplet, mixed with additional broth, as a series of separate drops on an appropriate medium, an additional check on the cell population of the recovered droplet is obtained; usually if an additional cell were present, it would give rise to another colony. Although droplets containing more than one cell are rejected, this manner of transferring the recovered droplet constitutes an additional check. The number of isolated single cells of *Agrobacterium tumefaciens*, *Pseudomonas syringae* and *Xanthomonas malvacearum* that were viable was approximately 4 or 5 out of 6 in each series. In our experience this is much above the ratio of viable cells isolated with other mechanical methods probably because with other methods the cells are lost during the recovery and transfer procedure. The potential use of this method in the purification of other microbial forms is apparent.

In regard to the preservation of bacterial cells, layering cultures with mineral oil, lyophylization or the storage of cultures at low temperatures on agar slants, are methods commonly used. Often, however, these methods are overly time-consuming and inconvenient. A rapid decline in cell viability or a subsequent loss of cells having desired characters such as pathogenicity due to selection pressures of the substrate or storage method may also occur.

Table 1. VIABILITY OF CELLS OF *Pseudomonas syringae* AFTER STORAGE IN DISTILLED WATER AT 10° C

Isolate	Viable cells/ml. Zero time	6 months	20 months
B-3	$1{\cdot}0 \times 10^8$	$2{\cdot}0 \times 10^5$	$8{\cdot}1 \times 10^8$
B-15	$5{\cdot}5 \times 10^7$	$1{\cdot}3 \times 10^5$	$9{\cdot}5 \times 10^5$
B-59	$1{\cdot}2 \times 10^8$	$5{\cdot}4 \times 10^6$	$1{\cdot}3 \times 10^7$
B-60	$2{\cdot}7 \times 10^8$	$3{\cdot}0 \times 10^6$	$8{\cdot}8 \times 10^6$
B-61	$1{\cdot}1 \times 10^8$	$1{\cdot}4 \times 10^6$	$1{\cdot}3 \times 10^8$
B-68	$3{\cdot}5 \times 10^8$	$2{\cdot}9 \times 10^6$	$1{\cdot}9 \times 10^8$
B-70	$3{\cdot}6 \times 10^8$	$8{\cdot}4 \times 10^6$	$8{\cdot}6 \times 10^7$
B-98	$7{\cdot}4 \times 10^8$	$5{\cdot}8 \times 10^5$	$9{\cdot}3 \times 10^7$
B-99	$1{\cdot}0 \times 10^9$	$1{\cdot}2 \times 10^6$	$4{\cdot}1 \times 10^8$
B-100	$9{\cdot}6 \times 10^8$	$2{\cdot}4 \times 10^6$	$4{\cdot}2 \times 10^7$

B-105	$8{\cdot}7 \times 10^8$	$2{\cdot}3 \times 10^7$	$7{\cdot}6 \times 10^7$
B-123	$4{\cdot}4 \times 10^7$	—	$3{\cdot}2 \times 10^9$
B-124	$7{\cdot}7 \times 10^7$	$2{\cdot}0 \times 10^4$	$2{\cdot}4 \times 10^5$

Recently, the use of sterile glass-distilled water as a storage medium has overcome many of the disadvantages of other methods and appears to be an ideal way of maintaining and preserving bacterial cultures[10,11]. No special facilities are needed for its use, and large numbers of cultures can be quickly processed. Reconstitution of cultures can be accomplished repeatedly with a random and representative sample of cells each time. So far the method has been extended to relatively few bacteria, but it has proved effective for *Agrobacterium tumefaciens*, *Corynebacterium insidiosum* and *Pseudomonas* sp. In the work recorded here, 100 isolates of *P. syringae* were stored at least 20 months with little or no decrease in viable cells. The stored cells also retained their pathogenicity and the ability to synthesize a wide-spectrum antibiotic. An increase in the number of viable cells was frequently observed in the stored populations. This may be explained by the manner in which the cells were suspended in the water before they were sampled. When sampled originally and after 6-months storage, the cells were suspended by swirling the contents of the tubes by hand motion, whereas the sampling at 20 months was made from cell populations agitated on a 'Vortex, Jr.' mixer.

No marked decrease on cell viability was evident from temperature fluctuations and the temperatures of storage within the limits of these experiments.

Investigations are now in progress on the physiological changes in cells that occur during their long-term storage in distilled water.

DIFFERENCES IN THE UTILIZATION OF TRITIATED LEUCINE BY SINGLE NEURONES IN NORMAL AND EXERCISED RATS: AN AUTORADIOGRAPHIC INVESTIGATION WITH MICRODENSITOMETRY

By DR. JOSEPH ALTMAN

Psychophysiological Laboratory, Massachusetts Institute of Technology

IT is commonly believed, though not adequately established, that the neural control of specific behavioural processes is dependent on the activity of circumscribed and localizable brain regions. In an attempt to verify this belief, various techniques have been devised to correlate changes in the physiological condition or behavioural activity of experimental animals with concomitant alterations in the functioning of the brain. One common procedure is the recording of changes in the electrical activity of the brain as a consequence of such

variables as sleep, induced sensory activity, drug action and the like. A less-common but relatively old approach is the cytological one, which attempts to correlate changes in the appearance or staining property of nerve cells in specific regions of the brain with prior manipulation of the physiological state or behaviour of the animal. The attempt to investigate functional brain localization by means of a morphological technique was prompted by Nissl's[1] demonstration, and subsequent confirmation by others, of chromatolytic changes in neurones as a consequence of such pathological processes as severance of the axon (retrograde degeneration) or structural de-afferentation (transneuronal degeneration). Can cytological changes be demonstrated in nerve cells as a consequence of behavioural activation or inactivation ? Several investigators[2–5] stimulated one eye of animals photically and blindfolded the other, and then compared the size and staining properties of retinal cells of the 'activated' eye with the 'inactivated' one. Unfortunately, the majority of investigators failed to obtain reliable results[6]. By now it is generally accepted that staining with conventional Nissl stains is not sufficiently sensitive or reliable for the demonstration of chromatophilic changes, if any, produced by normal physiological or behavioural activation[6–8]. More recently some investigators have introduced better stains[9] or applied direct biophysical techniques[10,11] to demonstrate changes in the nucleic acid and protein concentration of 'activated' nerve cells[12–17]. These results, however, have also been criticized[18,19].

Though we cannot rule out the possibility that alterations in the activity-level of neurones are accompanied by structural changes, a more promising approach to the problem may be the investigation of transient metabolic changes accompanying activation or inactivation. This rationale may underlie the recent attempts of Hydén *et al.*[20,21], using microchemical assaying procedures on single nerve cells in 'activated' animals, to show alterations in the concentration and composition of nucleic acids and proteins. Another promising approach, which we have used in this work, is the *in vivo* administration of radioactively labelled metabolic precursors, combined with fine-resolution autoradiography for accurate localization of the sites of altered metabolism. The use of autoradiography was prompted by our recent finding that if this technique is combined with microdensitometry one may obtain reliable quantitative indices of the utilization of tritium-labelled precursors of proteins[22] or nucleic acids[23].

In this experiment 8 young adult Long–Evans hooded rats weighing about 250 g were used. Pairs of animals were randomly assigned to three experimental groups and one control group. All the experimental animals were exercised in a motor-driven wheel, 14 in. in diameter, for 2 h; two groups at the speed of 7 r.p.m., one group at 12 r.p.m. All the animals, controls included, were injected intraperitoneally with 2 mc. of DL-leucine-4,5-^{3}H (specific activity 5·4 curies/millimole; the chemical dissolved in 2 ml. of sterile isotonic saline). The injections were made in two 1-mc. doses with 30 min elapsing between the two injections, and the animals were killed after a 1-h exchange period by cardiac perfusion with 10 per cent neutral formalin. Of the animals exercised at 7 r.p.m., the injection was made in one group immediately after completion of their 2-h exercise period and in the other group during exercise. The 2 animals which ran at 12 r.p.m. were injected immediately after their exercise. The control animals were resting both before and during injection. The removed brains were embedded in paraffin and serial sections were cut at 7μ. The deparaffinized sections were coated by the dipping technique[24,25] with Kodak '*NTB*-3' photographic emulsion, diluted at the ratio of 2 : 1 with water. The coated sections were exposed in lightproof slide-boxes containing a desiccant for 19 weeks at 5° C, and were developed in Kodak '*D*-19' at 20° C for 6 min, fixed and washed at the same temperature and left unstained. Alternate sections, which were not prepared for autoradiography, were stained with gallocyanin chromalum. Qualitative assessment of the regional density of the autoradiograms was accomplished with a Shea comparison microscope (American Optical Co.), which permits simultaneous comparison of a pair of sections, such as a control and an experimental section. Quantitative determination of the grain density of single neurones or surrounding 'neuropil' was carried out with a microdensitometer, consisting of a Zeiss photomicroscope, a vertical projection attachment with interchangeable slides of varying apertures, and a Photovolt model 501*M* photometer. Details of the apparatus and the procedure utilized are reported elsewhere[22], where it is shown that density readings obtained with this apparatus and grain counting are linearly related. In the investigation recorded here, density measurements were made on projected circular areas 12μ in diameter, at a magnification of about 320.

The speed of 7 r.p.m. (about 25 ft./min) is an apparently comfortable walking pace for rats, though they are forced to co-ordinate their locomotor rhythm so that they can step on the thin cross-bars spaced 0·5 in. apart. The distance covered at this speed is a very small fraction of what rats were reported to cover spontaneously in activity wheels[26]. Nor is the speed of 12 r.p.m. excessive; however, some animals encounter difficulties in maintaining a steady rhythm at this speed and may prefer a discontinuous jumping movement, taking occasional free rides by hanging on to the bars with their forepaws, and may be exhausted at the end of the 2 h of exercise. It is reasonable to assume, however, that locomotion at both speeds represents a 'normal' though possibly stressful pattern of behaviour.

As shown in Fig. 1, there is considerable increase ($P < 0{\cdot}001$) in the uptake of radioleucine in the motor

Table 1. Mean Grain Density of Single Neurones in Several Brain Structures in the Control Group and the Animals Exercised at 7 r.p.m. and Injected during Exercise

Rank ordering of structures in terms of percentage increase of uptake in the exercised animals

Structure	Density						Increase (per cent)	t	P
	Control			Exercised					
	N	Mean	$S.D.$	N	Mean	$S.D.$			
Motor cortex, neurones in second layer	40	0·185	± 0·036	40	0·307	± 0·043	66	13·6	< 0·001

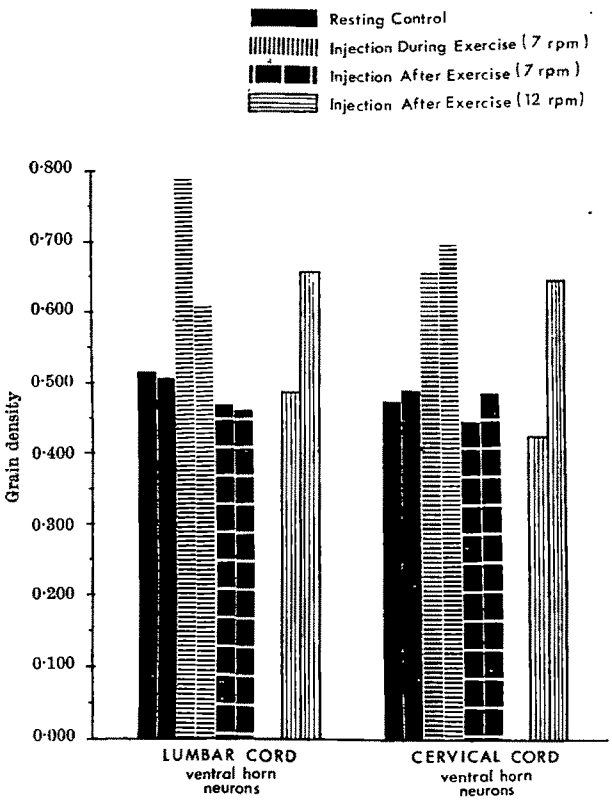

Fig. 1. Mean density of single neurones (N = 20) in the lumbar and cervical spinal cord. Each bar represents one animal

neurones of the lumbar and cervical spinal cord in the animals exercised at 7 r.p.m. with the chemical injected during exercise. In contrast, a slight decrease in uptake ($P < 0{\cdot}001$ in the lumbar motoneurones; $P < 0{\cdot}10$ in the cervical motoneurones) was seen in the animals exercised at the same speed with the chemical injected after exercise. A somewhat different result was obtained in the animals which ran at 12 r.p.m. and were injected after exercise. In one of the two animals (which showed no difficulty in keeping up with the higher speed) a small drop in uptake was seen, in a manner similar to the other two animals exercised at a lower speed and injected afterwards, while in the other animal (which virtually collapsed from fatigue at the end of the exercise period) a considerable increase in uptake was obtained. In summary, these findings brought evidence of appreciable increase in utilization of amino-acid in motor cells during mild activity and a slight decrease in uptake (possibly returning to normal) immediately after activity. The evidence of the effect of more strenuous exercise on amino-acid uptake after cessation of locomotion remains ambiguous since the two animals studied showed different reactions.

The increased utilization of amino-acid during mild exercise was further investigated in 15 different brain regions and the grain density of over a thousand neurones in these structures was measured. As presented in Table 1, there is a significant increase ($P < 0{\cdot}001$) in the density of all cell types, not only in motor but also in sensory regions. The rank ordering of structures in terms of percentage increase of leucine uptake during exercise shows that the relative increase is highest in some motor structures (such as neurones of the motor cortex and the ventral horn of the spinal cord), but the same applies to some sensory regions, such as the posterior (visual) cortex. Lowest increase in uptake was observed in other sensory structures (Deiter's nucleus, cochlear nucleus) and in the hippocampus. The increase in uptake does not appear to be related to the total density of neurones; the smallest percentage increase was seen in two structures (hippocampus and cochlear nucleus) the neurones of which are distinguished in the list by the lowest and highest grain density, respectively.

These findings indicate that fine-resolution autoradiography, combined with microdensitometry, is a suitable technique for demonstrating changes in the amino-acid utilization of single nerve cells during exercise. Whether such changes can be demonstrated by conventional histological techniques is controversial[27,28]. The autoradiographic technique may, therefore, be used as an indicator of chemical changes in nerve cells as a consequence of behavioural 'activation'. The exact interpretation of the changes obtained, however, poses some difficulties which we cannot resolve without further experimentation. While it is reasonable to assume that what was retained after perfusion and histological processing represents amino-acids incorporated into proteins, we cannot infer from this that exercise induces a higher rate of protein turnover in nerve cells. First, the direct effect of exercise may be a change in the local amino-acid pool with a consequent change of the specific activity of the pool (such an assumption would imply that the amino-acid pool is decreased as a consequence of exercise). Secondly, owing to previously demonstrated increase in local blood

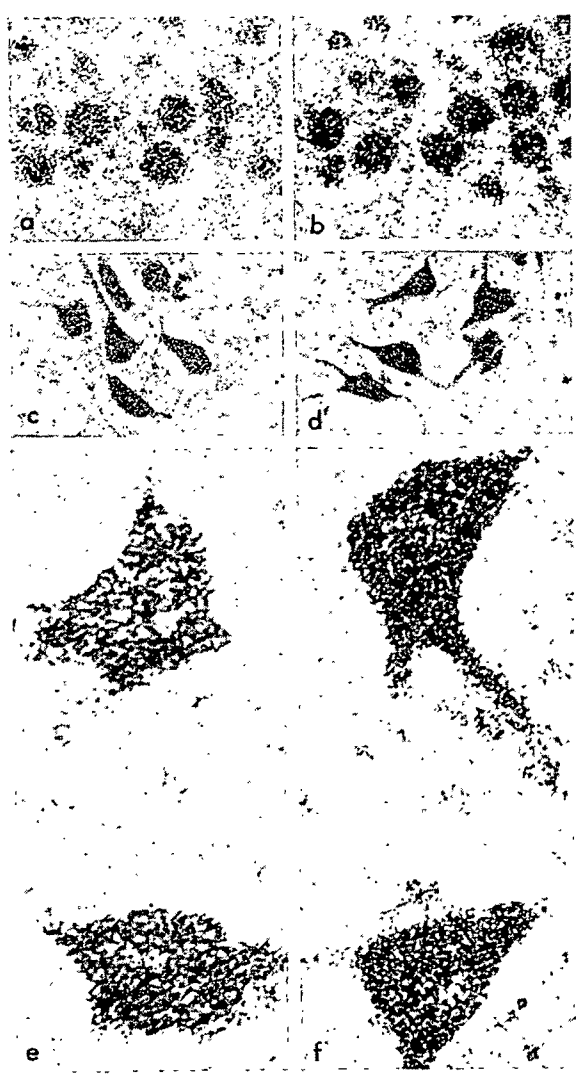

Fig. 2. Photomicrographs of unstained autoradiographs from a control animal (left column) and an animal exercised at 7 r.p.m. and injected during exercise (right column): *a–b*, Purkinje cells from cerebellum (× *c.* 256); *c–d*, motor horn cells from cervical spinal cord (× *c.* 128); *e–f*, higher power photomicrographs of motor horn cells (× *c.* 512)

circulation as a result of functional activation[29,30], the higher uptake of tritiated leucine may merely reflect greater availability. On the other hand, it could be argued that either explanation (depletion of local amino-acid pool or increase in local circulation) may indirectly reflect higher rate of metabolism. Indeed, evidence was recently obtained[31] of increased incorporation of methionine labelled with sulphur-35 into proteins of the brain stem and cerebral hemispheres of rats during the first few hours of forced swimming. Contrary to expectation, the changes of utilization of amino-acid were observed in this work not only in motor cells (or cells in motor structures) but also over the entire brain. Whether this is due to the non-specific nature of the behavioural task utilized (exercise might involve activation of sensory as well as motor structures) or whether any specific task produces a general metabolic activation remains to be investigated.

This work was supported by the U.S. Atomic Energy Commission.

LOW-VOLTAGE ELECTRON BEAM IRRADIATION OF NORMAL AND 5-BROMOURIDINE DEOXYRIBOSIDE-TREATED *L*-P_{59} MOUSE FIBROBLAST CELLS *IN VITRO*

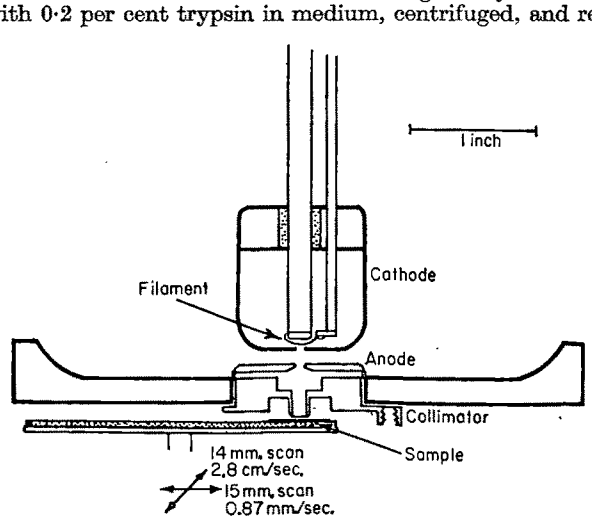
By Dr. ARTHUR COLE, Dr. RONALD M. HUMPHREY and Dr. WILLIAM C. DEWEY

Department of Physics, University of Texas M. D. Anderson Hospital and Tumor Institute, Texas Medical Center, Houston 25

NUCLEAR or chromosomal damage may be a major factor in radiation killing of mammalian cells[1–3]. The contribution of cytoplasmic effects, either directly or by induced nuclear effects, is not clear. It is known that the incorporation of 5-bromouridine deoxyriboside (BUdR) into the chromosomal deoxyribonucleic acid (DNA) of a cell[4,5] increases or potentiates both radiation-induced killing[6,7] and chromosomal damage[8]. It is of interest to determine whether the BUdR-effect occurs when only the cytoplasm is irradiated, that is, whether migration of radiation energy or effect from cytoplasmic to nuclear material occurs. Such an investigation may be carried out using electron beams to irradiate to selective depths within a cell[9–14].

Fig. 1 illustrates the electron-beam irradiation system. Accelerated electrons passed through a collimator slit (0·25 × 2 mm) into either a beam measuring system *in vacuo* or the biological sample. A collodion foil of about 1·5 μg/cm² mounted on the slit isolated the gun vacuum from the lower chamber. Collimator current was used as a reference for setting the beam current during irradiations. A mechanical scan system moved the sample 1 mm below the slit in a raster pattern covering a 0·5-in.² area in 17 sec (3 cm² in 55 sec in initial investigations). Each point on the specimen passed under the beam slit about 5 times during a complete raster pattern. The beam overlapping and the scattering by foil and gas were considered sufficient to provide a uniform exposure over the sample. The sample and mounting systems were cooled to 2° C before and during the irradiation. Air was evacuated from the lower chamber leaving an equilibrium water-vapour pressure of 6 mm mercury, that is, irradiation was carried out under anoxic conditions. The pre-absorption path of the foil and water vapour was about 2·5 μg/cm² Samples could be inserted, evacuated, irradiated and removed in a 1-min period (3 min in earlier work). Dehydration of the cells was limited by the low temperature and short exposure time.

L-P_{59} mouse fibroblast cells (2 × 10⁶ inoculum) were grown at 37° C as monolayers in stoppered *T*-60 flasks containing McCoy's 5*a* medium[15] supplemented with 10 per cent calf serum. Following a 24-h initial incubation, BUdR (2·0 μg/ml.) was added to one group of flasks and both the control and BUdR-treated groups were incubated for 3 more days. The BUdR treatment did not reduce plating efficiency or induce observable chromosomal effects. Cells were removed from the glass by treating with 0·2 per cent trypsin in medium, centrifuged, and re-



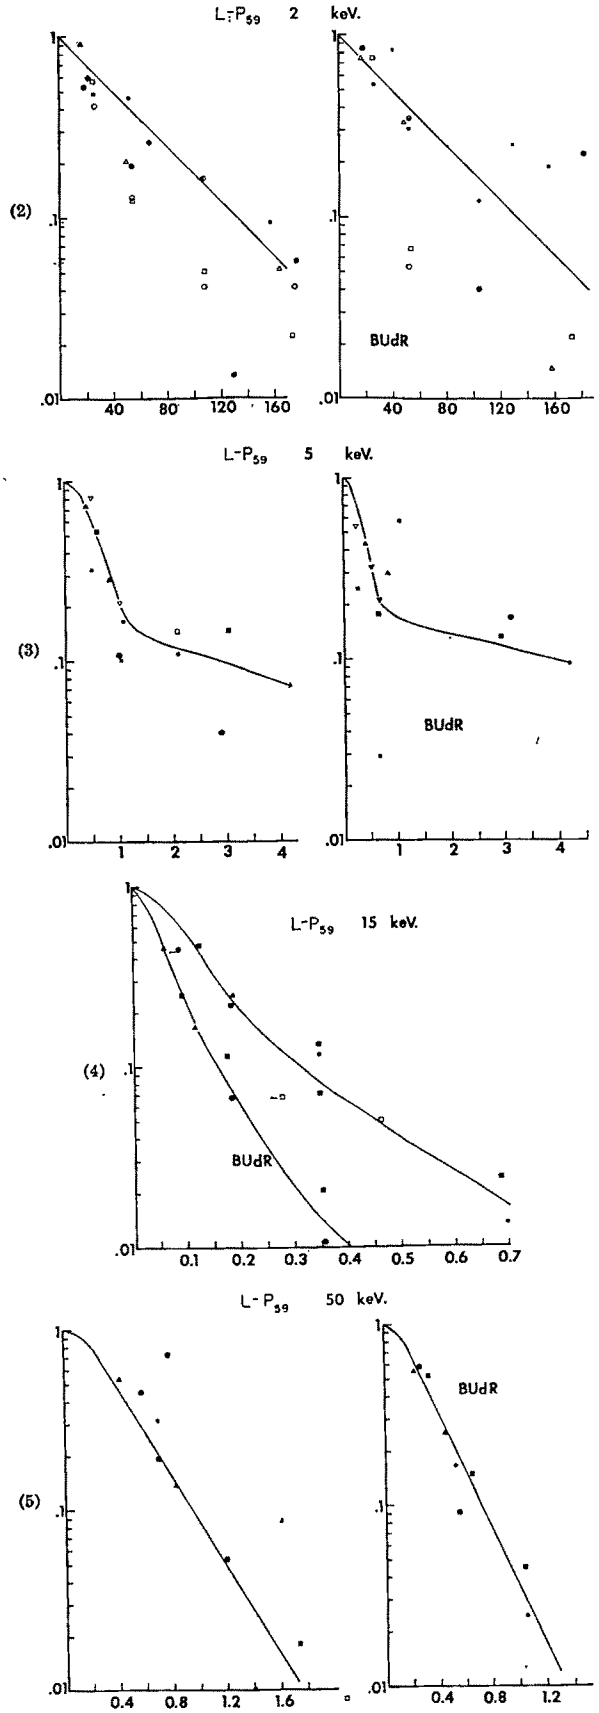


Fig. 1. Electron beam irradiation system

Figs. 2–5. Semilogarithmic plot of surviving fraction versus incident electron beam exposure in units of 10^{-9} coulombs/cm² for untreated and BUdR-treated L-P_{59} cells. A number of experiments are represented. Fig. 2, 2-keV beam; Fig. 3, 5-keV. beam; Fig. 4, 15-keV beam; Fig. 5, 50-keV beam

suspended in medium (2×10^5 cells/ml.). 40 μl. of this suspension were pipetted on to 0·5-in. diameter, 100-mμ porosity, membrane ('Millipore') filters placed on medium-soaked underpads. The fluid passed through the filters in about 5 min, leaving the cells exposed on the surface. The wet underpads prevented dehydration of the filter and specimen during the subsequent irradiation at the reduced pressure. Following irradiation, the filters were placed in medium and the cells released from the filter by sonication for 15 sec at the minimum operable power-level of a Raytheon 10-kc/s, 250-W sonic oscillator (this sonication had no effect on control plating efficiency). A number of cells sufficient to establish about 100 colonies were then plated into Petri dishes containing medium plus a feeder layer of L-P_{59} cells which had been irradiated 24 h previously with 4,000 rads of cæsium-137 γ-rays. The plates were incubated 10 days at 37° C in 5 per cent carbon dioxide, fixed and stained and the colonies counted. (The feeder layer formed giant cells but no colonies.) Control cells were treated as already described except that the cells were not irradiated. Additional controls included non-evacuated filter samples and direct plating of the initial suspension. Equal plating efficiencies were observed (~ 70 per cent) for all control systems.

Representative plots of the survival data are shown in Figs. 2–5. Exposure dose is given in units of 10^{-9} coulombs/cm². A summary of these results and those reported for 220-kVp. X-ray exposures[16] is given in Table 1.

Table 1

Voltage (keV)	Cell penetration (μ)	Treatment	Beam exposure (10^{-9} coulombs/cm²)	LD_{50} Cell dose (kilorads)	Local dose (kilorads)	LD_{50} dose reduction BUdR treatment
1·5 (0·75 residue)	0·07		~200	~13·5	~2,200	
2·0	0·15		~40	~5·2	~400	
		BUdR	~40	~5·2	~400	~0·95

Penetration depths and dose calculations were based on studies in air and collodion foils of the radiation properties of low-voltage electron beams[16,17] which included determinations in plastic foils of the penetration range, R (defined here as the thickness which transmits 2 per cent of the incident energy), the initial average rate of energy loss per electron per unit path length on dE/dx, and the rate of energy loss per electron per unit penetration depth or dE/dt. The following semi-empirical relations were fitted to the data between 20 eV and 100,000 eV:

$$\frac{dE}{dx} = 14{\cdot}5\,(E + 0{\cdot}4)^{-0{\cdot}761} \qquad (1)$$

$$R = 0{\cdot}0385\,(E + 0{\cdot}4)^{1{\cdot}77} - 0{\cdot}0075 \qquad (2)$$

E and dE are in keV and R and dx are in units of 100 μg/cm² or μ at unit density.

Fig. 6 shows a plot of dE/dt (5- to 50-keV beams) normalized in units of the dE/dx and R appropriate to the energy considered. The radiation dose at any depth in an absorber exposed to a broad electron beam becomes:

$$\text{Dose (kilorads)} = \frac{dE}{dt}\ (\text{keV}/\mu) \times \text{beam exposure } (10^{-9}\ \text{coulombs/cm}^2) \qquad (3)$$

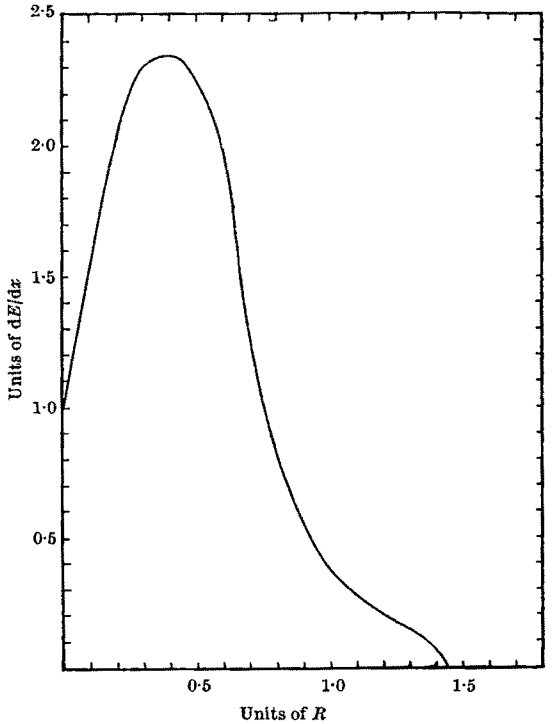

Fig. 6. Plot of the average energy deposited per electron per unit penetration depth in keV/μ (unit density) versus penetration depth for 5- to 50-keV electron beams. The plot is normalized in units of the dE/dx (initial rate of energy loss) and R (range) appropriate to the beam-energy considered

The cell LD_{50} listed in Table 1 represents, for 50 per cent survival, the energy deposited per cell divided by the cell mass while the local LD_{50} represents the actual average dose in the irradiated region.

The survival curves of Figs. 3–5 are sigmoidal with extrapolation numbers in the order of 1·5 or greater. The 'tailing' or upward concavity of the curves prohibits obtaining accurate extrapolations. The tailing is believed to be caused by a shielding of a small fraction of the cells by water, dirt, fragments, or by cell clumping, or overlapping, or a variable depth of the sensitive region.

Nuclear and cellular sizes were measured microscopically to be approximately 10 and 17μ respectively. The cell maintains a spherical shape in suspension, but it is uncertain exactly what shape the cell adopts during the 5- to 10-min period it remains on the membrane filter surface. It is reasonable to assume that some flattening of the cytoplasm occurs as is shown in Fig. 7.

Strictly reproducible results were not obtained with the 2-keV beams (Fig. 2). The 2- and 3-keV beams yielded cell LD_{50} of about 5 krads and local LD_{50} of about 400 krads (Table 1) for both untreated and BUdR-treated cells. The local dose to the cell surface or membrane was in the order of 1,500 krads. It was observed in initial studies that 1·5-keV beams (with residue energy of about 0·75 keV and residue penetration of about 70 Å) would induce cell fragmentation and death within a short period for local doses in excess of 2,000 krads or cell doses in excess of 13 krads. Although the 2-keV results, shown in Fig. 2 for seven experiments, are scattered, a comparison of the results with non-treated and BUdR-treated cells for each experiment gave no consistent difference in the radiation responses, that is, the ratio of the slopes of the log survival versus dose plots varied from 0·8 to 1·5. An exponential best fit to all the points yielded a BUdR dose reduction factor of 0·95 $\pm$ 0·20.

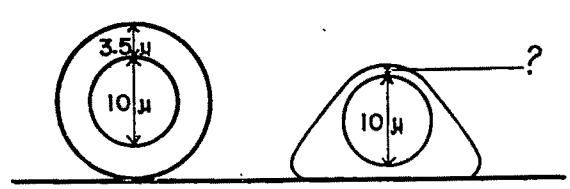

Fig. 7. Diagram illustrating uncertainty of cytoplasm thickness above nucleus when cell settles on the surface of the membrane filter

The 5-keV beam gave a cell LD_{50} dose of about 245 rads for untreated cells and about 164 rads for BUdR-treated cells. Thus, a BUdR dose reduction factor of 1·5 was obtained. The 5-keV beam penetrates only 0·75μ. If BUdR potentiation is to be associated with a nuclear effect, these results require an unexpectedly thin cytoplasmic covering. Flattening of the cell and dehydration of the cell surface during the evacuation may have appreciably reduced the absorption thickness of the upper cytoplasm.

Results obtained with the 15-keV beam are interesting in that cell LD_{50} were only 140 rads for untreated cells and 77 rads for BUdR-treated cells. This beam, which irradiated the upper one-fourth of the cell, was 3–4 times as efficient for radiation killing as fully penetrating beams. The result implies that the local energy was more favourably located in relation to a radiation sensitive region. The BUdR dose reduction factor of 1·83 is believed to be significantly larger than the values of 1·0–1·5 obtained for the other irradiations and implies that a radiation effect directly associated with DNA is more important at this energy. It is of interest that over one-half of the energy of a 15-keV beam is expended between 1–3 microns penetration depth. The peak local LD_{50} in this region (which are greater than the average local doses listed in Table 1) for the 15-keV beam were about 460 rads for untreated cells and 250 rads for treated cells which approximates the LD_{50} for beams which irradiated the whole cell.

Results obtained for fully penetrating beams (30, 50 and 90 keV) are in essential agreement with X-ray irradiation results[18]. LD_{50} of 450–500 rads for untreated cells and 330–360 rads for BUdR-treated cells and BUdR dose reduction factors of 1·40–1·46 were obtained.

If the BUdR potentiation effect is directly associated with DNA, these results suggest that one mechanism for radiation killing involves cell chromatin located on or near the nuclear membrane but that another mechanism for radiation killing, which is not subject to BUdR potentiation (and, therefore, does not involve the DNA or involves it indirectly), is significant when an appreciable fraction of the radiation energy is expended in the cytoplasm or nucleoplasm. Thus, the net BUdR potentiation observed will depend on the fraction of radiation energy distributed between the two mechanisms.

BEHAVIOUR OF MAMMALIAN HÆMOGLOBIN AFTER FREEZING AND THAWING

By S. SQUIRES and Dr. J. A. McFADZEAN
Research Laboratories, May and Baker, Ltd., Dagenham

IT was observed in the course of a routine procedure to lyse defibrinated blood by freezing and thawing that two changes occurred with rat blood. One was a change in colour, and the other the appearance of an amorphous deposit. Experiments were afterwards undertaken to investigate these two observations.

Blood was obtained from Wistar rats and defibrinated by shaking it with glass beads for 5 min. The defibrinated blood was then frozen in an alcohol/carbon dioxide bath, and when completely frozen allowed to return to room temperature. This procedure was repeated six times. Blood was also obtained and treated in a similar manner from the following examples of the class Mammalia:

Order	Examples tested
Primates	Monkey and man
Carnivora	Dog and cat
Perissodactyla	Horse
Artiodactyla	Cow and sheep
Rodentia	Mouse, rat, hamster, gerbil, guinea pig
Lagomorpha	Rabbit
Insectivora	Hedgehog

All the blood samples tested, with the exception of those from rats. When the defibrinated blood was frozen, the blood changed colour as it solidified. The colour produced was that of red lead (approximately British Standard Colour 0–005). On thawing, the blood resumed the normal colour of lysed red cells (approximately British Standard Colour 0–006) and the solution was clear and gave the absorption band of oxyhæmoglobin. In only one blood specimen did crystallization occur, and that was with guinea pig. Repeated freezing and thawing six times resulted in the same colour change when the material was in the solid state; but each time there was a reversion to the normal colour when the blood was allowed to thaw.

Rat hæmoglobin. On freezing, the defibrinated rat blood took on the colour of red lead as described here when it was in the solid-state, and this colour persisted when the blood was thawed, with some drop in the intensity of the colour. Repetition of the process produced intensification of this colour change when the blood was in the liquid state (Fig. 1). This change in colour was stable and persisted for at least 24 h. After the first thawing, it was clear that a precipitate had formed, which increased in amount as the procedure was repeated. After centrifugation the supernatant had the normal colour of a solution of oxyhæmoglobin (approximately British Standard Colour 0–006) and gave the typical absorption bands of oxyhæmoglobin, while the deposit had the red lead colour. Microscopic examination of the deposit showed it to be amorphous, as illustrated in Fig. 2. There was no evidence of crystallization. The deposit gave essentially the same reflectance spectrum as a sample of crystalline oxyhæmoglobin precipitated from whole defibrinated rat blood by the addition of one-sixteenth of its volume of ether[1] (Table 1 and Fig. 3).

Fig. 1. *A*, guinea pig blood, lysed by freezing and thawing; *B*, normal rat blood; *C*, rat blood frozen and thawed; *D*, lysed rat blood (water) frozen and thawed

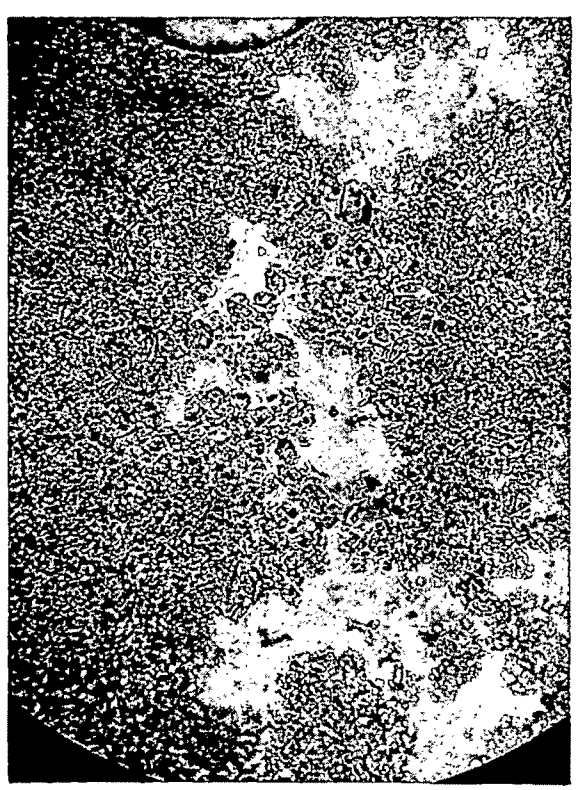

Fig. 2. Photomicrograph showing the amorphous deposit of oxyhæmoglobin after freezing and thawing defibrinated rat blood (× *c.* 750)

Table 1. Reflectance Spectra (Maxima and Minima (mμ)) of Normal Rat Hæmoglobin Crystals and 'Frozen' Rat Hæmoglobin

	Absorption in mμ	
	Normal rat blood	Frozen rat blood
Maximum	415	420
Minimum	510	510
Maximum	543	542
Minimum	563	563
Maximum	575	576

The spectra were determined on a Unicam *SP*'500 spectrophotometer with a reflectance attachment. The samples were diluted with water and filtered through Whatman No. 1 paper with gentle suction to obtain an even layer of hæmoglobin. Reflectance measurements were made on the samples covered with a microscope slide to exclude air. Wet filter paper similarly covered with a microscope slide was used as a blank.

The small differences in the shape of the reflectance curves (Fig. 3) are attributed to difficulties in obtaining reproducible values because of the low reflectivity of the samples, while the difference in optical densities between the two curves arises because of the different amounts of hæmoglobin on the filter paper in the two cases. It is the area of the reflectant surface which is the significant factor determining the optical density, but this is not easily controllable or measurable, since equal weights of the two samples do not possess equal surface areas, owing to the difference in particle size. The results indicate that there is no chemical difference between the normal rat blood and the frozen rat blood, and would suggest that the apparent difference to the eye is a difference of colour saturation (optical density) and not of hue (colour), arising from the differing particle sizes in the two cases.

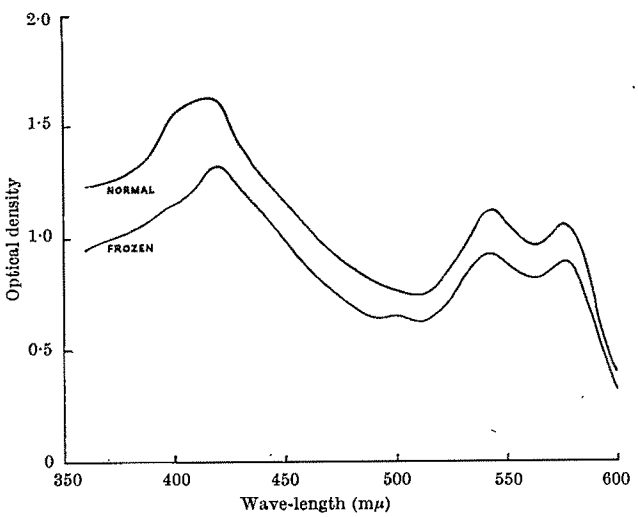

Fig. 3. Reflectance spectra of the amorphous rat hæmoglobin and crystals of rat oxyhæmoglobin

These changes also occurred with rat cells which had been washed three times in saline and finally suspended in saline, and in defibrinated blood previously lysed with water. Similar changes were also observed with blood from two further groups of Wistar rats from other breeders, and from a group of hooded rats. Freezing and thawing in an ice/salt bath, a much slower procedure, produced similar changes.

The addition of saponin or water to defibrinated cells resulted in rapid crystallization of the oxyhæmoglobin.

The addition of a reducing agent, such as sodium hydrosulphite, to a suspension of the amorphous material resulted in the material going into solution. Re-oxidization caused the reappearance of the amorphous deposit, in contrast to normal rat hæmoglobin, which gave a crystalline oxyhæmoglobin on standing. The addition of a reducing agent before freezing and thawing inhibited both the change in colour and the appearance of the precipitate, and resulted solely in a solution of reduced hæmoglobin with typical absorption bands.

We have been unable to find any reference in the literature to the change in colour which appears on freezing blood or to the deposition of amorphous oxyhæmoglobin after freezing and thawing solely in the case of rat blood. Haurowitz and Harden[2] state that "it is remarkable that hæmolysis in some cases, such as in the red cells of the rat, leads directly to the crystallization of oxyhæmoglobin. Evidently the concentration of hæmoglobin and oxyhæmoglobin in the red cell is higher than that of a saturated aqueous solution". Direct crystallization was not observed by the freezing technique, although crystals, indistinguishable from normal rat hæmoglobin, tended to occur afterwards if the amorphous deposit was left overnight on a microscope slide. These crystals did not appear if the amorphous material was left standing in its own mother liquor.

We thank Prof. C. Rimington for his advice and interest in this work, and Mr. Threlfall, of the Applied Physical Chemistry Division of these Laboratories, for carrying out the spectrophotometric measurements.

IMMUNOASSAY OF HUMAN GROWTH HORMONE IN PLASMA

By Dr. SEYMOUR M. GLICK, Dr. JESSE ROTH, Dr. ROSALYN S. YALOW and Dr. SOLOMON A. BERSON

Radioisotope Service, Veterans Administration Hospital, Bronx 68, New York

IMMUNOASSAY of circulating human growth hormone (HGH), utilizing hæmagglutination inhibition[1] or HGH labelled with iodine-131 (ref. 4), has been hampered by insufficient sensitivity[2,3] or by non-specific interference from substances in plasma[2–4] that can be removed only by extraction procedures that do not always ensure complete recovery of hormone. In a recent abstract[5], Hunter and Greenwood have reported a radioimmunoassay of improved sensitivity for HGH in plasma extracts, but a detailed description of their methods and results has not yet appeared.

The present report describes a radioimmunoassay that provides a high degree of specificity and sensitivity, and permits determination of HGH in unextracted plasma (Table 1). By application of this assay acute changes in endogenous plasma HGH-levels have been demonstrated for the first time[6,7].

The hormone-^{131}I immunoassay method, originally used for measurement of endogenous plasma insulin[8], has been modified for the determination of endogenous plasma HGH. This method, like the previously reported HGH-^{131}I immunoassay methods[4,5], exploits the ability of endo-

Table 1. IMMUNOASSAY METHODS AND RESULTS: ADULTS

Assay method* and adult cases reported	Samples used for assay	Sensitivity (mμg/ml.)	Non-specific reaction with plasma	Plasma HGH concentration Acromegaly cases	Acromegaly HGH	Normal cases	Normal HGH

* Results obtained with the hæmagglutination inhibition method utilizing unextracted plasma samples are not included because of evidence that the method lacks specificity (refs. 2, 3).

† Hunter and Greenwood have recently reported (personal communication) that plasma can be assayed directly but that concentrated plasma extracts are utilized for measurements in a large proportion of adults. Present sensitivity is 0·1 mμg/ml. Non-specific reaction with plasma does not occur.

genous HGH in plasma to inhibit competitively, in a quantitative manner, the binding of HGH-^{131}I to specific antibody.

Antisera are produced in rabbits and in guinea pigs by the administration of HGH (Wilhelmi *HS* 269), emulsified in complete Freund's adjuvant, by any of a variety of routes and dosage schedules. To maintain a completely soluble system at all concentrations of antiserum the antiserum is digested with papain by the method of Porter[9].

HGH is labelled with iodine-131 at specific activities of 400–500 mc./mg by the method of Hunter and Greenwood[10]. Unreacted iodine-131 is removed by dialysis. HGH-^{131}I is purified by electrophoresis on starch-gel (borate buffer 0·3 M, *p*H 8) (ref. 11). The fraction of HGH-^{131}I eluted from the pre-albumin region of the gel binds completely to HGH antibodies and competes for binding to HGH antibodies in a manner quantitatively identical with that of unlabelled HGH.

For assay purposes, we use a dilution of antiserum in which 50–65 per cent of a small tracer of HGH-^{131}I (approximately 0·03 mμg/ml.) is bound to antibody at equilibrium (about 5 days at 4° C). Thus, the ratio (*B*/*F*) of antibody-bound HGH-^{131}I (*B*, bound) to unbound HGH-^{131}I (*F*, free) is about 1 or 2 in the absence of unlabelled HGH; the *B*/*F* ratio falls progressively with increasing concentrations of unlabelled HGH. A 'standard curve' is obtained by plotting *B*/*F* vs. HGH concentration in known 'standard solutions' (Fig. 1). Plasma sample samples are assayed by preparing mixtures that contain the same concentrations of HGH-^{131}I and antibody as in the standard solution, but in which the unknown plasma is substituted for standard HGH. The plasma concentration of HGH in the unknown is determined from the observed *B*/*F* ratio by comparison with the standard curve (Fig. 1).

Free HGH-^{131}I and antibody-bound HGH-^{131}I are separated by chromato-electrophoresis[8] in strips of *ECTEOLA*, DEAE, or Whatman 3 *MM* paper. (Variations in the adsorptive qualities of different batches of these papers make it advisable to test each batch before large-scale use.) Free HGH-^{131}I is adsorbed at the site of application whereas antibody-bound HGH-^{131}I migrates anodally with the γ-globulins. After the γ-globulins have moved about 3 in. (1–1½ h at 4° C) the strips are dried and scanned for radioactivity in an automatic strip counter (Fig. 1).

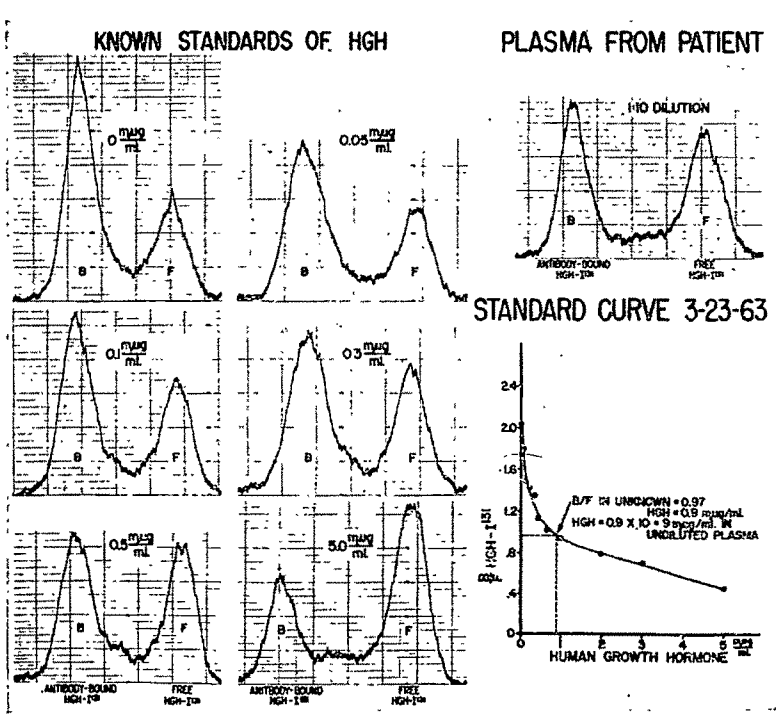

Fig. 1. Standard curve and scans of radioactivity of several chromatoelectrophoretograms. Antibody-bound and free HGH-^{131}I were separated by chromatoelectrophoresis on strips of *ECTEOLA* paper that were then scanned for radioactivity. Areas under the peaks corresponding to bound (*B*) and free (*F*) HGH-^{131}I were determined by planimetry. All mixtures contained identical concentrations of HGH-^{131}I and of antibody. Standard solutions contained known concentrations of unlabelled HGH as shown (left). HGH concentration in a patient's plasma is obtained from the observed *B*/*F* ratio (upper right) by comparison with the standard curve (lower right)

Small amounts of labelled hormone that may become damaged during incubation with plasma also migrate away from the site of application. From control mixtures prepared without antiserum the damage is corrected, as previously described for insulin[8].

In general, plasma was assayed at 1 : 10 dilution. For greater accuracy in certain samples we have used dilutions from 1 : 2 to 1 : 500.

It has been found that the HGH concentration in heparinized plasma is not significantly altered by storage at −20° C for several months or by repeated freezing and thawing. The HGH concentration in serum is identical with that in plasma.

With selected antisera, HGH concentrations of 0·1 mμg/ml. are detected by this method. HGH added to plasma is recovered quantitatively. Purified HGH preparations from several sources (Raben homo 6, 13, 14; Wilhelmi *HS* 269; British Medical Research Council) react identically. More recently, Wilhelmi has supplied a more highly purified preparation (372*B*) which on immunoassay is about twice as potent as the others

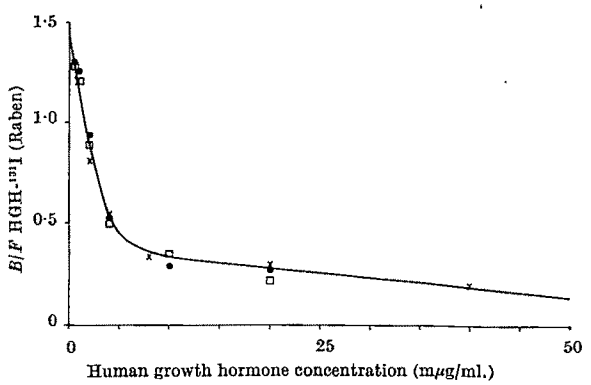

Fig. 2. Comparison of pituitary and plasma HGH. B/F ratio of HGH-^{131}I (Raben) as function of concentration of unlabelled HGH. Known concentrations of unlabelled Raben HGH were used for the pituitary curve (solid line). The plasma samples, diluted 1 : 50 for assay, yielded HGH concentrations, in undiluted plasma, of 100 mμg/ml. (normal adult following stimulation by hypoglycæmia, □), 90 mμg/ml. (umbilical cord, ●), and 200 mμg/ml. (acromegalic, ×). From the values obtained by assay, each of the three plasmas (diluted from 1 : 5 to 1 : 250) was used as the source of known concentrations of unlabelled HGH. The results demonstrate that endogenous plasma HGH and purified pituitary HGH react identically in this system

listed. HGH concentrations reported here were assayed using Raben No. 6 as standard.

In the system reported here endogenous plasma HGH and purified pituitary HGH react identically (Fig. 2). In two cases studied HGH concentrations in blood from the internal jugular vein were 40 and 110 per cent higher respectively than in blood simultaneously obtained from the inferior vena cava. HGH has not been detected in plasma from twenty-one patients, totally hypophysectomized for non-pituitary disorders (diabetic retinopathy, carcinoma) (Fig. 3). Four of these subjects had been studied pre-operatively at which time two had measurable plasma HGH. Bovine and porcine growth hormone preparations, and whole plasma from several non-primate

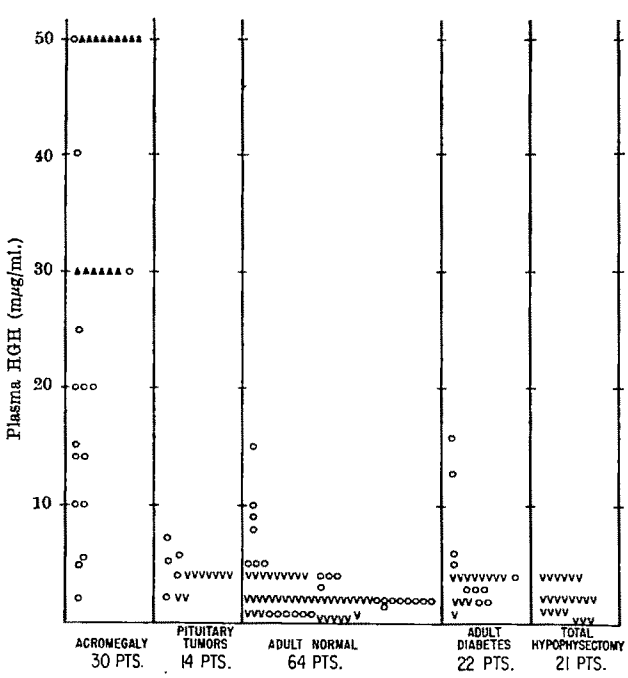

Fig. 3. HGH concentrations in plasma samples randomly obtained from 150 adult subjects. Since the sensitivity of the assay increased during the course of these studies, HGH concentrations, when measureable, are plotted as "less than . . ." the lower limit of sensitivity of the particular assay. In recent investigations (not shown), HGH was detectable (≥ 1 mμg/ml.) in seven of eight normal subjects after an overnight fast. Most of the acromegalic patients had been treated by radiation or surgery; clinically active and inactive cases are included V, Less than; ▲, more than; O, equal to

species (cattle, hog, rat, mouse, horse, sheep, rabbit and guinea pig), did not inhibit binding of HGH-^{131}I to antibody. Simian growth hormone (Wilhelmi *M655A*) inhibited the binding of HGH-^{131}I but not so strongly as did HGH. Thus, the assay is specific for primate growth hormone and free from interference by non-specific components of plasma.

Plasma HGH concentrations have been determined in 212 adults (Fig. 3, Table 2). Most plasma specimens were obtained from 1 to 3 h after the patients had eaten. Recent investigations of this laboratory indicate that hypoglycæmia and prolonged fasting result in elevation of plasma HGH (ref. 6), and that feeding or glucose ingestion is followed by an abrupt fall in plasma HGH (refs. 6 and 7). Assays of plasma from normal subjects fasted for 12–18 h generally yield moderately higher levels of HGH than reported here in non-fasting subjects. The occasional very high level obtained in non-acromegalic subjects (for example, in a patient with anorexia nervosa, plasma HGH was 35 mμg/ml.) may be directly related to a prolonged period of under-nutrition.

Table 2. Plasma HGH Concentration

	Total No. of patients	No. of cases with concentrations in range indicated < 5 mμg/ml.	5–9·9 mμg/ml.	> 10 mμg/ml.

Endometrial carcinoma	3	1	0	2
Other	11	9	2	0
	62	48	7	7

Plasma HGH concentrations (umbilical cord venous blood) in two new-born babies were 40 and 100 mμg/ml.; in the former case HGH concentration in arterial cord blood obtained simultaneously was also 40 mμg/ml. In four infants, two months to one year old, plasma HGH concentrations were 2–8·5 mμg/ml. A small number of plasma specimens from normal children at other age-levels does not permit further conclusions regarding plasma HGH-levels in childhood.

In view of the great changes in plasma HGH which have recently been shown to occur after fasting, hypoglycæmia, glucose administration and exercise[6,7], a comparison of values obtained by different methods would have greater significance if plasma samples had been obtained under standardized conditions. Nevertheless, even for samples obtained at random, such comparison is of interest (Table 1).

Non-specific substances in plasma have been reported to interfere with previous immunoassay methods for determination of HGH in plasma[2–4]. In particular, bovine and porcine plasmas appear to contain HGH (refs. 2–4), although pure growth hormone or pituitary extracts from these species do not inhibit the HGH–antibody reaction or show any cross-reaction with the human hormone in a variety of immunological test systems[12]. Previous workers have reported that serums from totally hypophysectomized[2] and hypopituitary[3,4] human subjects appear to contain HGH and have therefore resorted to a variety of extraction procedures to remove the interfering substances from plasma (Table 1). In the present method, non-specific inhibition does not occur. As little as 0·1 ml. of plasma can be assayed conveniently, permitting serial determinations even on infants. The method is ideally

suited for processing large numbers of specimens. As many as 200 plasma samples have been assayed in a single experiment.

The separation of antibody-bound and free hormone by chromato-electrophoresis on DEAE and *ECTEOLA* papers appears to be superior to the separation by electrophoresis on cellulose acetate[5]. The present technique not only separates the two peaks more clearly but also permits analysis of volumes up to 0·4–0·5 ml., compared with 0·025 ml., the maximum that can conveniently be applied to cellulose acetate; the potential sensitivity of the method is thereby considerably enhanced. We thank the following investigators for materials supplied: J. Fisher, R. Fraser, M. Graff, M. Grumbach, A. Pazianos, O. Pearson, M. Raben, A. Rudolph, M. Sonenberg and A. Wilhelmi.

EFFECTS OF AMPHETAMINE AND PENTOBARBITONE ON EXPLORATORY BEHAVIOUR IN RATS

By Dr. ROGER STRETCH

Animal Behaviour Laboratory, Department of Psychology, The Queen's University of Belfast

EXPERIMENTS have shown that many mammals reveal a persistent tendency to explore the environment in which they live and, in doing so, they are often exposed to unfamiliar objects and situations which evoke investigatory responses. The study of exploratory behaviour and curiosity has attracted much attention in recent years; even so, the determinants of this kind of behaviour are not fully understood[1]. A central problem in this area has been concerned with the extent to which exploratory behaviour is affected by conditions that evoke fear or anxiety. One approach has been to suggest that novel stimuli may elicit fear as well as an exploratory drive simultaneously, thus generating an approach–withdrawal conflict[2]. According to this view, exploration will be inhibited or checked as a function of the intensity of fear aroused by the situation.

In a recent investigation, Barry and Miller[3] examined the effects of several drugs on an approach–avoidance conflict in rats. It was found that an avoidance tendency induced by electric shocks could be mitigated by alcohol and also by a barbiturate drug. According to Steinberg, Rushton and Tinson[4], results of this kind suggest that drugs which can alleviate fear or anxiety would increase exploratory activity in an unfamiliar environment; such drugs might have little effect, however, on exploration of a familiar environment where responses induced by fear are likely to have been eliminated. Steinberg *et al.* tested the prediction by investigating the effects of amylobarbitone (15 mg/kg) and amphetamine sulphate (0·75 mg/kg), separately and as a mixture, on the exploratory activity of rats in an enclosed maze. Some of the animals (the 'experienced' rats) were exposed to the maze repeatedly before drug tests were made and others (the 'inexperienced' rats) were given the drugs prior to the first maze trial. The results showed that both drugs, when given separately, tended to increase the activity of inexperienced rats but only to a limited extent. When the drugs were given in combination, however, a significant increase in activity was observed. Neither of the drugs administered separately, nor the mixture, produced any significant change in the activity of the 'experienced' rats, when compared with controls.

The experiment recorded here was undertaken partly with the view of extending previous research by myself as well as the findings reported by Steinberg *et al.* The effects of a central depressant (pentobarbitone) and a central stimulant (amphetamine) on a similar measure of exploration have been investigated. Although the drugs have been administered separately, it was thought that by varying the dosages of each drug and by increasing the length of individual trials, a clearer appraisal of their effects might be made.

35 male and 35 female black-hooded rats[5], aged 56–71 days, were used; the rats had not been used for any previous experiment nor were they deprived of food or water during this experiment.

The apparatus consisted of an enclosed symmetrical Y-maze; the arms were 24 in. long, 6 in. wide and 6 in. high, and they were covered by wire-mesh lids. The maze was made of wood and unpainted except for a thin black line that divided each arm into two 12-in. segments; it was situated within an enclosure made of angled steel and covered with butter-muslin to afford a uniform extra-maze environment. Five 6-in. loudspeakers were mounted 4 ft. above the maze and they transmitted masking white-noise at a uniform intensity of 70 db s.p.l. (ref. 0·0002 dyne/cm^2), as measured by a sound level meter. Illumination was provided by a 15-W red lamp suspended 8 in. above the intersection of the maze pathways and, apart from a reading lamp, the room was in darkness. Subjects were weighed individually and, after injection, a rat was placed in a restraining box in the experimental room for 20 min before testing. A trial began when a rat was placed into the end segment of one arm of the maze; observations of activity were then made by counting the number of segments entered in each minute of a 10-min period. Two such trials were given with an inter-trial interval of 24 h.

Subjects were assigned at random to seven groups each consisting of 10 rats (5 males and 5 females). One group (controls) received saline injections according to the ratio of 1 c.c./100 g body-weight. Three other groups were given pentobarbitone in the dosages 3·5 mg/kg, 7·0 mg/kg, and 10·5 mg/kg, respectively; the remaining groups received amphetamine sulphate at dosages of 0·75 mg/kg, 1·5 mg/kg, and 2·25 mg/kg. All injections were made via the intraperitoneal route 20 min before testing and each injection was adjusted to individual weights according to the ratio of 1 c.c./100 g body-weight. Each group received the same drug treatment on both maze trials.

The main results are shown in Figs. 1 and 2; data points refer to the mean activity of the groups derived by calculating the mean of the two trial totals for individual rats on which group means were then based. Tests were made to determine whether the separate variances fulfilled the condition of homogeneity of variance; Bartlett's

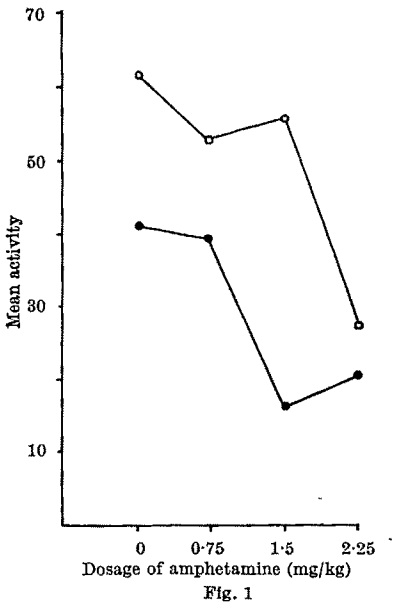

Fig. 1

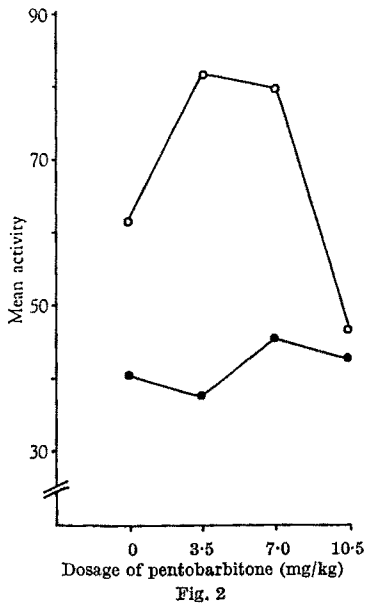

Fig. 2

Figs. 1 and 2. Graphs showing the effects of amphetamine and pentobarbitone at different dosages on exploratory activity; closed circles (●) denote the mean activity of males, and open circles (○) that of females

test indicated that the data fulfilled this requirement (amphetamine: $\chi^2 = 17{\cdot}8$ (uncorrected), $D.F. = 7$, $P > 0{\cdot}01$; pentobarbitone: $\chi^2 = 6{\cdot}6$, $D.F. = 7$, $P > 0{\cdot}3$).

Two analyses of variance, involving the data summarized in Figs. 1 and 2 respectively, were then carried out. (Control observations, based on the results obtained from 5 males and 5 females that received saline injections throughout, are common to each of the analyses and also to Figs. 1 and 2.) In each case, the sex-dosage interaction proved to be significant at beyond the 0·01 level and, therefore, simple effects analyses were carried out with respect to the sex and dosage variables separately. These analyses established: (1) amphetamine reduced the activity of males ($F = 1197{\cdot}5/229{\cdot}5$, $D.F. = 3$ and 32, $P < 0{\cdot}01$) and females ($F = 3523{\cdot}2/229{\cdot}5$, $D.F. = 3$ and 32, $P < 0{\cdot}001$); (2) pentobarbitone was not found to affect the activity of males ($F = 161{\cdot}3/81{\cdot}7$, $D.F. = 3$ and 32, $P > 0{\cdot}05$); (3) females, with respect to both sets of data, were more active than males (pentobarbitone analysis: $F = 6566{\cdot}4/81{\cdot}7$, $D.F. = 1$ and 32, $P < 0{\cdot}001$; amphetamine analysis: $F = 4110{\cdot}8/229{\cdot}5$, $D.F. = 1$ and 32, $P < 0{\cdot}001$).

Reference to Fig. 2 suggests that although pentobarbitone exerted no effect on the activity of males, the drug increased the activity of females at the two lower dosages and decreased activity at the third dosage as compared with controls. It appears, therefore, that these results may be described by a curvilinear relationship and the significance of such a trend was examined by means of F-tests involving the use of orthogonal polynomials[6]. The analysis showed (1) that a significant effect attributable to dosage was present ($F = 1349{\cdot}8/94{\cdot}6$, $D.F. = 3$ and 16, $P < 0{\cdot}001$); (2) that this effect was represented mainly by the quadratic component of trend ($F = 3458{\cdot}4/94{\cdot}6$, $D.F. = 1$ and 16, $P < 0{\cdot}001$) since the F-ratio for the linear and cubic components failed to reach significance.

Finally, an analysis of activity scores during the first 3 min of the first trial was undertaken with respect to rats which received amphetamine to determine whether these data were consistent with those of Steinberg *et al.* The results showed no significant sex-dosage interaction nor did they reflect any significant difference attributable to sex. A significant difference attributable to dosage was found, however ($F = 5{\cdot}07$, $D.F. = 3$ and 32, $P < 0{\cdot}01$). Further analysis by the Scheffé method established that no significant difference was present between the activity scores of controls and rats that received 0·75 mg/kg amphetamine ($t = 2{\cdot}76$, $K = 2{\cdot}92$ at $P = 0{\cdot}01$); a significant reduction occurred, however, with respect to the higher dosages of the drug.

On the basis of several experiments, Montgomery[2] proposed that novel stimuli evoke an approach–withdrawal conflict through the simultaneous arousal of fear and exploratory drives. If this hypothesis is accepted, predictions may be made concerning the effects of drugs on exploratory behaviour. As already noted, Steinberg *et al.* suggested that a depressant drug known to alleviate fear will increase exploration in a novel environment. The results of their experiment were consistent with the prediction and essentially the same result has been found in the work recorded here with another barbiturate drug. By varying the dosage of pentobarbitone it was observed that the drug increased the activity or females at two lower dosages but, at a higher dosage, activity was reduced as compared with controls. Although the drug did not affect the activity of males, a second study (to be reported elsewhere) has shown that their activity is affected in a manner similar to that of females when the intensity of masking noise is raised from 70 to 90 db s.p.l.

No definite prediction was made by Steinberg *et al.* concerning the effects of amphetamine on exploratory behaviour and, although there was a slight tendency for the drug to increase the activity of 'inexperienced' rats in that study, the present results show that the drug leads to a reduction of exploratory activity during the same period. The effect was slight at 0·75 mg/kg but, at two higher dosages, a marked reduction of activity was observed as compared with controls—a trend that was confirmed over the experiment as a whole. An interesting feature of the present experiment was the finding that female rats are more active than males and this result agrees with several previous reports[7].

Although one might account for the effects of drugs on exploratory behaviour in terms of the dual-drive hypothesis[2], more information concerning the conditions under which investigatory tendencies are evoked is needed. In so far as these conditions have been incompletely specified, there is a danger of circularity in this formulation since the presence of an exploratory drive is sometimes inferred from, and at the same time used to explain, the approach of an animal towards an unfamiliar object. To circumvent the difficulty, an alternative concept has been proposed. The idea that exploratory behaviour represents an attempt on the part of an animal to maintain an optimal level of excitement or arousal was first suggested by Hebb and Thompson[8] and has appeared in various formulations[1]. For example, an experiment by Glickman[9] originated with the assumption that the optimal level of arousal is maintained centrally but is dependent on peripheral sensory receptors for neural input and modification. The author argued that depriving an animal of one of its main sources of sensory input would modify the course of exploratory behaviour; specifically, he suggested that blind rats might be more active in an exploratory behaviour test than rats without impairment of vision as they would have to cover more territory to attain an equivalent degree of arousal through the remaining sensory modalities. The results of the experiment were in agreement with the prediction since it was found that blind rats engaged in more ambulatory activity than controls.

To account for the present findings, and by analogy with Glickman's proposal, the suggestion may be made that

any drug that raises arousal thresholds for exteroceptive stimuli will lead, within certain limits, to an increase in exploratory behaviour; conversely, a reduction in perceptual thresholds through the action of a stimulant drug may mean that an equivalent level of arousal can be derived from less exploratory activity as compared with controls. This suggestion appears to be consistent with recent neurophysiological findings. Glickman has pointed out that the role of the reticular activating system of the brain-stem in maintaining the non-specific activity of the central nervous system[10] and as a system involved in habituation to novel stimuli[11] leads one to suppose that it may constitute a threshold mechanism underlying exploratory behaviour. Furthermore, Bradley *et al.*[12] have shown, using the *encéphale isolé* preparation in cats, that amphetamine leads to a progressive reduction in the threshold for arousal responses produced by direct stimulation of the reticular formation. Bradley states that when a dosage of 1·0 mg/kg was reached, the preparation remained permanently alert in terms both of behaviour and of electroencephalograph activity and he suggests that the stimulant effect of the drug may be largely independent of environmental stimulation since the full EEG arousal response occurred irrespective of whether extraneous stimuli were excluded or not. Conversely, the thresholds for behavioural and EEG arousal were raised by pentobarbitone at 3·5 mg/kg and when the dosage was increased beyond 8–10 mg/kg, arousal produced by direct stimulation was blocked completely, even though high stimulating voltages were used.

If the suggestion that exploratory behaviour represents a tendency to maintain "an optimal influx of arousal potential"[1] proves to be essentially correct, Bradley's results afford an explanation of the present data in so far as the drugs involved have been shown to raise or lower thresholds for central and behavioural arousal. It should be noted that the general conception is not necessarily at variance with Montgomery's proposal since the concept of an optimal level of arousal implies a continuum ranging from behavioural states of drowsiness and inactivity to states of acute emotional disturbance and hyperactivity. In a recent investigation[13], it was found that rats which have had a painful shock avoid an unfamiliar area immediately afterwards, preferring instead a familiar place; on the other hand, rats not exposed to shock but given the same choice between a familiar and an unfamiliar place tended to choose the latter. The experiment seems to suggest that investigatory behaviour is likely to occur when the alerting effects of novel stimuli are superimposed on a relatively low level of central arousal whereas behavioural withdrawal may be associated with higher levels of arousal induced by stressful stimulation.

I thank Prof. O. L. Wade and Miss D. Bell (Department of Therapeutics and Pharmacology, Queen's University) for providing the drugs. I also thank Prof. G. Seth for criticism of an earlier draft of the paper, Mr. M. Moore for statistical advice, and Miss E. Bradbury for assistance.

DRONE PRODUCTION IN HONEY-BEE COLONIES (*APIS MELLIFERA* L.)

By Dr. M. DELIA ALLEN

Beekeeping Research Department, North of Scotland College of Agriculture, Marischal College, Aberdeen

In summer a honey-bee (*Apis mellifera* L.) colony normally has a single fertile female (queen) and perhaps thirty thousand infertile females (workers); the number of males (drones) varies considerably but may be as high as several thousand in colonies allowed to develop without interference from the beekeeper[1]. Biologically this great number of males is interesting because their only important function seems to be the fertilization of the very few young queens (in temperate climates) which may be reared during the summer. However, this situation may be a survival from an environment where many swarms were produced every year, or it may serve some other function such as increasing the chances of cross-mating. In any event, though, one might think that it would be more advantageous for the colony to use its resources in producing more workers, which require less food as larvæ than the same number of drones[2].

Drone brood normally makes its first appearance in late April in Scotland and continues until approximately late August, with maximum amounts in early July[3], but the factors governing its production are not known. Colonies vary very greatly in their output of drone brood[3–6], and it appears likely that adverse environmental conditions, such as food shortage or bad weather, rapidly reduce the amounts present. Another factor thought to influence the extent of drone rearing is the area of drone comb available for laying. In the natural course of events the worker bees frequently replace limited areas of worker cells with the larger drone cells and may also repair damaged worker comb with drone comb, causing a gradual increase in the number of drone cells. But it is a common beekeeping practice to remove such 'deteriorating' comb, with the aim of discouraging drone rearing and thereby encouraging the rearing of workers which will increase the foraging strength of the colony.

The present account gives results from the first year of observations designed to provide information on the precise effect of different amounts of drone comb in the colonies, and on the influence of different levels of drone rearing on the production of worker brood and honey.

The work was begun on April 30, 1962, using 17 colonies which remained queenright throughout the experimental period. All the colonies, which were sited near Aberdeen, were housed in modified National hives, consisting initially of 2 brood chambers (22 combs). As the colonies expanded other brood boxes containing empty combs were added as required, in order that the amount of space available for laying was not restricted at any stage. There were two treatments: (1) Nine 'treated' colonies (*T*) were given one British Standard frame of drone base foundation (approximately 100 in.^{2} on each face). (2) Eight 'control' colonies (*C*) were given one British Standard frame of worker base foundation. In both groups the foundation was built out by the workers into the appropriate type of comb. All other combs used were carefully selected so

that only a minimum area of drone cells (a few square inches) was present on any of them.

From the start of the experiment until swarming or supersedure occurred (resulting in a natural change of queen) examinations involving the measurement of brood areas with a grid[7] were made on each colony, once a fortnight in May and weekly thereafter. Apart from these examinations there was no interference with the natural course of events.

For the first few weeks of the experiment, as Table 1 shows, there was no significant difference between the area of drone brood in the treated and control colonies, but by May 30 the mean amount in the treated colonies was higher than in the controls, and from June 13 onwards there was significantly more drone brood in the treated colonies (t test). The results, therefore, indicate that a reduction in the amount of drone comb in the spring causes a considerable decrease in the amount of drone brood reared. Furthermore, by July 12, all the treated colonies had almost completely filled their single drone comb with brood (185–200 in.^{2}), which makes it clear that shortage of comb remained a limiting factor even in these colonies. Further experiments are planned in which a greater area of drone comb will be added.

Table 1. Areas of Drone Brood (All Stages) in Treated and Control Colonies, 1962

Date	Treatment	No. of colonies	Mean area of drone brood (sq. in.)	S.E.	P
30.4.62	T	9	4	± 2·96	N.S.
	C	8	5		
15.5.62	T	9	13	± 5·61	N.S.
	C	8	13		
30.5.62	T	9	24	± 11·83	N.S.
	C	8	15		
6.6.62	T	9	76	± 25·97	N.S.
	C	8	26		
13.6.62	T	9	146	± 23·85	< 0·001
	C	8	47		
20.6.62	T	9	164	± 30·04	< 0·01
	C	8	59		
27.6.62	T	9	188	± 22·57	< 0·001
	C	8	61		
4.7.62	T	9	212	± 21·56	< 0·001
	C	8	85		
12.7.62	T	9	217	± 14·79	< 0·001
	C	8	78		
18.7.62	T	9	214	± 16·49	< 0·001
	C	8	84		
26.7.62	T	8	170	± 18·68	< 0·001
	C	7	55		

The treated and control colonies showed no significant difference in their production of worker brood at any time (Fig. 1), and therefore at the level of drone production in the treated colonies it appears that there was no appreciable loss of effective colony strength as a result of the greater production of drones.

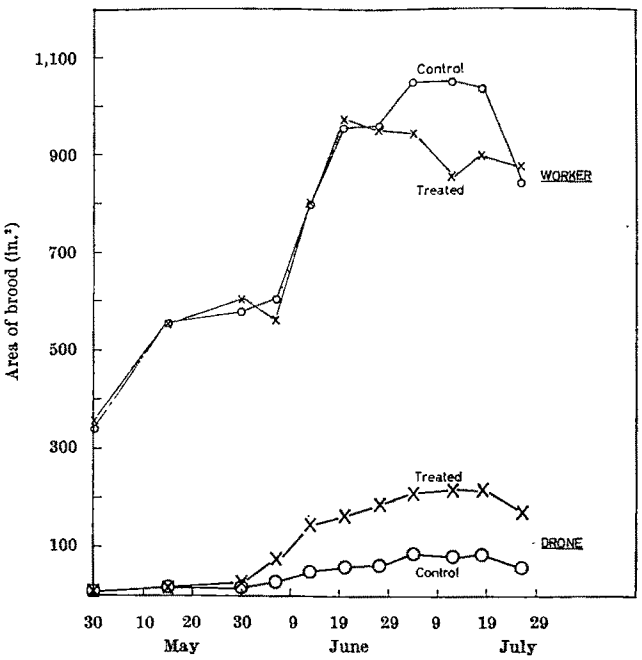

Fig. 1. Areas of drone brood and worker brood in treated and control colonies
1 sq. in. of drone brood, approx. 15 cells; 1 sq. in. of worker brood, approx. 26 cells

Similarly, honey production was not significantly different in the two groups (treated mean = 39 lb.; control mean = 50 lb.; $S.E.$ ± 15·4 lb.). This result is, of course, in accordance with the lack of difference in the production of worker brood in the two groups, since this would be reflected in the foraging strength of the colonies and their consequent honey-producing ability.

In conclusion, it should be mentioned that the summer of 1962 was exceptionally poor from the beekeeping point of view and it is possible that the results given here may have been somewhat affected by this. Nevertheless, the total production of brood (worker and drone) was similar to that of colonies studied in 1956, which was regarded as having a quite normal summer[2]. Results from future summers should show to what extent meteorological factors affect brood rearing.

MATRIX ANALYSIS AND ARCHÆOLOGY

SINCE Mr. J. Matthews, in his recent article[1], has apparently misunderstood my preliminary report on certain experimental aspects of matrix analysis and archæological data I would like to take this opportunity to reply pending the full publication of my work, especially as the practical difficulties and highly experimental nature of work in this field are clearly unrecognized in the article by Matthews.

The paper by Matthews falls into three sections: first, a lengthy summary of the Brainerd[2] and Robinson[3] articles: secondly, a lengthy summary of my preliminary article[4]; and finally, five original paragraphs. These summaries, besides being almost as long as the originals, are full of errors and in particular the "salient features of his [Brainerd's] work summarized here" bear little resemblance to the important contribution made by Brainerd. The following misrepresentation and errors are taken in sequence from Matthew's work:

(1) In paragraphs 4, 26 and elsewhere Matthews claims to quote the definitions of 'artefact' and 'type' from Brainerd and Clarke, using the term "constantly" recurrent groups of traits. The actual terms used by Clarke and Brainerd define artefact types as "consistently recurrent groups of humanly imposed traits . . . ". If indeed the recurrent trait groups were "constant" then all the artefacts in a given class would have to

be identical whereas there is always variation within limits[4].

(2) Similarly, it was not the primary aim of my paper to "place the kinds of beaker pottery in chronological order[1]" but to "examine the material for significantly recurrent groups of traits[4]". Admittedly I spent some time trying to explain one of the curious but least useful feature of archæological matrices, namely, their independently confirmed chronological linearity (with Brainerd's provisos[2]).

(3) Matthews further states that "Clarke has not made any adaptations of Robinson's method". This is not so. The sorting technique and programme details of the matrix in my article have not yet been published, and it is therefore surprising to read this statement. Of course they are based on Robinson's advance, but since he is concerned with types in assemblages and I was concerned with traits and types there are important differences. This is clearly stated in my article, in which I make it clear that several years work in collaboration with Mr. W. Easterbrook, Mr. J. Grant and Dr. R. Needham have considerably developed the programme.

(4) Again Matthews states that no coefficient has been used in the beaker matrices. I assume he means by this some coefficient to compensate for trait numerical rarity. This was quite deliberate since experiment showed that it was more desirable to compensate in the interpretive phase bearing in mind the total occurrence of the traits, this having the added advantage of presenting concisely on one diagram the actual situation regarding the data. This does not mean that compensated diagrams were not produced; in fact, several were produced for these data using the compensating factor developed by T. T. Tanimoto[5]. These confirmed the general pattern of the uncompensated matrix but in many ways were less clear for the following reason. Consider the case of beakers with cord decoration and decoration inside the lip. Roughly stated the data show that most internally decorated beakers are cord decorated; however, only a few corded beakers are internally decorated. In other words, the correlation is directional, a very high correlation one way, a very low correlation the other. The result under schemes like Tanimoto's is to average out the two and lose the significant relationship. Doubtless an efficient compensating or trait weighting scheme could be evolved and such work is going on, but it will be rather complicated and may involve prejudicing the information we are trying to gain from the matrix.

(5) Matthews once again wrongly assumes that my system of ordering and sorting are identical with that of Robinson. In any event, if Robinson's method "only applies to . . . assemblages for which the constituent types have been defined" then my method applies to assemblages of traits for which the constituent traits have been defined. The data may be heterogeneous in the quantitative and qualitative sense but are from a single artefact type varying with time, usually with more shared traits between beakers than otherwise.

(6) The concern with 'which' beakers are showing 'which' association of traits is a recognized limitation of trait correlation study. This simply means that the aspect must be dealt with by alternative methods; in this case the 'clumping' technique evolved by Dr. R. Needham (Cambridge) has successfully sorted part of these data in terms of groups of vessels with similar trait associations. This analysis confirms the breakdown suggested by the original sorted matrix and taking the three methods together—uncompensated matrix, Tanimoto matrix and clumping technique, the agreement is impressive.

(7) Matthews further alleges that there is no indication of the total number of individual beakers used for the analysis. The number of complete beakers used is in fact stated in my article, that is, 760.

(8) There remain the two original contributions put forward by Matthews. The first allegation suggests that the appearance of the trait correlation 141 in three separate parts of the matrix "cannot arise through coincidence; the suspicion is aroused that . . . the same 141 pots possess all six characteristics". This statement can be refuted on three independent accounts:

(*a*) Simple examination of the original data shows this statement to be wrong. The data are freely available for examination at Cambridge, and it is hoped will be published at some later date.

(*b*) It is impossible for these three pairs of traits to apply to the same 141 vessels since two of them, Nos. 37 and 38, are different ranges of the same rim height/waist diameter ratio. This would mean that each of the 141 vessels must have two shapes. It seems that Matthews did not check the trait key for these correlations[4] which likewise he refers to anonymously under *A/B,C/D,E/F*; they refer to my traits 5/37,11/38,15/20.

(*c*) Statistically it is wrong to suggest that because the number 141 occurs three times in a 39 × 39 matrix that these must refer to one and the same individuals. Since the matrix presents something like 700 pigeon-holes for frequencies of 0–244 (highest frequency 244 for traits 15/23) it would be statistically very surprising if some numbers in that range did not occur several times as they do. Why choose 141 ? One notes that 101 occurs four times and 11 no less than eleven times.

(9) This leaves the case of the hypothetical matrix, Tables 3 and 4. Matthews's main point seems to be that two different artefact assemblages can produce the same matrix pattern and that the groupings in these sorted matrices are not those in the imaginary initial grouping. The first point is quite well known and means nothing more than the pattern or relationship underlying often quite unrelated data maybe, and often is, similar just as two graphs of different material may be bimodal. There is no reason why unrelated material should not produce similar matrices when separately treated, so that some matrices of bacteria taxonomy show patterns very like that for the beakers, itself not unlike Tugby's Australian axe analysis. Brainerd even used this feature to produce a series of hypothetical matrix surface models illustrating various types of relationship in order that actual matrices could be compared with them[2]. I suggest that the matrix of Matthews's Table 4 shows a more proper classification of his Table 2 than the arbitrary allocation of the classes to groups shown therein. Compare Table 2, class 5, of group *B* and class 1 of group *A*; these two classes are called different 'kinds of artefact' at one point; class 5 shares no less than ten out of eleven traits with class 1 and yet they are said to belong not only to two "different kinds of artefact" but are even then attributed to two different type groups *A* and *B*. If group *A* class 1 is compared with group *B*, class 8, we find the reverse situation with puzzlingly the same allocation as before, that is, class 1 has 14 traits all mutually exclusive to the six traits defining class 8. In other words, on the basis of the trait disposition given in Table 2, I can see no evidence that the initial two-fold division into groups *A* and *B* was correct; therefore it would not be surprising if it was not borne out by the matrix sort, Table 4. In archæological terms the classes 1–8 might well be eight classes of one type, for example, beakers; hence the matrix would naturally be the same, especially since the figures used were identical for *A* and *B* leaving only three possible correlations, namely, 0, 10 or 20. Alternatively this theoretical matrix represents entirely diverse material, not compatible for examination on one matrix as is the case with a single type varying, for example, beakers; this would mean that classes one and eight on Table 2, which have no overlapping traits, might just as well be bronze shields on one hand and flint axes on the other. Meaningless questions often receive meaningless answers.

Most puzzling of all is Matthews's assumption that the sorting method he has used to produce Table 4 is necessarily the same as the unpublished programme technique used in my figures, even though they may both be *R*-matrices. Both *R* and *Q* matrices provide useful information about the data fed into them; they merely provide different aspects of the same material.

The mistaken view underlying the whole of Matthews's approach to my work seems to be his belief that I am relying entirely on this one experimental approach to classification. In fact, my whole thesis is devoted to the integration of various unrelated approaches to the same set of material in order to define the measure of agreement and the likely area of the 'real' situation. Any one of the methods used may be, and probably will be, biased by its line of approach. Another basis for misunderstanding is Matthews's apparent lack of comprehension of the pyramidal structure of archæological definitions so that the relationship trait/type is of the same nature as type/assemblage; thus matrices can be used at two different but similar levels (compare Clarke and Tugby with Brainerd). Hence the interchange as compared with Robinson's articles which was concerned with assemblages, the traits defining types show an exactly similar lenticular development and are subject to the same arguments. Just as identical assemblages of types are believed to define a single group or cultural facet so identical sets of traits are believed to define single types.

Finally, I would like to stress that the useful classification of data is the outstanding problem in many different disciplines providing, as it does, the model with which the student is taught and suggesting aspects for research.

The constant revision of classification is an essential task if old teaching models are not to conceal and condemn as ridiculous those lines of thought that imperil their validity and promise useful advance.

D. L. Clarke

Peterhouse,
Cambridge.

[1] Matthews, J., *Nature*, **198**, 930 (1963).
[2] Brainerd, G. W., *Amer. Antiquity*, **16**, 4, 301 (1951).
[3] Robinson, W. S., *Amer. Antiquity*, **16**, 4, 293 (1951).
[4] Clarke, D. L., *Proc. Prehist. Soc.*, **28**, 371 (1962).
[5] Tanimoto, T. T., "An Elementary Mathematical Theory of Classification Prediction", I.B.M. (1958).

I was interested to read the preceding communication commenting on my recent article in *Nature*. There are one or two points that I should like to make. The numbered paragraphs refer to the original paragraphs in Clarke's letter.

I think that anyone who is interested can read the papers by Brainerd and Robinson to which Clarke refers, and so judge the validity of Clarke's statements about the length and accuracy of my summary.

(1) Clarke is wrong. Brainerd[1] writes of "the criteria of *constant* combination of attributes in the defining of types". Neither Brainerd nor Robinson, in the articles to which Clarke refers, mentions types in terms of "consistently" recurring groups of traits.

(2) Clarke misquotes me here. I wrote[2], "The chronological purpose is only part of Clarke's endeavour. He is primarily concerned to define kinds and ranges of pottery". But if Clarke's intention is not to place kinds of beaker pottery in a chronological order, why has he concerned himself with Robinson's statistical technique ? This, in Robinson's words, is a method for chronologically ordering archæological deposits. The first part of Clarke's article[3] is a description of the method devised by Robinson, and the second part describes an application of this method to a collection of beaker pottery.

(3) In his article, Clarke states that he has made use of Robinson's method. He does not describe any adaptations that he may have made. He does mention the use of "an electronic brain" (*sic*) to sort his Tables, but this does not entail any modification of the statistical technique. Clarke does not mention either Dr. Needham or Messrs. Easterbrook and Grant in his article.

(4) On reading Clarke's article, I assumed that no coefficient had been entered in the unsorted matrix, and that the numbers of individuals observed to possess two characteristics had been entered directly. There are many suitable coefficients which can be used in this sort of situation[4]. Robinson has a very good coefficient, specially devised for his own method.

(5) This paragraph neatly summarizes Clarke's basic misunderstanding. The assemblages to which Robinson refers are archæological deposits which are compared in terms of the proportions of the various types which they contain. If Clarke were to arrange the beakers into assemblages from various archæological deposits, and then compare these assemblages in terms of the proportions of the various traits they contain, then he might be able to place those deposits in a chronological sequence.

(6) I am not impressed by the agreement which Clarke mentions here. The presentation of the data is in question, not the possible sorting techniques.

(7) Clarke misrepresents me here. I allege nothing in this context. I point out that there is no indication of the number of beakers used in the analysis in either of his two matrices. I also point out that the numbers of individual pots which possess each trait (which would occupy the main diagonal) are also missing from the Tables.

(8) Clarke is right and I am wrong. There is information contained in the matrix which demonstrates that the example to which I refer, concerning the number 141, is not appropriate for the point that I wish to make. I wish to submit the following errata to my article in *Nature*: p. 933, lines 35, 37, 38, 40, p. 934, line 1, for "141" read "149" ; p. 933, line 39, for *E* read *A*, for *F* read *E*; p. 934, line 1, for "six" read "five".

If my suggestion (it is only a suggestion) is inappropriate, then I shall be pleased to examine the beakers which demonstrate its inappropriateness.

(9) Is Clarke wise in his comment about imaginary figures and matrices ? The matrix which he gives in his article as Fig. 2, on which pivot the arguments substantiating his method, is filled with imaginary figures.

Clarke's comments on the matrices which I use as an illustration and which are included at the end of my article are quite interesting—although I am not sure that the point that Clarke is trying to make is very clear; but I am sure that Clarke has missed the point of my illustration.

In his article Clarke describes the statistical technique devised by Robinson for the chronological ordering of archæological deposits; he then applies this method to a collection of beaker pottery, and proceeds to arrange this collection in types and ranges of types which are presumed to have a chronological order. In my article[2] I have mentioned some of the reasons why Robinson's technique cannot be applied to collections of beaker pottery in this way. If Clarke is using some other method to analyse the collection of pottery in terms of significantly recurring groups of traits, then perhaps he could explain the principle on which this method is based and how this method can be expected to achieve his stated purpose.

LETTERS TO THE EDITOR

PHYSICS

A New Explanation of Domain Wall Creep in Thin Magnetic Films

We suggest an alternative explanation of the creep effect in thin magnetic films, and briefly outline experimental results which support it.

Creep is the phenomenon whereby domain wall motion in a thin magnetic film occurs when a number of magnetic field pulses are applied in a direction other than the easy direction, even though their magnitude is less than the d.c. threshold value. In our experiments we find it convenient to apply a d.c. field in the easy direction and pulse fields in the hard direction.

It has been suggested[1] that the transition of the domain wall from cross-tie or Bloch to Néel type, which occurs when a transverse field is applied, could itself be a cause of creep. However, the exact mechanism is not clear. According to the wall transition theory, creep would not be evident in a very thin film of thickness less than about 400 Å since no wall transitions can occur and the walls are always of the Néel type. However, we have observed that, whereas creep does not occur in these very thin films if the transverse pulses are all in the same direction, nevertheless the effect can be induced by applying the transverse pulses alternately in one direction and then the other. Fig. 1 shows typical thresholds for a 250 Å film with a d.c. field along the easy axis, and, in the hard direction, either (*a*) a d.c. field, or (*b*) a large number of transverse pulses (> 100,000) all applied in the same direction, or (*c*) 500 transverse pulses applied alternately in opposite directions. It is difficult to reconcile this result with the wall-transition theory.

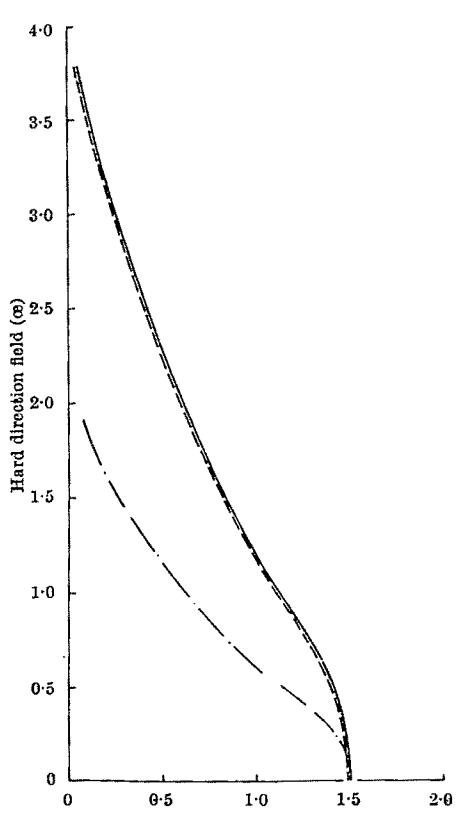

Fig. 1. Influence of bi-directional pulse fields on creep effect on thin magnetic film (250 Å). ——, d.c. threshold; – – –, uni-directional pulse threshold (> 100,000 pulses); —·—, bi-directional pulse threshold (500 pulses)

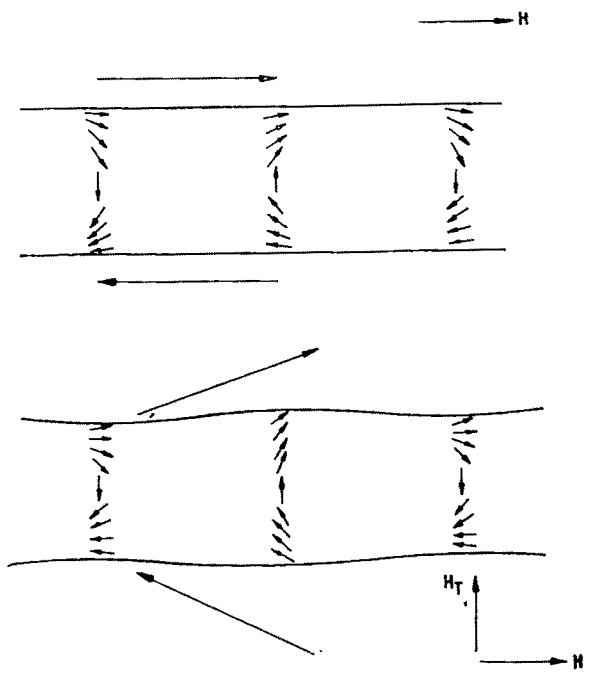

Fig. 2. Above, postulated Néel wall with alternate sections having different senses of rotation of magnetization vectors; below, effect of application of transverse field H_T

An alternative mechanism which we suggest, which does offer an explanation of creep, can be based on the change in structure of Néel walls when transverse fields are applied. Suppose the sense of rotation of magnetization in the Néel wall differs in alternate sections. When a transverse field is applied in conjunction with a d.c. field in the easy direction such that at no time is the d.c. threshold exceeded, then, as shown in Fig. 2, the transverse field creates greater or less divergence of the magnetization vector in alternate sections of the wall depending on whether the magnetization along the centre of the wall reinforces or opposes the applied field. The less divergent parts of the wall are comparatively unrestrained and can advance across the film under the influence of the easy direction field; nevertheless, any motion of the wall as a whole is prevented because the more divergent parts are unable to pass faults and inclusions. So long as the transverse field is in the same direction this state of affairs persists and the wall as a whole remains stationary. However, if the transverse field is reversed then the more divergent parts of the wall become less divergent and can now move past obstructions. The movement continues until again stopped by the retarding effect of those sections of the wall which have just become more divergent when the field reversed and are unable to progress past faults. Therefore, every time the transverse field is reversed so alternate parts of the domain wall advance; the overall effect is that the entire wall creeps.

We have observed visually using colloid techniques in conjunction with low-pulse repetition rates that alternate sections of Néel walls do indeed advance in the way we suggest when the field is reversed and the wall as a whole moves across the film.

If, as we suggest, creep is more likely when there are Néel walls in the film, then creep may be expected in those field configurations which result in the formation of Néel walls. Here we may well have the explanation of Middelhoek's experimental results which show that creep does indeed seem in some way related to wall transitions from either Bloch, or cross-tie, to Néel.

Although the mechanism we put forward is concerned primarily with Néel walls, there is nevertheless the possibility that a similar, though smaller, structural change may occur involving only Bloch or cross-tie walls. This aspect remains to be investigated in later work.

Primary and Subsidiary Condon Loci of Molecular Spectra

The Franck–Condon principle[1] predicts that the vibrational quantum numbers v', v'' of the strongest bands of a molecular spectrum lie on a family of open double-limbed quasi-parabolic curves in the $v'v''$ plane which are often roughly coaxial about $v'=v''$. The curves are called the primary (outermost) and subsidiary (inner) Condon loci. The loci are indicated on a number of recently published Franck–Condon factor arrays[2–4]. The smaller the difference Δr_e between equilibrium internuclear separations r'_e and r''_e of the molecular potentials involved, the narrower are the loci and the closer is the apex of the primary locus to (0, 0). The greater Δr_e, the more open the loci, and the further the apex of the primary locus is from (0, 0) down the diagonal $v'=v''$. The apices of the subsidiary loci are often spaced roughly two quantum numbers apart down the diagonal axis.

Apart from brief semi-classical discussions of the shape of the primary locus[5,6], little comment has been made on their geometry from a quantum point of view. The geometry of the primary and subsidiary loci, which is therefore discussed here, has obvious applications to identifications of molecular spectra in addition to being of general spectroscopic interest.

Intense bands have large Franck–Condon factors $q_{v'v''}=|\int\psi_{v'}\psi_{v''}dr|^2$ for which the non-cancelling overlap between vibrational wave functions ψ_v is large. Large overlap usually occurs when an antinode of one wave function and an antinode of the other wave function lie in the same region of r. The primary Condon locus passes through those v', v'' values for which the largest contribution to $q_{v'v''}$ occurs by strong overlap between pairs of terminal (outer) antinodes. Similarly the subsidiary loci pass through v', v'' values for which the largest contribution to $q_{v'v''}$ occurs by overlap between terminal and subsidiary antinodes.

The Franck–Condon principle, which in classical terms calls for equality of oscillator turning points[6], can thus be recast in quantum terms by calling for equality between the positions of an appropriate pair of antinodes, one for each of the levels involved.

Pairs of antinodes of order p are equally spaced about r_e for potentials which are symmetrical about r_e. There are $w+1$ such pairs of antinodes for even ($v=2w$) and for odd ($v=2w+1$) vibrational levels. The p'th antinodes of the v'th level of a symmetrical potential thus lie at $r_{v_1}(p)$ and $r_{v_2}(p)$ where:

$$r_{v_1}(p)=r_e-F_v(p) \tag{1a}$$

$$r_{v_2}(p)=r_e+F_v(p) \tag{1b}$$

$F_v(p)$ is the separation between the p'th antinode and r_e. It depends on the specific form of the potential. For a simple harmonic potential it is possible to show that:

$$F_v(p)=(k\omega)^{-1/2}\left\{\frac{v-b_p}{a_p}\right\}^{\frac{1}{n_p}} \tag{2}$$

where $1<a_p<3{\cdot}5$; $b_p=2(p-1)$, $1<n_p<2$, $0<p<10$, $k=4\Pi^2\,\mu c/h$ and ω is the oscillator frequency in cm^{-1}.

As the Franck–Condon principle calls for equality of antinode positions, the primary locus is:

$$r_{v'_{1,2}}(1)=r_{v''_{1,2}}(1) \tag{3a}$$

and the p'th subsidiary locus lies in the region where:

$$r_{v'_{1,2}}(1,p)=r_{v''_{1,2}}(p,1) \tag{3b}$$

For a simple harmonic potential, equation (3a) may be rewritten, using equations (1a), (1b) and (2), as:

$$\pm k^{1/2}a_1^{\frac{1}{n_1}}\Delta r_e=\pm\frac{(v'-b_1)^{\frac{1}{n_1}}}{\omega'^{1/2}}\pm\frac{(v''-b_1)^{\frac{1}{n_1}}}{\omega''^{1/2}} \tag{4}$$

where Δr_e is the magnitude of $r'-r''_e$. Equation (4) represents the primary locus in the v', v'' plane.

The choice of signs implied in equation (4) allows it to take the following physically meaningful forms:

$$\Delta r_e=V_1'^{a_1}+V_1''^{a_1} \tag{5a}$$

$$\Delta r_e=V_1'^{a_1}-V_1''^{a_1} \tag{5b}$$

$$\Delta r_e=V_1''^{a_1}-V_1'^{a_1} \tag{5c}$$

where $\alpha_1=1/n_1$ and $V_1=(k\omega)^{-1/2}a_1(v-b_1)/a_1$. The gross regional overlap between the two potentials involved determines where each of these equations is used to represent segments of the primary Condon locus as follows.

When Δr_e is sufficiently large that only one limb of one potential curve (for example, $r<r'_e$ or $r>r'_e$) lies in the same range of r as the other limb of the other potential curve ($r>r''_e$ or $r<r''_e$) equation 5a represents the primary Condon locus. It is a broad curve, well separated from (0, 0).

On the other hand, when Δr_e is small so that there is complete overlap between all of each potential, three segments (a, b, c) have to be treated separately. They are:

(i) If $r'_e>r''_e$; (a) $r<r''_e$, (b) $r''_e<r<r'_e$, (c) $r>r'_e$

(ii) If $r''_e>r'_e$; (a) $r<r'_e$, (b) $r'_e<r<r''_e$, (c) $r>r''_e$

Equation (5a) represents segments (ib) and (ii$b$). Equation (5b) represents segments (ia) and (ii$c$). Equation (5c) represents segments (ic) and (ii$a$). In each of these cases, equation (5b) represents the apex of the locus and equations (5a) and (5c) represent the limbs.

Equations 5a, 5b, 5c have been plotted for a number of band systems and have been found to represent the primary locus quite well for moderate values of quantum numbers ($v\sim10$) in spite of the obvious limitations of the potential used. Similar treatment of equation 3b has led to adequate representation of the subsidiary loci.

Predissociation and Perturbation in the Selenium Molecule

It is known that the predissociation produced by the radiationless transition from an excited stable molecular state to an unstable one is responsible for the broadening of the absorption rotational lines and the increase in intensity of the perturbed bands. In the emission spectrum, the bands vanish in the region of perturbation. This usual case is well illustrated in the band system $B^3\Sigma_u^- - X^3\Sigma_g^-$ of S_2. In the progression $v''=0$, the absorption spectrum shows sharp band heads up to $v'=9$, while the $v'=10, 11\ldots$ bands are very diffuse. At $v'=10$ a strong intensity increase occurs. This predissociation corresponds to the case I(c) of Herzberg[1] due to an interaction between two excited states one of which is stable and the other of repulsive type. The crossing of these two potential energy curves occurs above the dissociation limit of the repulsive level. So far it is the only well-established case of this kind.

The foregoing appearance is not found in the similar transition $B\Sigma - X\Sigma$ of Se_2. In the progression $v''=0$, absorption bands are observed up to $v'=22$, and are followed by a short-range continuous spectrum. The difference with S_2 is that in the small dispersion spectrum there is no apparent intensity increase. The perturbation seems so strong that the nearest diffuse bands have the aspect of a continuous background. The extrapolation of this progression gives for the short wave-length limit the value $\lambda_1=3200$ Å. On the other hand, the short wave-length limit of the continuous spectrum is $\lambda_2=2750$ Å. Thus, the continuous spectrum is actually made up from the broadened bands and a true short range continuum. The crossing point of the two interacting states is located near the dissociation limit of the stable state. Among the numerous sub-cases of predissociation of diatomic molecules discussed by Mulliken[2], only two may be considered here. In both cases the internuclear distance r_c of the crossing point is larger than r_e. If the perturbing state is a stable one, the case C^+ occurs, where both potential curves have a common asymptote and both molecules originate from the same atoms $S(^3P)+S(^1D)$. In the second case the perturbing state is of repulsive type and originates from different atoms. In order to obtain more information concerning the broadening of the line, we photographed again the absorption spectrum near the limit of the progression $v''=0$. Fig. 1 shows a part of the spectrum taken in the region 3200 Å–3600 Å with a JAco-Ebert spectrograph having a linear reciprocal dispersion of 0·6 per mm. The absorbing layer was 14·5 cm long and the pressure of selenium about 15 mm mercury. It is seen that the width of the rotational lines of the (18·0) band (Fig. 1, below) is about 3 times smaller than that of the (20·0) band (Fig. 1, above). In the same spectral region the rotation structure is simple and seems to correspond to a $^1\Sigma$–$^1\Sigma$ transition. The rotational lines are well separated, and the effect of the perturbation is to broaden the lines in consequence of the decrease of the life-time of the excited state; but the broadened lines do not overlap in the (20·0) band. This is why there is no intensity increase of that band.

The following (21·0) band shows no rotational structure with the dispersion here used. Under small dispersion this band does not seem to be stronger than the (19·0) band. Therefore, we have to conclude that in the present case the decrease of the lifetime is associated with a greater width of the lines but not necessarily with a higher intensity of the perturbed band. It is known indeed that for a single line the total intensity absorbed is not sensitive to the shape of the line profile and basically depends on the product of the oscillator strength and the concentration of absorbing particles. The increase of the band intensity could only originate from the overlapping of the neighbouring lines.

To sum up, the perturbations in the $B\Sigma - X\Sigma$ transition are basically similar for the two molecules, Se_2 and S_2. In both cases diffuse bands are observed. Their number only varies. Contrary to what is observed in sulphur, selenium bands do not get sharp again when v' increases from the perturbation region, owing to the proximity of the dissociation limit. This results from the relative position of the potential curves of the stable excited state and the repulsive state, which cross each other near the dissociation limit of the stable molecule.

High-current Cathode for Electron Linear Accelerator

For many years, the bombarded tantalum cathode gun has acted as a reliable source of electrons for injection into demountable linear accelerator systems[1,2]. An important advantage of the pure metal cathode, such as tantalum or tungsten, is its high resistance to poisoning under adverse vacuum conditions which exist in linear accelerators during multipactor resonances, during high energy beam collision and clipping on inner surfaces, and, in particular, when the microwave structure is initially out-gassed by application of the radio-frequency power. Furthermore, after the cathode has cooled, the accelerator may repeatedly be opened to atmosphere, re-evacuated and the cathode returned to operating temperature without loss of emission and without additional precautions or special restrictions. On several occasions, vacuum systems containing pure metal cathodes at elevated temperatures have been inadvertently opened to atmosphere, and it has been possible to re-operate these guns satisfactorily.

Even with the assurance of an extremely clean system and a higher order of vacuum (10^{-8}–10^{-6} torr) as offered by the application of sputter-ion pumps[3] to high-power linear accelerators (the first such combination was a machine constructed for the Danish Atomic Energy Commission and operated in December 1959), preference remained for the bombarded tantalum cathode because it did not require bake-out procedures, isolating valves, or activation schedules as is the case, for example, with coated emitters.

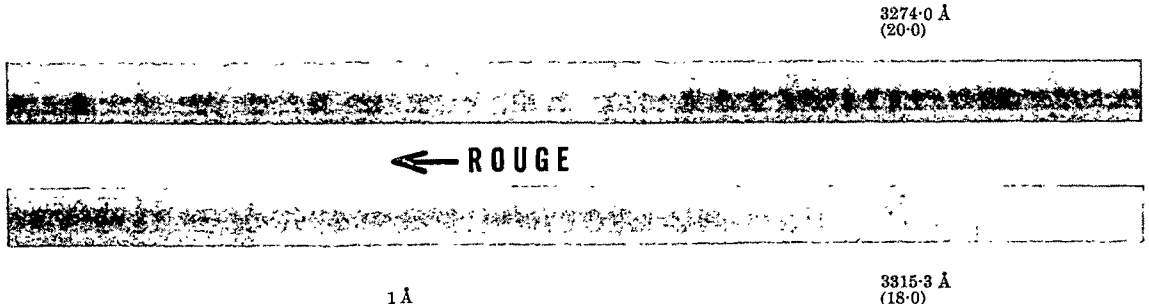

Fig. 1

Earlier accelerator applications required pulsed gun emission currents of the order of 1–2 amp, and the cathodes were operated under temperature-limited conditions which necessitated the use of sensitive control systems to maintain the injected pulse current at a constant level. An operating temperature of approximately 2,000° C (brightness) provided 250 m.amp/cm² and the larger sizes required 1,200–1,700 W of bombarder power at 3 kV plus 150 W of filament dissipation. Under these conditions tantalum cathodes are characterized by long life, and earlier installations have demonstrated in excess of 4,000 h.

Tantalum cathodes which have been operated at temperatures closer to the melting point have shown a tendency to exhibit large crystals which, becoming displaced with respect to each other, distort the original curved surface of the cathode and adversely affect the beam optics. Metallurgical examination of these cathodes indicates that the displacements are due to stresses set up by differential expansions between the cathode and its support structures, causing sliding of the crystal boundaries at the higher temperatures.

A further consideration in the application of a pure metal emitter is its relatively high evaporation rate at temperatures which are required for thermionic emission[4]. These high rates can result in appreciable loss of material over the working life of the cathode. The vapour pressure for tantalum at 2,200° C (about 2,000° brightness) is 10^{-6} torr corresponding to an evaporation rate of approximately 10^{-8} g/cm²/sec, and at 2,500° C these figures are about 40 times greater.

The vapour pressure for tungsten at a given temperature in the working range is an order lower than tantalum, but the emission per unit area is also lower (approximately one-third). Consequently, the required operating temperature to obtain the same total emission is higher, and the resulting vapour pressure is similar to that of a tantalum cathode. Also, additional heater power is needed to supply radiation losses.

Hence it became apparent that earlier established bombarded pure metal cathode designs would be impracticable for emission densities in excess of about 300 m.amp/cm² as occurs, for example, when the beam optics requirements of a high current injection system demands a cathode of relatively small diameter.

The suppression of pulse shortening[5,6] and the increasing popularity of short-pulse, high-current accelerator operation, that is, the stored energy régime, established a need for a reliable source which could: (1) provide emission densities of about 1 amp/cm²; (2) ensure a high degree of geometric stability; (3) operate under adverse vacuum conditions.

Earlier experiments (in 1960) in our laboratories using impregnated barium dispenser cathodes in a radiographic linear accelerator confirmed that very high emission densities could be obtained at moderate cathode temperatures (1,100° C), but considerable difficulty was encountered with residual gas poisoning. Failure of the impregnated cathodes could with some degree of certainty be ascribed to poor vacuum conditions. Nevertheless, it was considered that they were unnecessarily sensitive and impractical for this type of linear accelerator[7], which featured an X-ray target requiring a rotating high vacuum seal. A tungsten cathode was afterwards fitted and has since demonstrated life-times in excess of 3,000 h.

Storage of impregnated cathodes is also a problem as they tend to pick up water and carbon dioxide from the air which may cause them to swell and crack. Dispenser cathode studies are continuing and various activators are being investigated in an attempt to reduce residual gas poisoning sensitivity and field emission effects due to sputtered barium and barium compounds. In general, this type of emitter is seriously affected by oxygen and normally requires a guaranteed vacuum of better than 5×10^{-7} torr.

As a result of these experiences, we decided to investigate the possible application of thoriated tungsten type cathodes in linear accelerators. It was considered that this type of source would operate satisfactorily in relatively poor vacuum and that it would produce a space charge limited beam at considerably less temperature than the previously discussed bombarder designs.

According to Jenkins and Trodden[8], carburized thoriated tungsten thermionic emitters can operate satisfactorily in partial pressures of oxygen up to 10^{-5} torr, carbon dioxide up to $2{\cdot}5 \times 10^{-5}$ torr, and water vapour up to $0{\cdot}6 \times 10^{-5}$ torr. These gases are the most detrimental that are likely to be present in a demountable system. (This compares with a 10^{-7} torr upper limit for partial pressure of oxygen for operating impregnated barium dispenser cathodes[9].) The remaining residuals, hydrogen, nitrogen, carbon monoxide and organic vapours, have no harmful effects on these cathodes up to much higher pressures. Since the actual cathode region of the accelerator may reach total pressures estimated to be up to 5×10^{-5} torr and the emission capability, at comparatively low temperatures, of the thoriated tungsten cathode far exceeds the required 1 amp/cm², it will be appreciated that on the basis of this evidence the thoriated tungsten cathode appeared to offer a chance of satisfying the requirements of high current linear accelerators.

Cathodes were prepared by special machining techniques from solid tungsten which contained 2 per cent thoria. The emitting surface, usually in the form of a concave dish, was carburized by first uniformly spraying the surface with a suspension of pure graphite powder in a suitable binder solution and then vacuum furnacing the cathode to 2,000° C until all the carbon had reacted. This process was repeated until a carbide layer of about 0·010 in. was obtained. Carburized surfaces prepared in this manner had exceedingly uniform appearances. However, when layers thicker than 0·010 in. were attempted the cathode surface tended to blister and distort.

A number of cathode assemblies have been made with outside diameters of 0·75 in., 1·5 in., and 2·375 in. Each cathode was attached to a molybdenum ring and supported by tantalum strips welded between the molybdenum ring and the surrounding heat shields.

The 1·5-in. cathodes were assembled in 0·11 microperveance gun structures and produced space charge limited beams at a temperature of 1,580° C (brightness). These guns have been operated for several hundred hours at a pulse voltage of 105 kV and at total pressures of between 10^{-7} and 5×10^{-5} torr without sign of emission deterioration. The amount of carbon present should enable free thorium to be produced at an adequate rate for many thousands of hours. This type of cathode is not chemically active when brought out into the atmosphere and has no tendency to pick up water vapour and carbon dioxide from the air. No special storage or handling procedures are necessary, and geometrical changes during life have been avoided.

The high thermionic activity of these cathodes enabled the guns to be operated space charge limited with the attendant advantage of emission insensitivity to heater power fluctuations and the avoidance of a critical regulation control circuit. The lower temperature of operation required only 500 W of bombarder power for space charge operation compared with 1,800 W for a tantalum cathode of the same dimension (1·5 in. diameter).

In the event of cathode emission failure by loss of carbon or severe poisoning, it should be possible to raise the cathode temperature and recover the pure metal emission, thus permitting the completion of a run before replacing the source.

A recently constructed two-section, 45-Mc/s-band-width, *S*-band linear accelerator, model *V7709X*, specifically designed for high-beam current with a rating of 1 amp at 10 MeV and utilizing a 5-amp thoriated tungsten cathode electron gun has demonstrated a peak beam current of

2·5 amp at 8 μsec pulse-length without sign of pulse shortening. This cathode and wave-guide system had sufficient beam-loading capability not only to reduce the effective residual radio-frequency power to zero and readily achieve the maximum conversion efficiency, which was in excess of 85 per cent, but it also enabled a large proportion of the 8 MW input coupler radio-frequency power to be transferred back to the microwave circuit by beam induction and to appear in inverse phase at each wave-guide termination. This regenerated power condition was previously achieved in our laboratory, October 1962, also without pulse shortening, and using a bombarded tantalum cathode in a two-section, *S*-band high power accelerator, model *V*7709, of lower current rating and with a different wave-guide design concept than the *V*7709*X* machine. These higher beam currents and induced powers have encouraged further investigation of high-power radio-frequency generation by relativistic bunches of electrons in addition to offering alternate lay-out arrangements of multi-section linear accelerator systems.

A thoriated tungsten cathode of larger diameter and a higher perveance electron gun have been designed and constructed for attachment to the existing inflector type injection system on the *V*7709*X* machine. Replacement of the 5-amp gun with this higher current source will enable the ultimate beam loading condition to be attained. Additional high-current studies will be conducted for both the steady-state and the stored-energy (short-injection-pulse) modes of operation. It is also planned to increase the existing relatively low electric field of 9 MeV/m (loaded at 1 amp) by doubling the input peak power-level.

In conclusion, it should be reported that, on three separate occasions during the foregoing tests and while operating with a 2·5-amp beam at 6·0 μsec, a pin hole puncture developed in the accelerator output window causing a vacuum failure and closing down the system. The thoriated tungsten cathode was left *in situ* on each occasion and the system was re-evacuated. During out-gassing of the accelerator, the cathode was maintained at approximately 1,000° C for 15 min, and a space charge limited beam of the original magnitude reappeared when the cathode temperature was raised to its normal operating value.

The ability to produce beam pulses of greater than 100 joules in a 5-mm cross-section now poses a difficult beam extraction problem requiring an alternative approach to that of a simple transmission assembly.

RADIOPHYSICS

Back-scatter of Radio Waves from the Equatorial *F* Region

The spread-*F* which is observed at equatorial latitudes varies in its appearance during the night[1], but may be divided into two basic types, which have been termed equatorial type[2] and temperate latitude type[3] respectively. As it is known that irregularities giving rise to equatorial type spread-*F* are capable of scattering radio waves with frequencies greater than the critical frequency of the *F* layer, it was decided to carry out, at Accra, an investigation of the irregularities, using a back-scatter radar operating on a frequency of 18 Mc/s. Such an equipment has a number of advantages over the normal ionosonde, including greater sensitivity, and the possibility of using directional aerials.

The equipment used for the experiment described in this communication consisted basically of an 18-Mc/s transmitter of 1-kW peak power, 300-μsec pulse duration, and 16·7-c/s repetition frequency, and a pulse receiver having a band-width of approximately 6 kc/s. The aerial used was a three-element Yagi, steerable both in elevation and azimuth; the same aerial was used both for transmitting and receiving.

Observation, on an *A* scan display, of the echoes obtained using the equipment already described, showed that during the period 1900–2200 G.M.T. there occurred echoes which could not have been caused by the mechanism of ionospheric reflexion and ground scattering which is responsible for the echoes normally observed on back-scatter radars. These echoes occurred at ranges shorter than the range of normal ground back-scatter, and at angles of elevation which on some occasions were approximately vertical; it was clear, therefore, that the echoes were due to direct back-scatter from irregularities in the *F*-region.

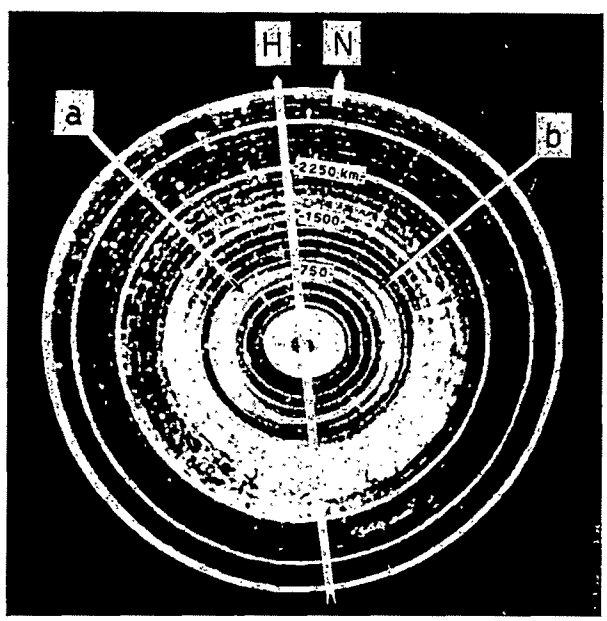

Fig. 1. Back-scatter, 2030 G.M.T., October 31, 1962

In order to record the occurrence of direct back-scatter echoes in a convenient form the equipment was arranged to produce plan position indicator photographs at pre-set intervals. A typical plan position indicator picture is shown in Fig. 1, where, in addition to the ground back-scatter echo at a range of 1,000–2,000 km, two direct back-scatter echoes (labelled *a* and *b* in Fig. 1) are also present, at ranges of 600–900 km in the west, and 750–950 km in the east (in Fig. 1 the range markers are at intervals of 150 km with every fifth marker accentuated; the directions of geographic and magnetic north are denoted by *N* and *H* respectively). It will be noted from Fig. 1 that the direct back-scatter echoes are present only to the west and to the east, and not to the north or south, and that the direction from which maximum scattering occurs is perpendicular to the magnetic meridian rather than the geographic meridian. The angular spread over which the echoes are observed approximates to the beam-width of the aerial and hence the actual angular

spectrum of the back-scattered signal in the horizontal plane is probably quite small. It will also be noted from Fig. 1 that the echoes have a fairly small spread in range. The most frequently observed range spread, allowing for the length of the transmitted pulse, is about 100 km, but occasional echoes occur showing a range spread as great as 400 km; on no occasion have echoes been observed simultaneously from all parts of the sky "visible" to the sounder. The aspect sensitivity, indicated by the observation of echoes to the east and west only, is undoubtedly due to field alignment of the elongated irregularities responsible for the echoes (the elongation and field alignment of irregularities in the equatorial F region has previously been noted by a number of workers[4,5]).

The range spread of echoes indicates that the irregularities occur in patches with east–west dimensions of approximately 100 km; this is in good agreement with the results of Kent[5], who found that the irregularities responsible for the scintillation of satellite signals at Ibadan occurred in patches approximately 100 km in horizontal extent; but is not in agreement with the findings of Cohen and Bowles[6], who observed that patches of irregularities, capable of supporting 50-Mc/s forward scatter near to the magnetic equator in South America, frequently extended over distances of up to 1,000 km in the east–west direction. This difference in the patch size may be due to the fact that the measurements of Cohen and Bowles were made at sunspot maximum, whereas the measurements reported here were made nearer to sunspot minimum; the measurements made by Kent[5], however, were carried out at the end of 1959, nearer to sunspot maximum than minimum.

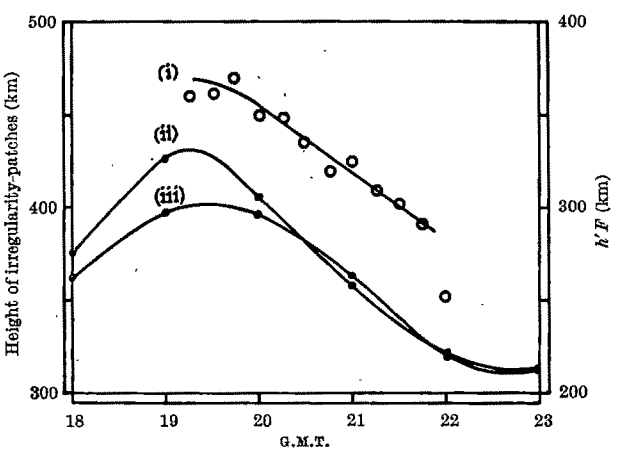

Fig. 2. Nocturnal variation in height of irregularity patches and $h'F$. (i) Back-scatter; (ii) $h'F$, back-scatter present; (iii) $h'F$, back-scatter absent

The plan position indicator records enable one to determine when a patch of irregularities is vertically overhead the sounder, and hence, from the minimum range of an echo produced by such a patch, to determine the height of the patch. The heights of some sixty patches determined in this manner were used to construct an average variation in height with time over the period during which echoes are observed. The variation in height is shown in Fig. 2 along with the variation in $h'F$ for the same period. It will be noted that the variation in height of irregularity patches is very similar to the variation in $h'F$, but the actual height of patches is approximately 150 km above that of $h'F$, which means that the irregularities occur in the region of h_m. It may also be seen from Fig. 2 that the post-sunset rise in $h'F$ is greater on days when scatter is present than on days when it is absent; a similar phenomenon has previously been reported by Lyon *et al.*[1] in connexion with equatorial type spread-F. The height of 150 km above $h'F$ may be compared with that of 50 to 100 km above $h'F$ observed by Kent and Koster[7] for the irregularities giving rise to scintillation of satellite signals observed at Accra during 1961.

A comparison between the occurrence of direct back-scatter at 18 Mc/s and the presence of equatorial type spread-F on ionograms taken at Accra has been made, and the result is given in the form of a contingency table (Table 1). It may be seen from Table 1 that although there is a strong correlation between the occurrence of direct back-scatter and equatorial type spread-F (the probability of independence is less than 0·01), and scatter is never observed in the absence of spread-F, scatter does not invariably occur when spread-F is present.

Table 1. Contingency Table for Occurrence of Direct Back-scatter and Equatorial Type Spread-F

		Spread-F Present	Spread-F Absent
Back-scatter	Present	26	0
	Absent	11	11

The period of time over which echoes are observed is 1900–2200 G.M.T., which is approximately the same as the period of occurrence of severe flutter fading[8], and abnormal Doppler shift of obliquely propagated signals[9]. Measurements made during 1962 indicate that the seasonal variation in the occurrence of direct back-scatter shows an equinoctial maximum similar to that reported by Koster[8] for flutter fading. It seems probable that the irregularities responsible for direct back-scatter at 18 Mc/s are similar to those which cause flutter fading and Doppler shift of obliquely propagated signals.

I thank Prof. R. W. H. Wright and Dr. J. R. Koster for many helpful discussions. This work was sponsored by the Cambridge Research Laboratories, OAR, through the European Office, Aerospace Research U.S. Air Force.

CRYSTALLOGRAPHY

Whisker-like Growth of Polyoxymethylene from Solution

High-molecular-weight polyoxymethylene is known to crystallize very readily. Various forms of single crystals of this polymer have been described: crystals about 1 mm in size can be grown directly from monomeric formaldehyde[1–3], fibres are formed by polymerization of crystalline trioxane[4–6], while hexagonal lamellæ and thin star-shaped crystals have been grown from solution of the polymer[7,8].

We wish to report a new morphological variant of crystalline polyoxymethylene, which we obtained in copious yield from dilute solutions. As this type of crystal shares many characteristics with 'whiskers' grown from low-molecular-weight materials, we tentatively consider them as polymer 'whiskers'.

These characteristics are:

(*a*) Although the crystals possess a rather complex shape, they behave like single crystals, so far as can be

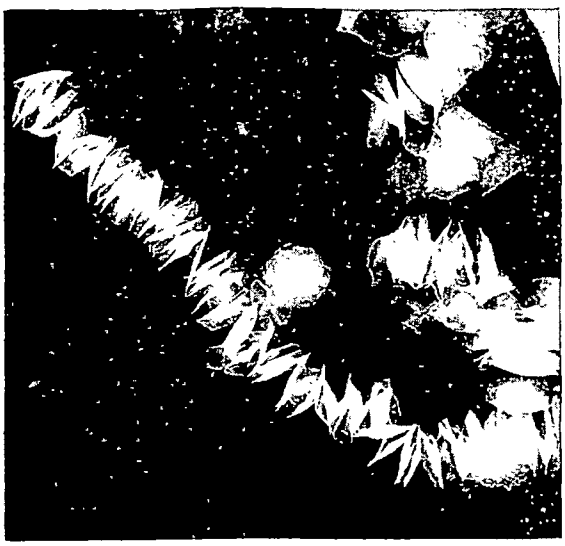

Fig. 1. Polyoxymethylene 'whisker' (× *c.* 3,200; platinum/carbon shadowed)

Fig. 2. Enlarged portion of Fig. 1 showing helicoidal structure of centra fibril

judged from microscopic observation between crossed polarizers.

(*b*) Growth in one direction, that of the crystallographic c-axis, is strongly preferred. The crystals may grow 10–100 times as long as they are thick.

(*c*) The crystals have a periodic shape, which microscopically gives at first sight the impression of a zig-zag chain of fibrils, or a string of beads.

Electron micrographs (Figs. 1 and 2) of some specimens show they actually consist of a central filament, from which hexagonal lamellæ grow at short intervals. It seems as though the central filament itself is helicoidal. The growth of helicoidal forms, and also of lamellæ on filamentous crystals has often been observed in the study of whiskers of low-molecular-weight materials[9]. Growth of (straight) whiskers on thin 'leaders' has been observed in the crystallization of hydroquinone[10].

(*d*) The crystals also show the normal phenomena of kinking and branching.

While in their extreme (but by no means exceptional) development these crystallites therefore exhibit an obvious analogy with low-molecular-weight 'whiskers', they do not appear different in their initial stages from the 'sheaves' observed so often in polymers crystallized from solution[11]. There is also a possible relationship to the 'axialites' described by Keller[12]. Very recently, Bassett and Keller[13] have reported on a chain-like structure apparently akin to those described here, although an order of magnitude smaller, which was formed by quenching heated polyethylene crystals.

I have obtained these 'whiskers' (besides the single hexagonal lamellæ) invariably when polyoxymethylene made by polymerization of irradiated trioxane in the crystalline state was recrystallized from dilute solutions (in phenol or in diethylene glycol dimethyl ether). From a commercial polyoxymethylene, 'Delrin', I have never obtained them, either under comparable or under different conditions. Even from mixed solutions of the two polymers each crystallizes in its own habit, which shows that an essential characteristic of the polymers themselves is involved, and not some extraneous influence like that of an additive. This characteristic might be the nature of the end groups.

I thank Miss G. Abels for obtaining the electron-micrograph.

Regular Inclusion Pattern in Crystals

INCLUSIONS containing mother liquor are found quite commonly in many natural and manufactured crystals. Usually they seem to be at random positions within the body of the crystal. However, in the case of hexamine (hexamethylene tetramine) the inclusions often form a regular pattern which is related to the crystal symmetry. One of us has commented on this effect previously[1]; but we give below what we believe to be the first photograph.

Hexamine crystallizes from aqueous solution as regular dodecahedra although often with rounded faces. In the present instance the crystals were obtained by evaporating solution under vacuum at 40°–60° C with occasional stirring. Many crystals in the batch showed the same symmetrical pattern of inclusions, as in Fig. 1*a*, each pattern consisting of twelve members. These have spatial positions corresponding to the centres of the faces of a regular dodecahedron aligned with its faces parallel to the crystal

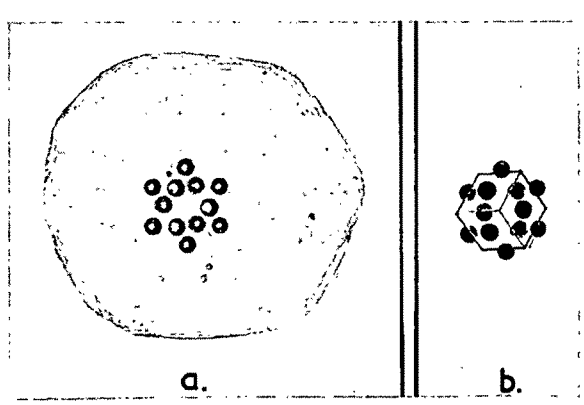

Fig. 1

faces. This may be seen by comparing Fig. 1*a* with Fig. 1*b*, which is a photograph of a 'Perspex' dodecahedron with spheres at the centres of each face.

The crystal photographed was about 315μ across and the inclusions were about 20μ across. The regularity of their pattern suggests that the mechanism of their formation is closely linked to the crystal symmetry and work is in progress to elucidate this mechanism.

METALLURGY

Electrochemical Properties at the Curie Point

Some preliminary work with gadolinium (Johnson, Matthey and Co., Ltd.: Curie point, 16° C) has shown that this metal exhibits maximum electropositivity in the curie point region (Fig. 1).

The apparatus used consisted of an *H*-cell and each limb was connected by a closed and ungreased tap. The limbs and connexion were filled with the appropriate electrolyte. Each limb was provided with a similar electrode, thermometer and temperature control, one limb (the reference electrode) being kept at 21° C. The *H*-cell e.m.f. was measured directly with a 'Vibron' electrometer.

The selection of electrolyte, and preparation and ageing of electrodes, were governed by the requirement that a reproducible and steady cell e.m.f. should be quickly attained under standard conditions. It is emphasized that, in this type of comparative work, steady-state potentials (whether mixed or not) can be used without recourse to fulfilling stringent thermodynamic requirements for the sake of obtaining equilibrium or standard electrode potentials[1]. When a temperature difference exists between the two limbs, or half-cells, then it can be shown that the plot of *H*-cell e.m.f. versus temperature should be smooth. This smooth or normal behaviour was exhibited only by the copper, zinc and Monel electrodes.

Thus the electrolyte used for gadolinium was N potassium chloride + hydrochloric acid (*p*H 5) and a small amount of hydrogen evolution occurred in both half-cells.

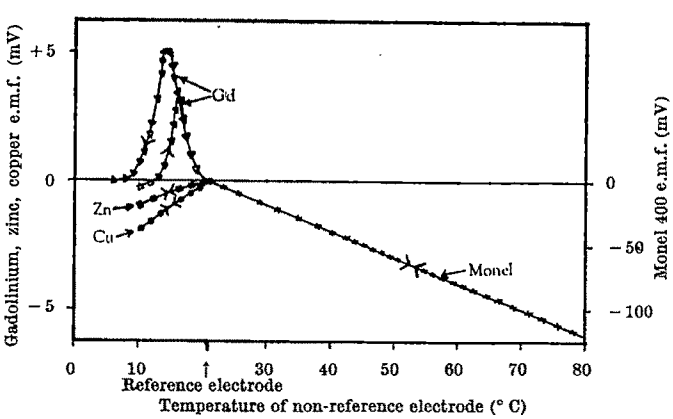

Fig. 1. Graph showing plot of *H*-cell e.m.f. versus temperature of non-reference half-cell for various metal-electrolyte systems. The sign of the e.m.f. is that of the non-reference electrode and, for the purpose of clarity, the plots have been confined to temperatures: (*a*) below 21° C for gadolinium, zinc and copper and (*b*) above 21° C for Monel 400

Fig. 1 also shows the results obtained using: (*a*) zinc, in N potassium chloride + hydrochloric acid (*p*H 5)—a system similar to gadolinium since very slow hydrogen evolution occurred; (*b*) copper, in N copper sulphate + N sulphuric acid—a system where no hydrogen evolution occurred; (*c*) Monel 400 (Henry Wiggin and Co., Ltd.) in N potassium chloride + hydrochloric acid (*p*H 1)—this alloy possesses a Curie point in the range 45°–60° C, but no 'gadolinium effect' was observed.

The gadolinium effect suggests that the rearrangement of 4*f* electron energy-levels at the onset of ferromagnetism affects also the valency electrons. The factors contributing to the e.m.f. of the type of cell used in these experiments which are affected by the ferromagnetism of one electrode are the work function φ and sublimation energy *S* (ref. 2). Changes in these quantities $\Delta\varphi_f$ and ΔS_f due solely to ferromagnetism can be estimated in the case of a copper–nickel alloy such as Monel, in which there is overlap between the nearly filled 3*d* band and the 4*s* band, on the basis of the collective electron theory of ferromagnetism[3,4]. The dominant term is $-\frac{1}{9}\int_0\sigma^2$ in $\Delta\varphi_f$ where σ is the temperature-dependent relative spontaneous magnetization and $\int_0$ the common Fermi energy of 3*d* and 4*s* electrons below the top of the 3*d* band at absolute zero (where ferromagnetism is absent). Using Wohlfarth's data[4] the net effect on the cell e.m.f. can be estimated to be for Monel 0·011 $(1 - T^2/\theta^2)$ V, where *T* is the absolute temperature and θ the Curie temperature, and in such a sense as to make the ferromagnetic electrode more electropositive. This effect is so small in Monel (due to a small $\int_0$) that no change in slope at θ is evident in the e.m.f. versus temperature graph.

The gadolinium effect, though complicated by hysteresis and possibly by a short-range order effect above θ, could perhaps be explained by a similar approach if more were known of the density of states function of the half-filled 4*f* band and the extent of overlap with the valency electron bands. However, in order to establish any mechanisms, further work is clearly necessary, but it is believed that the electrochemical approach may be useful in exploring the difficult subject of ferromagnetism.

Epitaxial Oxide Growth on Thin Single-crystal Gold – Nickel Alloy Films

The oxidation characteristics of binary alloys and the growth and structure of oxidation products on such alloys have been examined by various investigators[1–3]. However, the only published evidence on the oriented growth of such oxidation products is that of Honjo[3]. He has reported on selective oxidation of beryllium in a beryllium-copper alloy and observed that the BeO phase grows with a preferred orientation in which the [00,1] axis is perpendicular to the free surface of the specimen. The origins of this orientation were not explained. This communication describes a novel orientation effect observed in the oxidation of thin epitaxed films of a noble metal alloy containing a small percentage of an easily oxidizable transition metal. The alloy examined was a gold–nickel alloy containing 5 wt. per cent of nickel. The growth and structure of the alloy and its oxide were investigated by transmission and reflexion electron diffraction techniques.

Gold–nickel alloy films were prepared by cathodic sputtering and also by vacuum evaporation. Cathodic sputtering has been shown by us to have advantages over vacuum evaporation as a preparative technique in that the source material is transferred to the film without change in composition[4]. The gold–nickel alloy films, usually 600–700 Å in thickness, were epitaxially grown on cleaved surfaces of rocksalt and mica maintained at 440° C, after preheating to 500° C. The orientations observed in the alloy films were:

(100) alloy‖(100)NaCl; [011] alloy‖[011] NaCl
(111) alloy‖(001)mica; [1$\bar{1}$0] alloy‖[100] mica

Fig. 1 shows an electron diffraction transmission pattern from a (100) gold–nickel alloy film, epitaxially grown on sodium chloride and then stripped from it for observation. The pattern shows that the film consists of a single phase with the face-centred cubic structure. The lattice constant of the alloy is found to be 4·02 Å using that of gold ($a_0 = 4{\cdot}078$ Å) as a reference. This is in good agreement with Fukano[5], who prepared gold–nickel alloy films by simultaneous deposition of the constituent metals of the alloy.

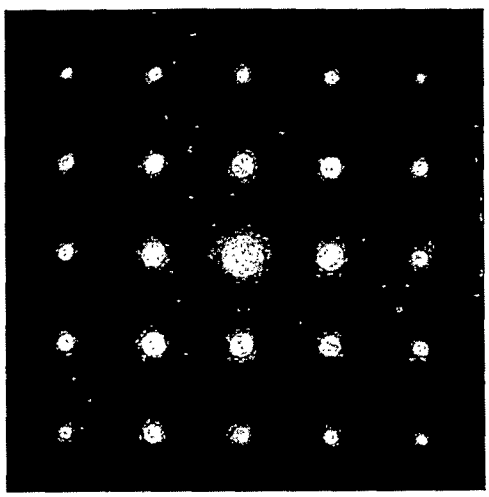

Fig. 1. Diffraction pattern from a (100) gold–nickel alloy film

The single crystal alloy film was first homogenized in argon–hydrogen at 390° C for several hours and then oxidized at about the same temperature either in air or in oxygen atmosphere for various lengths of time from a few minutes to several hours. The oxidation product, which could be identified as nickel monoxide, was observed to crystallize with the rocksalt structure. The lattice constant of NiO was calculated to be 4·17 Å, using that of gold ($a_0 = 4{\cdot}078$ Å) as a standard. The oxidation of the single crystal gold–nickel alloy films resulted in the formation of a double-layered structure: (100) nickel monoxide on (100) gold. The parallelism between the oxide and gold lattices is illustrated in Fig. 2, which is a transmission pattern obtained after oxidizing the alloy film in oxygen atmosphere for 45 min at 390° C. The photograph shows two spot patterns—one corresponding to gold and the other (inner spots, slightly arced) to nickel monoxide. The degree of orientation in the oxide layer was observed to depend on the atmosphere in which the oxidation occurred. The orientation was more pronounced in oxygen than in air. Similar orientation effects were obtained for gold–nickel films epitaxed on mica, and afterwards oxidized.

The oxidation of a one-phase binary alloy, of which one component is a noble metal, is the simplest example of alloy oxidation. In this case one is concerned presumably only with the oxidation of the base metal and the diffusion process by which it reaches the reaction site. It may be envisaged that as oxidation proceeds oxygen is dissolved at the surface of the gold–nickel alloy, and owing to concentration gradients, nickel from the alloy diffuses out and reacts with the adsorbed oxygen to form nickel monoxide, while gold remains inert. The orientation we have observed in the nickel oxide film might be explained on the basis of the diffusion of nickel atoms through the single-crystal gold–nickel alloy structure. Moreover, the parallel epitaxial relationship which develops between the oxide and the metal is plausible on considerations of misfit, which for (100) nickel monomide on (100) gold is very small ($\sim +2$ per cent).

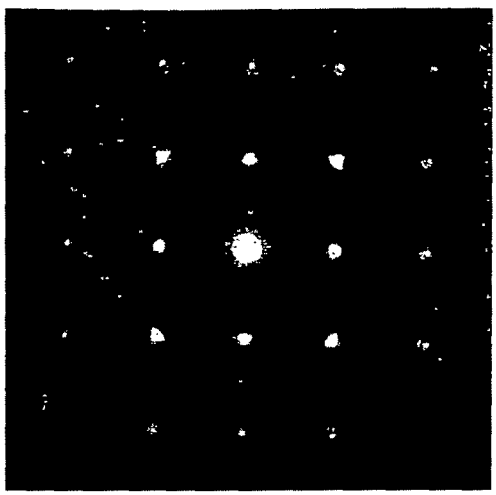

Fig. 2. Diffraction pattern from a (100) gold–nickel alloy film after oxidation

Further investigations on the thermodynamics of the oxidation process in these films are in progress and the results will be described in detail in a separate publication.

GEOCHEMISTRY

Experimental Data bearing on the Role of Liquid Immiscibility in the Genesis of Carbonatites

The recognition of low-temperature melts in the system $CaO—CO_2—H_2O$[1] has opened a new field of heterogeneous phase equilibrium studies in systems containing both water and carbon dioxide, the volatiles most abundant in the Earth's crust and among the most important in igneous and metamorphic processes. Liquids in this system may be regarded as simplified carbonatite magmas. The petrogenetic relationships between carbonatite magmas and the associated alkaline rocks can be examined by determining the phase relationships in systems containing $CaO—CO_2—H_2O$ and silicate minerals. In a programme supported by the National Science Foundation, we have been investigating selected portions of complex systems in order to test the feasibility of the petrogenetic relationships which have been proposed on the basis of petrological investigations.

Two of the hypotheses which have been proposed for the origin of magmatic carbonatites are: (1) Carbonatite magmas are primary, possibly extremely rich in alkali carbonates[2], and the alkalis in the parent carbonatite magma are responsible for fenitization. Attention has been directed to this hypothesis by the recent volcanic

eruption in Tanganyika which produced a lava flow composed almost entirely of carbonates of sodium and calcium[3]. (2) Magmatic carbonatite is formed at a late stage in the crystallization of a peralkaline magma as a precipitation product of alkali–alkaline earth exchange reactions. Tomkeieff[4] postulated that sodium carbonate within the magma reacted with "shadow mineral molecules" to produce reactions of the type: anorthite + sodium carbonate ⇌ nepheline + calcium carbonate. Phase relationships determined in parts of the system CaO—Na_2O—Al_2O_3—SiO_2 in the presence of carbon dioxide and water under pressure have bearing on both these hypotheses.

The phase fields intersected by the join $NaAlSi_3O_8$(Ab)—Na_2CO_3 in the presence of 10 weight per cent of water have been delineated in the temperature-range 600°–950° C at a total pressure of 1 kilobar[5]. The results are illustrated in Fig. 1. In the presence of excess water at 1 kilobar pressure albite melts at 910° C. Addition of sodium carbonate lowers the saturated liquidus temperature to 730° C, with the solution of about 18 weight per cent sodium carbonate in the liquid. This liquid quenches to a glass. At temperatures above about 750° C (for this pressure and for this composition join) there exists a wide miscibility gap between the silicate liquid (L_1) and a liquid containing at least 90 weight per cent sodium carbonate (L_2). The second liquid does not quench to a glass. The solidus temperature is 690° C.

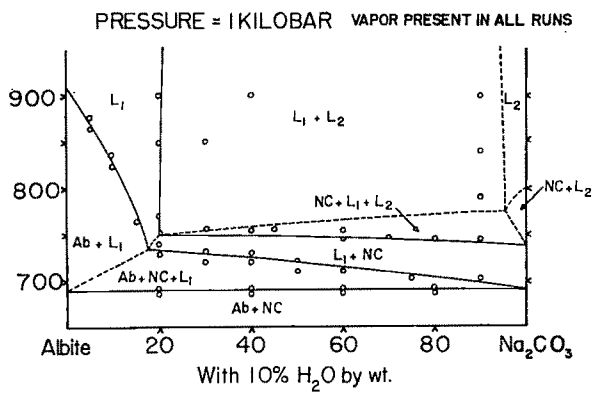

Fig. 1. Phase fields intersected by the composition join $NaAlSi_3O_8$—Na_2CO_3—H_2O (10 weight per cent) at 1 kilobar pressure. Albite, Ab; Na_2CO_3, NC; liquids, L_1 and L_2

The phase relationships in this composition 'join' form a necessary basis for interpretation of phase relationships in the more complex system involving anorthite ($CaAl_2Si_2O_8$, An) as well. We have recently determined the phase fields intersected by the silicate end of the join 80Ab20An—sodium carbonate in the presence of 10 weight per cent of water. The results obtained prove that the miscibility gap persists between the silicate and carbonate melts in the lime-bearing system, although it appears to be somewhat smaller. Several additional phase fields are intersected by this composition join, involving the phases plagioclase feldspar, nepheline, wollastonite, a cancrinite, a mineral with the sodalite structure, and calcite. Details of the experimental method, the phase relationships, and the evidence for the existence of two liquids will be published in due course. However, it is of interest at this stage to consider the bearing of these results on the petrological hypotheses outlined here.

In connexion with the first hypothesis, it is difficult to understand how a deep-seated primary magma composed largely of alkali carbonates could form in the silicate mantle of the Earth. Furthermore, if such a magma does develop, it is difficult to understand how it could persist until it reached a high level in the Earth's crust without the occurrence of almost complete reaction with the silicates of the crust. An immiscibility relationship between the alkali carbonatite magma and the silicates is a possible explanation. The lava flows from Oldoinyo Lengai in Tanganyika, whatever their origin, managed to reach the surface without becoming contaminated with silicates[3]. Again, it is difficult to imagine how such a reactive melt could persist unless there is a miscibility gap between the carbonate liquid and silicate liquids.

The appearance of calcite as a crystalline phase in equilibrium with liquids in the join 80Ab20An—sodium carbonate—water indicates that the exchange reaction postulated in the second hypothesis does occur in melts of appropriate compositions. The solution of sodium carbonate in the hydrated plagioclase feldspar melt leads to the development of several new mineral phases, and nepheline and calcite are among them, as predicted by Tomkeieff[4]. The nature of the exchange reactions occurring between alkalis and basic oxides is of fundamental importance not only for the origin of carbonatites and associated alkaline rocks, but also for many other petrogenetic problems.

It is worth emphasizing the fact that the two liquids illustrated in Fig. 1 are true melts. These liquids coexist with a third fluid phase (vapour), which is a dense aqueous solution containing a small proportion of dissolved silicate and an unknown proportion of sodium carbonate.

Of course, much experimental work remains to be completed before direct comparisons can be made between the synthetic systems and the natural rocks. However, the recognition of immiscibility between silicate melts and carbonate melts in a system with an alkali and a basic oxide present as components does direct attention to the possible significance of liquid immiscibility in the genesis of carbonatites and associated igneous rocks.

CHEMISTRY

Ion Specific Polymer Membrane

Membranes, the permeability of which is based on complexing, are of interest because of their analogy to biological membranes. In the lipoid theory of permeability it is assumed that the permeating species dissolves in the cell membrane by complexing with it. Apart from their biological significance, synthetic membranes of this kind can be expected to be useful because their selectivity is far greater than that of any modified ion-exchange membrane. An example of a modified ion-exchange membrane, with an increased capacity for iron (III), has recently been described by Kargin[1]. His membrane consisted of a copolymer of an electrolyte, acrylic acid, and a complexing agent, the dibutyl ester of vinyl phosphonic acid. However, no uncharged membrane has yet been described the permeability of which is due solely to complexing.

We have recently prepared several membranes which, by virtue of selective complexing, were able to effect complete separation of a mixture of iron (III) and aluminium chlorides in strong hydrochloric acid solution. This was achieved either by dialysis or by electrodialysis. Under strongly acid conditions iron (III) is known to exist as a negatively charged chloro-complex which can be extracted by various organic solvents[2]. The extraction is explained by simultaneous solvation as well as hydration of the complex anion[3]. No similar complex of aluminium is formed under these conditions.

We tested several solvents as 'liquid membranes'. 'Liquid membranes' consisted of a porous film of polyvinyl chloride soaked with one of the solvents. All those tested turned out to be completely impermeable to aluminium chloride, but were permeable in varying degrees to iron chloride. The permeability properties of these membranes are best characterized by their resistance and transference number in an electrodialysis experiment. In the case of β,β′-dichlorodiethyl ether a resistance of 3×10^3 ohm cm² was measured in a solution which was 1·5 M in aluminium chloride, 0·3 M in ferric chloride and 1·5 M in hydrochloric acid. A resistance of 10^6 ohm cm² was measured in a solution containing the same concentration of aluminium chloride and hydrochloric acid, but without iron chloride. The average transference number of the $FeCl_4'$-ion in an electrodialytic separation of this mixture was 0·45; this means that, with the passage of 1 faraday, 0·45 mole of iron was transported through the membrane to the anode. The transference number of the $FeCl_4'$-ion in an experiment in which an ordinary ion-exchange membrane was used was 0·02, due to the large excess of chloride ion present in the system. In a diffusion experiment on the same system the transport of iron through the membrane was 10^{-6} mole/(h cm²). No transport of aluminium through the membrane occurred. The diffusion process was highly dependent on the concentration of hydrochloric acid. In the same mixture of iron (III) and aluminium chlorides but at a three times higher concentration of hydrochloric acid, values of the diffusion transport as much as 30 times larger were observed.

As analogues of these 'liquid' membranes we synthesized polymer membranes the monomer units of which showed the greatest possible similarity to the solvents previously tested. The analogue of β,β′-dichlorodiethyl ether synthesized was polyvinyl chloroethyl ether. A membrane of this polymer reinforced with glass fibres possessed considerable permeability for iron, but was impermeable to aluminium. Its resistance measured in the same mixture of iron and aluminium chloride was 10^4 ohm cm². Its transference number in an electrodialytical experiment was 0·34. The diffusion transport through the membrane was 5×10^{-7} mole/(h cm²).

The transport behaviour of ferric, aluminium and cupric ion across alginate membranes has been examined by Seno *et al.*[4]. Seno *et al.* expected an alginate membrane to show selective transport for ferric ion, since alginic acid resins preferentially adsorb ferric ion. However, they found the opposite, indicating, in our opinion, that the complex formed between the metal-ion and the membrane matrix was too strong.

Binding of the Thiocyanate Ion in Complexes with Palladium (II)-containing Tertiary Phosphines

The infra-red spectra of several thiocyanate complexes of platinum and palladium suggest that these metals must be bound to nitrogen in compounds with the general formula $[M(PR_3)_2(CNS)_2]$ (R = aliphatic tertiary phosphine)[1]. Adams and Booth more recently reported that platinum must be co-ordinated to nitrogen in the complexes *trans*-$[Pt(CNS)CH_3(PEt_3)_2]$ and *trans*-$[Pt(CNS)(COCH_3)(PEt_3)_2]$ (ref. 2). On the other hand, palladium and platinum invariably appear to be bound through sulphur in a variety of complexes with the thiocyanate ion and other different ligands[3]. It thus appears that the binding of these metal ions with the thiocyanate group is peculiarly affected by the presence of phosphine ligands in the molecule of the complex. The occurrence of this unexpected nitrogen-metal binding may be of more general interest, being clearly related to important changes in the binding properties of the metal ions brought about by the presence of the phosphine ligands. However, all the previous evidence on which these conclusions were based came exclusively from infra-red spectra. A more direct demonstration of the nature of the metal-thiocyanate bond seemed desirable to us. Therefore, a determination by X-ray analysis of the structure of the compound $[Pd(PPr_3^n)_2(CNS)_2]$ was undertaken to resolve the question of the bonding of the thiocyanate group.

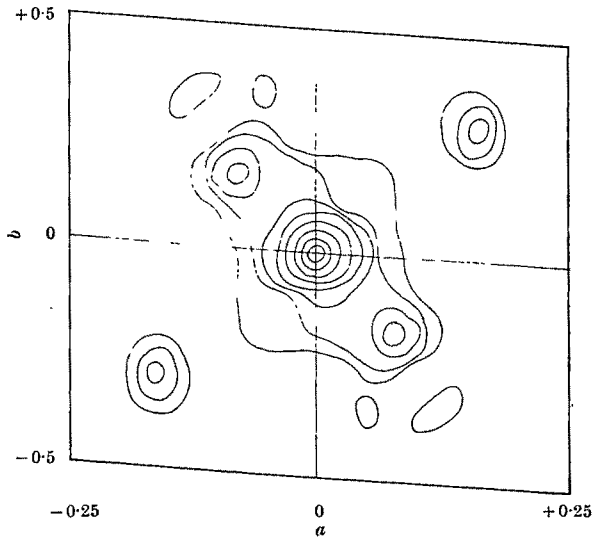

Fig. 1. Patterson projection on (001) for $[Pd(PPr_3^n)_2(NCS)_2]$. Contours at arbitrary but equal intervals

The compound crystallizes in the triclinic system. The space group may be either the $P1$ or $P\bar{1}$. The centrosymmetric space group has been chosen on the basis of intensity statistics. The unit cell has the following constants $a = 19{\cdot}53$ Å; $b = 8{\cdot}72$ Å; $c = 9{\cdot}36$ Å; $\alpha = 87°\ 58'$; $\beta = 119°\ 04'$; $\gamma = 94°\ 12'$ and contains two molecules of complex. The $hk0$ and $h0l$ reflexions were recorded on Weissenberg equatorial photographs. The intensities were determined by means of photometric integration. From the vector analysis of the Patterson projections on (001) and (010) it can be concluded that the molecule is square *trans*-planar and that the complex is actually an isothiocyanate with nitrogen atoms co-ordinated to palladium. The projection on (001) is shown in Fig. 1. There are four Patterson maxima arising from the relatively heavy phosphorus and sulphur atoms. Two of them are at 4·6 Å and therefore cannot represent the palladium-phosphorus distance. Since the Pd–NCS grouping must be approximately linear this must be the palladium-non-bonded sulphur distance expected for Pd–NCS units. It can be compared with the distance 4·8 Å between platinum and non-bonded sulphur in $[Pt_2(SCN)_2Cl_2(PPr_3)_2]$[4]. The other two maxima are at 2·2 Å in agreement with the expected palladium-phosphorus distance (2·16 Å in the platinum compound[4]).

These results show that the conclusions derived from the infra-red spectra were correct. The reasons for the change from the usual Pd–SCN co-ordination to the Pd–NCS co-ordination are not apparent at present. With metals of the first transition series, tertiary phosphines apparently affect the metal-thiocyanate bonding in a more complicated way. Cobalt (II), which is usually co-ordinated through nitrogen, is reported to be bound to sulphur in $[Co(PPh_3)_2(SCN)_2]$[5] and to be bound to nitrogen in $[Co(PCy_3)_2(NCS)_2]$ (Cy = *cyclo*hexyl)[3]. It is interesting to

note that in the complex $[Pd(PPh_3)_2(NCS)_2]$ the palladium atom must be bound to nitrogen as it is in the compounds with aliphatic phosphines. This is clearly shown by the value of the CS stretching frequency (850 cm^{-1})[6].

Dissociation Energies of the Alkaline Earth Monofluorides

Although the gaseous alkaline monofluoride molecules have been known for many years[1], the stabilities of these molecules have not been accurately established. The Birge–Sponer extrapolations which Gaydon[2] used to arrive at dissociation energies are in doubt because of the limited number of vibrational levels used and the fact that the data were often based on head measurements of bands of a weakly degraded system. Furthermore, these extrapolations are not expected to be normal for such molecules in which ionic forces make an appreciable contribution to the binding. This communication presents new results and theoretical calculations which indicate consistently high dissociation energies for all the alkaline earth monofluorides.

Experimental results were obtained by utilizing a 12-in., 60° sector, single-focusing mass spectrometer to analyse the vapours effusing from a heated tantalum Knudsen cell containing an alkaline earth fluoride salt with aluminium present as a reducing agent. Ionization efficiency curves were obtained and temperature dependence investigations were made to determine the molecular precursor of the ions observed.

Fragmentation effects were minimized by working at low ionizing electron energies. In the case of magnesium fluoride, MgF^+ was found to be formed from both $MgF(g)$ and $MgF_2(g)$. The $MgF(g)$ contribution was determined from the ion intensity of MgF^+ at 5 V above the AP (MgF^+) from MgF, while the MgF_2 contribution was calculated from the MgF^+ intensity 5 V above the AP (MgF^+) from MgF_2 by subtracting the MgF^+ from MgF intensity extrapolated to this same ionizing energy, assuming the cross-section for ionization to be a linear function of the energy above onset. Pressures of the gaseous species used in the equilibrium constants for the various reactions were calculated by making use of the ion current-pressure relationship[3], $P = kI^+T$.

Free energy functions for $Ca(g)$, $Sr(g)$ and $Ba(g)$ were taken from Stull and Sinke[4]; for $Al(g)$, $AlF(g)$, $Mg(g)$, $MgF(g)$, $MgF_2(s)$ and $MgF_2(g)$ from the *JANAF Tables*[5]; for $CaF_2(s)$, $SrF_2(s)$ and $BaF_2(s)$ from Brewer *et al.*[6]; and for $CaF(g)$, $SrF(g)$ and $BaF(g)$ from Kelley[7] and Kelley and King[8]. The values of the equilibrium constants at different temperatures were then used together with the free-energy functions to calculate the third law heats of reaction at 298° K which are presented in Table 1. The uncertainties given are standard deviations, and the true uncertainties may be somewhat greater. Whenever possible, these heats were checked by the second law method, but the third law values are expected to be more reliable due to the small temperature range covered (about 100° K) and the low intensities of some of the ion currents measured.

From reaction (1), $D^0_{298}(MF)$ may be obtained by combining the observed ΔH^0_{rxn} with the known value (157·7 ± 2·0 kcal/mole) of $D^0_{298}(AlF)$ [5,9]. From reaction (2), $D^0_{298}(MF)$ may be obtained by combining the observed ΔH^0_{rxn} with $\Delta H^0_f(MF_2,s)$ [6,10], $\Delta H^0_{sub}(M)$ [4] and $D^0_{298}(F_2)$ [5]. From reaction (3), $D^0_{298}(MgF)$ may be obtained by combining ΔH^0_{rxn} with $\Delta H^0_f(MgF_2,s)$ [10], $\Delta H^0_{sub}(MgF)_2$ [11], $\Delta H^0_{sub}(Mg)$ [5] and $D^0_{298}(F_2)$ [5]. The results of these calculations are presented in the first two rows of Table 2.

When the difference, $IP(M) - EA(F)$, is small, the ground-state potential energy curve for the MF molecule will be primarily determined by the coulombic attraction of the M^+ and F^- ions. One useful rule[1] for deciding when ionic character will predominate is $R = r_s/r_e \geqslant 1{\cdot}5$, where r_s is the internuclear distance at which electrostatic attraction has just compensated for the energy $IP(M) - EA(F)$, and r_e is the equilibrium separation. Values of R for each of the MF molecules were calculated using experimentally measured values of r_e when known and addition of ionic radii for SrF and BaF [12]. The ratios obtained were $R(BeF) = 1{\cdot}82$, $R(MgF) = 1{\cdot}99$, $R(CaF) = 2{\cdot}73$, $R(SrF) = 3{\cdot}09$ and $R(BaF) = 3{\cdot}79$. Therefore, all the alkaline earth monofluoride molecules, with the possible exception of BeF, should be expected to have an ionic ground state. It should be noted here that the spectroscopically observed[1] ground states ($^2\Sigma^+$) of these molecules may be correlated with the states of the ions: $M^+(^2S) + F^-(^1S)$.

A calculation of $D(MF)$ was then made using Rittner's[13] ionic model. To do this, an estimate of the metal ion polarizability was made using the equation[14] $\alpha = 3\bar{r}^2/2I_2$, and $\bar{r}^2$ was obtained from the prescription of Hirschfelder *et al.*[15]. The polarizabilities used were $\alpha(Be^+) = 0{\cdot}84A^3$, $\alpha(Mg^+) = 2{\cdot}2A^3$, $\alpha(Ca^+) = 6{\cdot}0A^3$, $\alpha(Sr^+) = 8{\cdot}6A^3$ and $\alpha(Ba^+) = 11{\cdot}3A^3$. The resulting values of $D(MF)$ (Table 2) have the expected trend, and are in good agreement with the experimental results, especially when the heats of ionization, the actual quantities calculated, are compared.

Comparison of the atomization energies of the monofluorides and the difluorides[6] yields an average value of $D(MF)/D(MF_2) = 0{\cdot}46$, which does not agree with the

Table 1. Heats of Various Reactions for the Al–MF_2 Systems

Reaction	ΔH^0_{298} (kcal/mole) for M = Mg	Ca	Sr	Ba
(1) $M(g) + AlF(g) = Al(g) + MF(g)$	(⩾ 45·2)	32·7 ± 0·2	33·1 ± 0·3	23·9 ± 0·2
(2) $M(g) + MF_2(s) = 2MF(g)$	128·2 ± 0·8	120·7 ± 0·8	116·0 ± 0·8	97·9 ± 0·4
(3) $Mg(g) + MgF_2(g) = 2MgF(g)$	37·8 ± 1·0	—	—	—

Pre-ionization Phenomena in the Appearance of Some Polyatomic Molecular Ions

IT has been shown elsewhere[1-4] how the photo-ionization yield curves of ethylene and of some halogenated derivatives of the ethylene molecule can be interpreted by means of step functions resulting from vibrationally electronically excited states of the molecular ions.

As will be shown elsewhere[4], the photon energy-range used (between the first I.P. and 11·5 eV) enables us to detect in the same curves a number of sharp peaks in addition to the successive step functions characterizing vibronic states of the ions. The comparisons made with the same experimental device between the position in energy of these sharp peaks and the position of strong absorption bands in the C_2H_3Cl far ultra-violet spectrum above the first I.P., correlated with the existence of photographically recorded bands of absorption, in the same region, in the spectra published by A. D. Walsh[5], enabled me to conclude that the sharp peaks observed in photo-ionization yield curves are due to the so-called 'pre-ionization phenomenon'. In this phenomenon, it is possible to assess that the interaction of the light with the molecule results in an excitation to any electronically excited state of the molecule, the energy of which is greater than the value of the first I.P. This excitation is followed by a non-radiative transition to any ionization continuum covering the same energy-range. The characteristic function governing this phenomenon is the excitation function by light of the molecule for the vibronic states concerned. It is, therefore, not surprising that this function is a very sharp one. Similar conclusions have been drawn previously for a similar behaviour as observed in I_2 and CH_3I molecules by J. D. Morrison *et al.*[6]. They have never been generalized and analysed as I try to do here.

Three main causes are to be postulated in order to explain such a behaviour in more complicated molecules; they are: (*a*) excitation of one electron more strongly bonded in the molecule than the electron removed by the lowest energy ionization process; (*b*) simultaneous excitation of two electrons resulting in any excited state of the molecule situated well above the first I.P.; (*c*) excitation of the electron in Rydberg states leading to the appearance of the ion in an electronically excited state.

In order to test hypotheses (*a*) and (*b*), enquiries have been made on the possibilities of exciting in the molecules studied any or several other electrons than the electron removed by the first ionization process. The results of these enquiries are shown in Table 1. Some of these results (the starred ones) have been obtained on the following experimental basis: a smooth curve can be drawn through the values of excitation potentials, namely, I.P. of the excited electron, and the starred values result from interpolations on this curve.

Table 1

Substance	Electron	First pot. (eV)	I.P. (eV)	Absorption	Ref. (Exc.)	Ref. (Ionized)
CH_3I	$d\ \pi$ (I)	6·15	9·50	Discrete	7	8
C_2HCl_3	π (C—C)	6·32	9·47	Discrete	5	9
$I\text{-}2C_2H_2Cl_2$	π (C—C)	6·52	9·66	Discrete	5	1–4
C_2H_3Cl	π (C—C)	6·70	10·00	Discrete	5	4
CH_3Br	$p\ \pi$ (Br)	(7·75)*	10·53	?		8
C_2H_3Cl	$p\ \pi$ (Cl)	8·46	10·89	Discrete	10	9
CH_3Cl	$p\ \pi$ (Cl)	8·85	11·47	Discrete	7	8
C_2H_4	σ (C—C)	(9·00)*	11·65	Continuous		9
CH_3Br	σ (C—Br)	(9·00)*	11·62	?		8
CH_3Cl	σ (C—Cl)	(9·35)*	12·07	Discrete in CH_3Cl_2	11	9
CH_3F	σ (C—H)	9·75	12·85	Continuous	12	9
CH_4	σ (C—H)	9·90	13·16	Continuous	13	9
CH_3F	σ (C—F)	10·58	15·27	Discrete	12	9

Owing to the results presented in Table 1 we are in a position to regard the occurrence of mechanisms like those postulated in (*b*). The simultaneous excitation of two electrons of the types described in Table 1 would require energies well above the 11·5 V characterizing the ultra-violet radiation cut-off in the device used for our experiments. In addition, mechanisms like (*c*) have not been taken into account owing to the distribution of intensities in the pre-ionized peaks, mainly irregular, opposed to the normal distribution of intensity in Rydberg series which is well known to diminish with the convergence of the series.

It would be impossible to give an extensive discussion of all the results in such a short article. We should point out two main results: (*a*) For ethylene itself, as for the numerous hydrocarbon molecules studied by B. Steiner *et al.*[14], no pre-ionization structure is present. This is easily understood on the basis of Table 1. The possible excitations in such molecules result only in continuous absorption; that is to say, if such absorption occurs joining any ionization continuum, it is not able to give discrete peaks in the photo-ionization yield curve but only a continuous variation of the photon yield. (*b*) For all the halogen substituted ethylenes studied here, numerous peaks occur in photon-yield curves. For Table 1 and to the position in energy of the first of these peaks, it is possible to make some assumptions in each case about the excited electron and also to consider the successive peaks as forming the vibrational structure of the absorption band associated with the excited electron. The results obtained in this way are given in Table 2.

The values of the observed frequencies require comment. Frequencies lower than 1,000 cm^{-1} observed in all the molecules studied (except C_2H_3Cl) are probably to be associated with motions involving mainly the carbon and halogen nuclei. As to the frequencies around 1,000 cm^{-1}, the cases of C_2H_3Cl and C_2D_3Cl show a reduction in the frequency due to the deuteration which is only consistent

Table 2

Substance	Pre-ionization threshold (eV)	Excited electron	Associated frequencies (cm^{-1})
C_2H_4	None	—	—
C_2H_3F	10·645	σ (C—F)	1,136 – 327
1–1 $C_2H_2F_2$	10·510	σ (C—F)	1,008 – 484 – 404
C_2H_3Cl	10·050	σ (C—Cl)	1,150
C_2D_3Cl	10·050	σ (C—Cl)	1,030
$C_2H_2Cl_2$ *cis*	10·300	σ (C—Cl)	767 – 685 – 404
trans	10·015	σ (C—Cl)	756 – 620 – 363
C_2HF_3Cl *cis*	10·300	σ (C—Cl) σ (C—F)	1,104 – 722 – 675 – 379
trans	10·205	σ (C—Cl) σ (C—F)	1,073 – 806 – 721 – 556
$C_2H_2Br_2$ *cis*	9·520	σ (C—Br)	766 – 655 – 283
trans	10·037	σ (C—Br)	746 – 530 – 484 – 242

with the existence of the (C—C) valence vibration strongly reduced by the excitation from its value in the ground state (1,623 cm^{-1}), instead of the CHCl bending vibration which is equal to 1,279 cm^{-1} in the ground state[15]. This phenomenon occurs sometimes and I shall refer to the case of CH_3I in which the excitation of a $d\pi$(I) electron results in the apparition of vibrational frequencies related with C—H bond motions[16].

Owing to this discussion, it is difficult to decide for the fluorinated molecules if the presence of a frequency of about 1,000 cm^{-1} is due to the (C—F) valence bond frequency which is around the same value in the ground state or to the π (C—C) valence bond vibration as in the vinyl chloride molecule.

I thank Prof. W. C. Price for permission to use his Vacuum Grating Monochromator in spring 1961 and in autumn 1962.

I also thank the British Council, the Royal Academy of Belgium, the Fonds National de la Recherche Scientifique and the Patrimoine de l'Université de Liège for financial support during my stay in King's College, London.

I thank Prof. L. D'Or for his interest in this work.

Possible Use of Gallium as Negative Electrode in Galvanic Cells

From the electrochemical aspect gallium is notable for its relatively negative standard reference voltage, which for the equilibrium :

$$Ga + 4OH^- \rightleftarrows H_2GaO_3^- + H_2O + 3\ e^-$$

amounts to $-1{\cdot}22$ V (NHE)[1]. Apart from its low equivalent weight of 23 g/F, another remarkable feature is the high polarization with respect to hydrogen[2], which results in it having a high resistance to corrosion, in spite of its base character.

Also, the easy anodic dissolution and cathodic deposition of gallium in various electrolytes is well known, that is, it can act in a reversible manner. These properties and particularly the advantages for storage and transport arising out of its low melting point (29·8° C) and the ease with which gallium can be sub-cooled induced us to investigate closely the suitability of gallium as a negative electrode for galvanic primary or secondary cells.

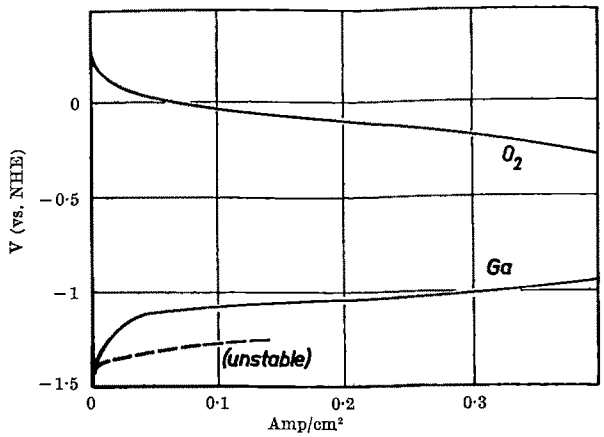

Fig. 1. Characteristic of an oxygen and a gallium electrode in 6 N potassium hydroxide at 80° C

Measurements of the rate of corrosion of pure gallium only yielded low values, even at high temperatures. In a 6 N solution of potassium hydroxide, without any flow of current, the amount of gallium that dissolves corresponds to a corrosion current of about 8 m.amp/cm^2.

Anode characteristics of gallium half-cells were plotted for different electrolytes in the temperature-range 20°–80° C. It was thereby established that in 2 N sulphuric acid the polarization is extraordinarily high (0·6 V at 50° C and 20 m.amp/cm^2), due to the formation of a surface layer of $Ga_2(OH)_4SO_4$. In 8 N hydrochloric acid the polarization was very low (0·1 V at 50° C and 200 m.amp/cm^2).

The anodic behaviour of gallium in 6 N potassium hydroxide was examined more closely, owing to the possibility of combining most cathode materials of conventional cells with the gallium anode in this electrolyte. Here the polarization amounted to 0·66 V at 20° C and 100 m.amp/cm^2 (with solid gallium). At 50° and 80° C and the same current, the respective figures were 0·45 and 0·37 V (Fig. 1). It was established that, in each case, about 0·2 V of the total polarization could be attributed to the drop in voltage across a suddenly formed passive layer on the surface of the gallium[3]. The steady-state potential of the gallium in 6 N potassium hydroxide amounted to about $-1{\cdot}42$ V (NHE). With increasing enrichment of the alkali with gallate, the polarization remained almost constant up to a content of roughly 300 g gallium per litre, after which it began to rise. With anode current densities of 100 m.amp/cm^2 the current yield at 80° C was 100 ± 5 per cent for all gallate concentrations.

The deposition again of the gallium from 6 N potassium hydroxide containing a high proportion of gallate occurred at 100 m.amp/cm^2 and 80° C with a polarization of only 0·05 V and a current yield of about 90 per cent. Only

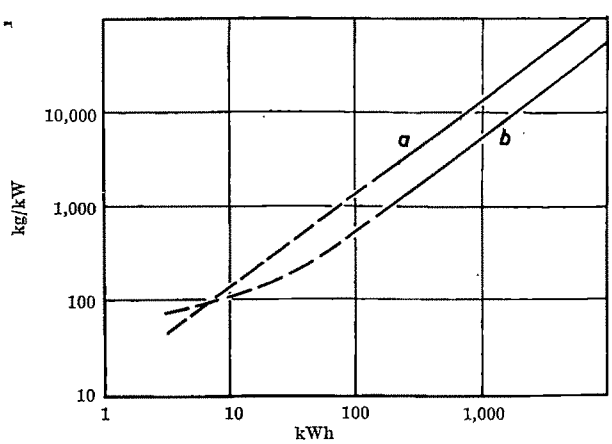

Fig. 2. Gross weight per unit output (kg/kW) of gallium cells as a function of their capacity (kWh)

when the gallate concentration dropped below 50 g gallium per litre did the polarization rise to 0·3 V and the current yield about 50 per cent.

Fig. 1 shows the anode characteristic of a gallium electrode together with the cathode characteristic of porous silver operating as oxygen electrode[4] (electrolyte 6 N potassium hydroxide at 80° C) from which the current-voltage characteristic of the primary cell Ga|6 N KOH|O_2, Ag can be deduced.

Based on rough estimates the gross weight per unit output (kg/kW) of 1-kW units of gallium-consuming galvanic cells is plotted against the visualized capacity (kWh) in Fig. 2. Curve *a* applies to the primary cell Ga |6 N KOH|O_2 (stored under pressure), silver with a cell voltage of 1·0 V at 100 m.amp/cm². Curve *b* refers to the secondary cell Ga|6 N KOH|NiO, Ni. The cell voltage was assumed to be 1·4 V at 100 m.amp/cm².

As the shape of the curves shows, the primary cell is superior to the secondary at higher capacities. The curves are both somewhat uncertain in the region of small capacities. The reason for this is that, so far, no suitable technical solution has been found to the question of the design of the cells, especially for the anodes of liquid gallium. Technical difficulties of this kind and especially the high price of the gallium therefore tend to stand in the way of the use of gallium for the electrochemical generation and storage of electricity at present.

BIOCHEMISTRY

Alteration of the Biochemical Effects of Ethidium Bromide by Exposure of Cells to Hypotonic Media

Ethidium bromide (3,8-diamino-5-ethyl-6-phenylphenanthridinium bromide) has been shown to inhibit completely the incorporation of preformed purines (adenine, guanine and hypoxanthine) into nucleic acids in Ehrlich ascites tumour cells *in vitro*, but does not appreciably impair the incorporation into nucleic acids of purines synthesized *de novo*[1]. This specific effect on preformed purine metabolism is not due to inhibition of their entry into these cells, conversion to nucleotides, or phosphorylation to nucleoside di- and tri-phosphates. Thus the purine nucleotides derived from exogenously supplied preformed purines are differentiated from those synthesized via the *de novo* pathway of purine nucleotide biosynthesis by this action of ethidium bromide. This suggests that these two types of purine nucleotides—chemically identical but derived from different sources—are separated within the cell. The nucleotides synthesized from exogenously supplied purines must mix with those made *de novo* at some point prior to their polymerization into nucleic acids, and it has been suggested that ethidium bromide interferes with this mixing process, which may be considered to be a movement of nucleotides from one compartment into another[1].

These results are most easily understood if ethidium bromide also is 'compartmented' within the cell and has access to only one compartment. The alternative to the postulated mixing of purine nucleotides prior to polymerization into nucleic acid would seem to be the existence of duplicate sites of nucleic acid polymerizing systems which could distinguish their chemically identical substrates by their source. Consequently, the synthesis of nucleic acid molecules by these enzymes would be dependent on the nutrition of the cells. This seems unlikely.

This intracellular compartmentation of purine nucleotides is most easily understood if there be some structural unit within the cell which separates the compartments. It was reasoned that if this barrier could be distorted or destroyed, ethidium bromide might either lose its inhibitory effects on preformed purine metabolism, or might now also inhibit the metabolism of purine nucleotides synthesized *de novo*. In order to distort cell structure in as gentle a manner as possible, cells were incubated in media of varying osmotic pressure. Using isotonic calcium-free Krebs–Ringer phosphate medium as a standard, hypotonic media having 90, 75 and 50 per cent the osmolarity of the standard medium were prepared by dilution of the standard medium with distilled water. The effect of 0·25 mM ethidium bromide on the incorporation of radioactive adenine into nucleic acids and of radioactive glycine into nucleic acids and proteins in Ehrlich ascites tumour cell was then tested when both drug and substrate were added simultaneously and the cells incubated for 1 h. Incorporation of radioactivity into macromolecules was measured by the membrane filtration technique, as previously described[1].

Control flasks without drug were incubated in media which were 100, 90, 75 and 50 per cent of the normal (isotonic) osmotic pressure. Adenine incorporation into nucleic acids at 90 and 75 per cent of normal osmotic pressure was slightly and progressively decreased, while that at 50 per cent was markedly depressed (Fig. 1). The slight diminution in the incorporation of glycine at 90 and 75 per cent was similar to that observed with adenine (Figs. 2 and 3). Although 50 per cent of normal osmolarity reduced incorporation of glycine markedly, this inhibition was not quite so profound as that of adenine incorporation.

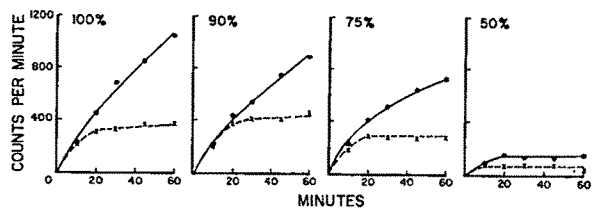

Fig. 1. Effect of hypotonic media on the inhibition of adenine incorporation into nucleic acid by ethidium bromide. Tumour cells, 24 mg wet weight, were incubated in calcium-free Krebs–Ringer phosphate media, *p*H 7·4, which were adjusted to 100, 90, 75 or 50 per cent the normal osmolarity of the media, with 5·5 mM glucose, 0·1 mM adenine-^{14}C, and 0·25 mM ethidium bromide

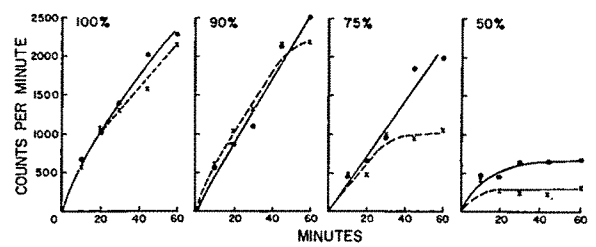

Fig. 2. Effect of hypotonic media on the inhibition of glycine incorporation into nucleic acids by ethidium bromide. Tumour cells were incubated as described in Fig. 1, but with 2 mM glycine-^{14}C

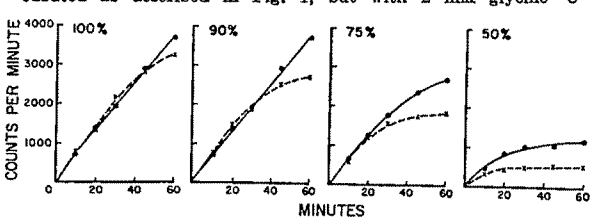

Fig. 3. Effect of hypotonic media on the inhibition of glycine incorporation into proteins by ethidium bromide. Tumour cells were incubated as described in Fig. 2

The usual inhibition by ethidium bromide of adenine incorporation into nucleic acids was not appreciably altered by hypotonic media, when due allowance was made for the effects of hypotonicity on control rates (Fig. 1). Even the drug's effect in 50 per cent hypotonicity was almost as great as that of cells in isotonic media.

In contrast to these results, however, hypotonicity markedly increased the inhibitory effect of ethidium bromide on glycine incorporation both into nucleic acids and into proteins (Figs. 2 and 3). The inhibitory effect increased with increasing hypotonicity, and the plots of these data became similar in shape to those seen with the radioactive adenine. These results appear to indicate that the swelling of the cells in hypotonic media destroyed or diminished the basis for the compartmentation of purine nucleotides and of drug postulated here.

Unsuccessful attempts were then made to localize and identify the specific basis for compartmentation. Attempts to localize the drug within the cells by conventional sub-cellular fractionation indicated that the drug was found more or less uniformly in all fractions. Fluorescence microscopy of whole cells incubated with ethidium bromide under different osmotic pressures was also attempted, but, under all conditions tried, fluorescence attributable to the drug was found uniformly in all parts of the cell.

Incubation of ascites tumour cells in hypotonic media has thus markedly altered the biochemical effects of ethidium bromide, which under these conditions does not distinguish between the two types of purine nucleotides. These data may be interpreted in the following ways: that the lowered ionic strength allowed some new action of ethidium bromide; that the target of its attack was now susceptible to inhibition; or that the drug was now able to be present at a locus which it previously had not reached in sufficient concentration. The latter interpretation seems most likely, and rupture of an intracellular barrier during the swelling of the cells would allow the drug to attain inhibitory concentrations at new loci. Such an occurrence is probably accompanied by a loss of compartmentation of purine nucleotides; but no direct evidence on this point is available. These observations cannot be due to an increased ethidium bromide concentration within the cells as a whole, as unpublished experiments have shown that incubation in hypotonic media does not change the total amount of drug entering the cells or the rate at which it enters.

The observations made following sub-cellular fractionations and fluorescent microscopy that ethidium bromide is apparently uniformly distributed within the cells do not necessarily dispute these conclusions. Newton[2] has found that resting cells of the trypanosomid flagellate, *Strigomonas oncopelti*, take up appreciable amounts of this drug and bind it irreversibly, although inhibition of growth is not exerted even when these cells are transferred to fresh medium and grown. Only drug which is taken up while these cells are actually growing produces growth inhibition. Non-specific binding of ethidium bromide within tumour cells could effectively mask any intracellular redistribution in hypotonic media.

These experiments have revealed new facets of the action of ethidium bromide which are consistent with the hypothesis that the drug interferes with a mixing of purine nucleotides from two intracellular compartments separated by a barrier which can be broken during the swelling of the cells in hypotonic media. These observations raise more questions than they answer, and such matters as the nature of the barrier, the size and even exact number of compartments involved, the detailed mode of inhibition by ethidium bromide, etc., must remain the subjects of future studies. The alteration of a drug's action on a non-excitable tissue in hypotonic media is unusual, and one may ask if this approach might shed light on the actions of other drugs as well.

Influence of Testosterone and Polyuridylic Acid on the Incorporation of Phenylalanine into Peptide Linkage by Prostatic Ribosomes

Recent studies[1] on the transfer of radioactivity from soluble ribonucleic acid-(*s*RNA)-valine-^{14}C to protein-like material by isolated prostatic ribosomes suggested that the levels of template RNA associated with these particles are controlled by testicular hormones. In line with this conclusion was the observation that randomly ordered copolymers of uridylic and guanylic acids (poly UG) stimulated valine incorporation by prostatic ribosomes from orchiectomized animals to a much greater extent than was found with ribosomes prepared from castrates which were treated with testosterone. However, two considerations complicate interpretation of the response of cell-free valine incorporating systems to poly UG. First, poly UG (prepared by the action of polynucleotide phosphorylase on a mixture of uridine and guanosine diphosphates) represents a complex mixture of polyribonucleotides of varying size and base sequences, the exact composition of which is difficult to ascertain. Secondly, the effects of guanine-containing polyribonucleotides on ribosomal amino-acid incorporating systems seem to depend not only on the base compositions of the polymers, but also on the degree of ordered secondary structure which they may exhibit in solution[2]. It became of interest, therefore, to examine the response of prostatic ribosomes to polyribonucleotides containing only one base. It is well established that polyuridylic acid (poly U) directs the entry of phenylalanine into peptide linkage in the presence of ribosomes from a number of tissues[3–8]. The following experiments concern factors which influence the transfer of radioisotope from *s*RNA-phenylalanine-^{14}C to acid-insoluble products by prostatic ribosomes, incubated in the absence and presence of poly U.

Charging of liver *s*RNA with L-phenylalanine-^{14}C and 19 other ^{12}C-amino-acids, the isolation of prostatic ribosomes by method 2, and most other methods are described elsewhere[1]. Poly U was prepared by the action of partially purified polynucleotide phosphorylase of *Micrococcus lysodeikticus* on uridine diphosphate. The source of soluble protein factors needed for the incorporations was either a crude dialysed protein fraction obtained by ultracentrifugation of rat ventral prostate homogenates[1], or the proteins present in '*p*H 5 supernates' prepared from the latter fraction, and afterwards dialysed exhaustively against the medium *D* of Liao and Williams-Ashman[1].

Prostatic ribosomes catalysed a swift and extensive transfer of radioactivity from added *s*RNA-phenylalanine-^{14}C to products which were insoluble in hot 5 per cent trichloroacetic acid, and also in ethanol/ether (3 : 1, v/v)[1].

Table 1

System	Radioactivity transferred to protein fraction (c.p.m.) − Poly U	+ Poly U
Complete	258	1,326
Omit phosphopyruvate, pyruvic kinase and ATP	88	494
Omit GTP	203	1,169
Omit phosphopyruvate, pyruvic kinase, ATP and GTP	13	68
Omit supernatant protein fraction	24	36

Co-factor requirement for transfer of phenylalanine-^{14}C to protein-like material by prostatic ribosomes. Reactions carried out in a final volume of 1·0 ml. containing 51 μmoles *tris*-HCl buffer, *p*H 7·8; 11 μmoles $MgCl_2$; 51 μmoles KCl; 11 μmoles β-mercaptoethanol; 1 μmole ATP; 1 μmole GTP; 9 μmoles phosphopyruvate; 50 μg pyruvic kinase; 1·1 mg dialysed '*p*H 5 supernatant' proteins; 0·04 mg liver *s*RNA charged with L-phenylalanine-^{14}C and 19 other ^{12}C-L-amino-acids (3,600 c.p.m.) and prostatic ribosomes from adult Sprague–Dawley rats equivalent to 54 μg total ribosomal RNA. If added: poly U, 0·1 mg. Incubated for 50 min at 37°.

With prostatic ribosomes isolated from adult albino rats with every evidence of normal testicular function, the incorporation of phenylalanine was stimulated from 4- to 10-fold by saturating levels of poly U (approximately 0·1 mg per 1 ml. of reaction mixture). In the presence of an excess of poly U, as much as 40 per cent of the radioactivity initially added as *s*RNA-phenylalanine-^{14}C entered the acid-insoluble fraction. The phenylalanyl transfers were unaffected by a large excess (3 mM) of cold free L-phenylalanine, and were depressed more than 80 per cent by 'Puromycin' (0·2 mM), when tested in the presence of '*p*H 5 supernate' proteins. Neither polyadenylic acid nor polycytidylic acid increased the incorporation of phenylalanine into the protein fraction. However, addition of a two-fold molar excess of polyadenylic acid (but not of polycytidylic acid) completely nullified the stimulatory effect of poly U. Table 1 shows that in the absence or presence of poly U the amino-acyl transfers were enhanced to only a small extent by guanosine triphosphate. However, the incorporations were markedly increased by addition of a high-energy phosphate generating system (phosphopyruvate and pyruvic kinase), and also by the soluble protein fraction. The requirement for the energy-generating system is probably related to maintenance of adequate levels of guanosine triphosphate during the course of the reaction. No incorporation of phenylalanine into the protein fraction was observed in the absence of the prostatic ribosomes. If the soluble proteins were added in excess, the incorporations were proportional to the quantity of ribosomal material added to the reaction mixtures (Fig. 1).

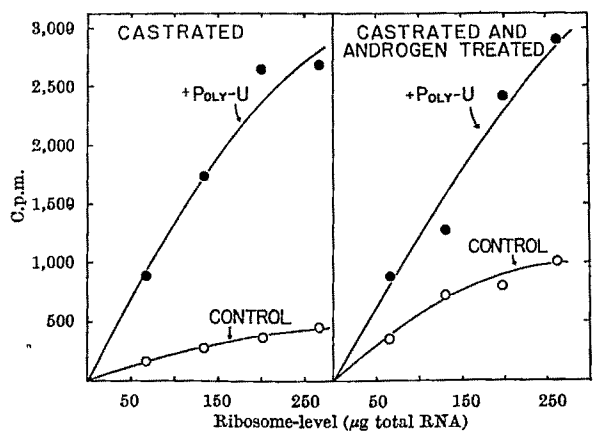

Fig. 1. Effect of polyuridylic acid on transfer of phenylalanine-^{14}C to acid-insoluble material by prostatic ribosomes from orchiectomized rats, with or without treatment with testosterone. Adult Sprague–Dawley rats castrated and killed 72 h after surgery. Testosterone propionate (2 mg) injected into each animal of one group just prior to orchiectomy, and also at 27 and 54 h thereafter. Controls injected with the same volume (1 ml.) of sesame oil solvent. Ventral prostate ribosomes isolated from pooled tissue derived from 60 castrates, and also from 30 androgen-treated castrates. Reaction mixtures as in Table 1. To all tubes was added: 1·1 mg dialysed '*p*H 5 supernate' proteins from testosterone-treated animals and 0·22 mg rat liver *s*RNA charged with L-phenylalanine-^{14}C and 19 other ^{12}C-L-amino-acids (16,800 c.p.m.). Polyuridylic acid (if added): 34 μg. Incubated for 60 min at 37°. Ordinate: radioactivity transferred to protein fraction (ref. 1). Abscissa: amount of ribosomal material (μg total ribosomal RNA) added to each tube

The ability of prostatic ribosomes isolated from recently orchiectomized rats to incorporate phenylalanine from *s*RNA-phenylalanine-^{14}C into the protein fraction was compared with that of similar particles prepared from castrates which were injected with testosterone propionate. In these experiments, the soluble prostatic proteins mandatory for the incorporations added to all vessels were isolated from the androgen-treated castrates, and were present in excess. The experiment depicted in Fig. 1 shows that, in the absence of poly U, the extent of phenylalanine incorporation by prostatic ribosomes isolated from orchiectomized rats was less than a half that found with ribosomes prepared from testosterone-treated castrates. Poly U markedly increased the aminoacyl transfers by ribosomes derived from both groups of creatures. But the stimulatory effect of poly U was greater with ribosomes isolated from the untreated castrates, so that in the presence of poly U the extent of the phenylalanyl transfers by both types of ribosomal preparation was nearly the same. These experiments are in accord with previous investigations[1] on the incorporation of valine into proteins by prostatic ribosomes, and are consistent with the view that testosterone governs the levels of template RNA associated with prostatic ribonucleoprotein particles.

Stimulation of Amino-acid Incorporation by Nuclear Ribonucleic Acid from Normal and Methylcholanthrene-treated Rats

A SINGLE *in vivo* administration of 3-methylcholanthrene (MC) into rats increases the activity of a number of liver microsomal enzyme systems[1–4], and the *in vitro* rate of microsomal amino-acid incorporation into protein when either free or soluble RNA bound amino-acids are used as precursors[4,5]. The stimulatory effect of MC on the microsomal enzymes, benzpyrene hydroxylase[6] and amino-azo dye demethylase[7] is prevented by puromycin, an inhibitor of protein synthesis at the microsomal level. These findings suggest that the MC-induced changes in enzyme activity are due to enzyme synthesis. The *in vivo* administration of actinomycin *D*, an inhibitor of DNA directed RNA synthesis[8], prevents the MC-stimulation of microsomal amino-acid incorporation and inhibits the MC-induced increases in benzpyrene hydroxylase activity[9]. These results indicate that the MC-induced changes in both amino-acid incorporation and benzpyrene hydroxylase activity are dependent on DNA directed RNA synthesis. Since 'messenger RNA' is synthesized by a DNA directed polymerase, these results suggested the possibility that MC may induce alterations in the production of 'messenger RNA'.

Barondes[10] *et al.* have shown that RNA extracted from rat liver nuclei stimulates amino-acid incorporation into protein in an *E. coli* system. They have suggested that the amount of stimulation may represent an assay of the amount of 'messenger RNA' present. We have examined the effect of MC pretreatment on nuclear RNA content and measured the ability of the isolated nuclear RNA to stimulate the incorporation of phenylalanine into protein in an *E. coli* system.

Table 1. Effect of 3-Methylcholanthrene on Nuclear DNA and RNA Content

	DNA (mg) / Wet liver (g)			Nuclear RNA-P / DNA-P		
	Normal	MC	Diff.	Normal	MC	Diff.
Exp. I	2·45	2·54	+ 4%	0·24	0·33	+ 37%
Exp. II	2·52	2·36	− 6%	0·20	0·30	+ 50%
Exp. III	2·48	2·49	< 1%	0·20	0·23	+ 15%

RNA and DNA were extracted from isolated nuclei by the procedure of Fleck and Munro (ref. 15). Homogenates and nuclei were assayed for DNA by the diphenylamine procedure of Dische (ref. 16). RNA was assayed by the orcinol procedure of Albaum and Umbreit (ref. 17).

Groups of eight Sprague–Dawley male rats weighing 35–45 g were injected with 1 mg of MC in 0·25 ml. of corn oil or corn oil only. Sixteen h later the rats were decapitated, the pooled livers homogenized, and the nuclei isolated and purified by centrifugation through hypertonic sucrose[10]. Table 1 shows the results from three experiments. MC pretreatment did not significantly alter the amount of DNA/g rat liver. However, the amount of nuclear RNA was significantly increased by treatment with MC. In three experiments the nuclei from MC-treated rats contained 37, 50 and 15 per cent more RNA than did the nuclei from control rats.

Table 2. Stimulation of ^{14}C-Phenylalanine Incorporation into Protein by Nuclear RNA From Normal and MC-treated Rats

	Nuclear RNA (μg)	Specific stimulatory activity: μμmoles of phenylalanine incorporated per 100 μg of nuclear RNA		
		Normal	MC	Difference
Exp. I	8	11·3	16·2	+ 43%
Exp. II	11	14·8	23·2	+ 57%
Exp. III	25	12·3	15·9	+ 29%

The reaction mixture contained the following in a total volume of 0·33 ml.: 25 μmoles *tris*-hydrochloric acid *p*H 7·8, 3·5 μmoles magnesium acetate, 12·5 μmoles potassium chloride, 1·4 μmoles β-mercaptoethanol, 0·25 μmoles adenosine triphosphate (sodium salt), 0·0075 μmoles guanosine triphosphate (sodium salt), 1·87 μmoles sodium phosphoenolpyruvate, 4 μg crystalline phosphoenolpyruvate kinase (Cal.Biochem.), 0·66 μmoles of potassium acetate, 0·05 μmoles each of 19 L-amino acids, 0·05 μmoles of L-phenylalanine-(U)-^{14}C (S.A. 61·7 mc./μmole in Exp. I and 19·8 mc./μmole in Exps. II and III), 0·050 ml. of dialysed and pre-incubated *E. coli* extract (ref. 11) containing 1·6 mg of protein and 0·1 μg of crystalline DNase. The added nuclear RNA contained less than 2 per cent DNA and less than 2·5 per cent protein. The tubes were incubated for 30 min at 37° C., the reaction stopped with 2·5 ml. of 10 per cent trichloroacetic acid and the proteins isolated by a modification of the method of Siekevitz (ref. 18). Radioactivity was determined by suspension counting in a liquid scintillation counter (ref. 19). The values shown represent the difference between incorporation with added nuclear RNA and the control values without added RNA. The control tubes incorporated 1·6, 5·7 and 2·6 μμmoles of phenylalanine in Exps. I, II and III, respectively. The values represent the averages of duplicate determinations.

A comparison was made of the 'messenger activity' present in the nuclear RNA derived from normal and from MC-treated rats. Nuclear RNA from normal and MC-treated rats was isolated by phenol extraction[10] and tested for its ability to stimulate the incorporation of L-phenylalanine-(U)-^{14}C in the *E. coli* amino-acid-incorporating system of Matthaei and Nirenberg[11]. Table 2 shows that nuclear RNA derived from MC-treated rats stimulates phenylalanine incorporation to a greater extent than equivalent amounts of nuclear RNA from normal rats. In three experiments pre-treatment with MC increased the specific stimulatory activity of nuclear RNA by 43, 57 and 29 per cent. In this incorporating system, microsomal RNA had one-tenth the activity of nuclear RNA and soluble RNA had a slight inhibitory effect.

Methylcholanthrene has been shown to induce several microsomal enzymes in rat liver[1–4] and to increase benzpyrene hydroxylase in a number of other rat tissues[12]. The observed changes in the liver are paralleled by alterations in the protein synthetic apparatus[5,9] and by changes in both the amount and 'messenger activity' of the nuclear RNA. The relationship, if any, between those early MC-induced changes and chemical carcinogenesis remains to be elucidated. Our findings are consistent with the suggestion[13,14] that an early event in carcinogenesis may involve an alteration in the expression of genetic information which would be reflected in an altered metabolism of 'messenger RNA'.

We thank Dr. Creed Abell and Dr. Marshall Nirenberg for assistance and advice concerning the *E. coli* system, and Mr. Haywood Waters for assistance.

Action of 5-Bromo-3-*sec*-Butyl-6-Methyluracil as Regards Replacement of Thymine in Mouse DNA

McGahen and Hoffmann[1] were unable to demonstrate thymine replacement by 5-bromo-3-*sec*-butyl-methyluracil (I) in a thymineless *Escherichia coli* while 5-bromouracil (II) replaced 21 per cent of the thymine under the same test conditions. It was concluded that 5-bromo-3-*sec*-butyl-6-methyluracil is not, therefore, a biological analogue of thymine. The results of an investigation with juvenile mice are presented here.

Weanling Swiss-Webster white mice weighing 7–8 g, 15 days old, were obtained from Pied Piper Farms, Newark, Delaware. Five mice each were injected by oral intubation with (I) (2^{14}C) and with (II) (2^{14}C). The specific activities were 1·13 mc./mmole and 6·05 mc./mmole respectively. Dose schedules were 100 mg/kg twice daily for two days and 50 mg/kg twice daily for the subsequent 8 days. Weights were followed and compared with mice which did not receive compound. Sixteen hours after the final injection, the mice were killed and the livers and spleens were removed. DNA was isolated by the procedure of Marmur[2] and assayed by the diphenylamine method of Burton[3]. Radioactivity was determined by proportional counting.

Table 1. Incorporation of Labelled 5-Bromo-3-*sec*-Butyl-6-Methyluracil (I) and Labelled 5-Bromouracil (II) in Liver and Spleen DNA of Juvenile Mice

Compound	Tissue	Total DNA (μg)	Total compound (μg)
(I)	Liver	1,188	< 0·009
	Spleen	335	< 0·009
(II)	Liver	964	0·243 ± 0·057
	Spleen	232	0·023 ± 0·002

Dosage schedules of 100 mg/kg twice daily for 2 days and 50 mg/kg for the subsequent 8 days by intubation were followed for both compounds. Tissues were taken 16 h after final injection.

Both compounds at 100 mg/kg depressed gain in weight but, at 50 mg/kg, gain in weight was comparable with that of control mice. Livers and spleens appeared normal at death.

As is shown in Table 1, labelled (I) was not detectable in either liver or spleen DNA. Labelled (II), in contrast, was incorporated into the DNA of both liver and spleen.

Thus, it appears that 5-bromo-3-*sec*-butyl-6-methyluracil is not recognizable as a thymine analogue by the mouse within the limits of the test systems utilized in this experiment.

An Antibiotic-like Effect of *Lactobacillus acidophilus*

Until a few years ago, the beneficial effects resulting from the ingestion of the *Lactobacillus acidophilus* in cases of gastro-intestinal disturbances were attributed to the simple overgrowth of the offending pathogen by the *Lactobacilli*. Recently a number of workers have indicated that there was more to the reaction than just competition between strains. The substance produced by *L. acidophilus* has been called variously antagonist[1], lactobacillin[2], lactocidin[3], and antibiotic[4]. All these workers found that the substance was extremely labile, and attempts to isolate it met with failure. A successful method for the visual demonstration of the phenomenon is described here but isolation has not yet been successfully accomplished.

The technique used was similar to the cup-plate assay for antibiotics. Skim milk–digest–tomato juice agar heavily inoculated with a *Staphylococcus* isolated from fæces (Fig. 1) or nutrient agar inoculated with *E. coli* (Fig. 2) was poured in a Petri dish, and allowed to harden. Cups were cut with a sterile, stainless steel ring and the depression so formed filled with agar seeded with *L. acidophilus* and incubated at 37° for 24 h. The plates were then photographed and zones of inhibition stand out clearly. The suppression of growth by production of acid was ruled out because there was no difference in the *p*H of the agar in the cup, in the inhibition zone or in the outer zone. A logical explanation of the therapeutic value of *L. acidophilus* can be predicted on the excretion of an antibiotic-like substance which, although weak and labile, is being continuously produced by the rapidly growing

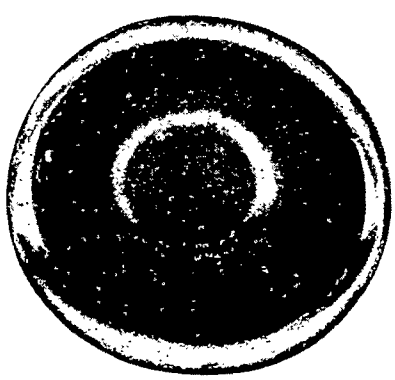

Fig. 1. The plate was seeded with a culture of *Staphylococci* isolated from human fæces and the inner cup seeded with *L. acidophilus*. After 24 h incubation at 37° C, the zone of inhibition is clearly visible

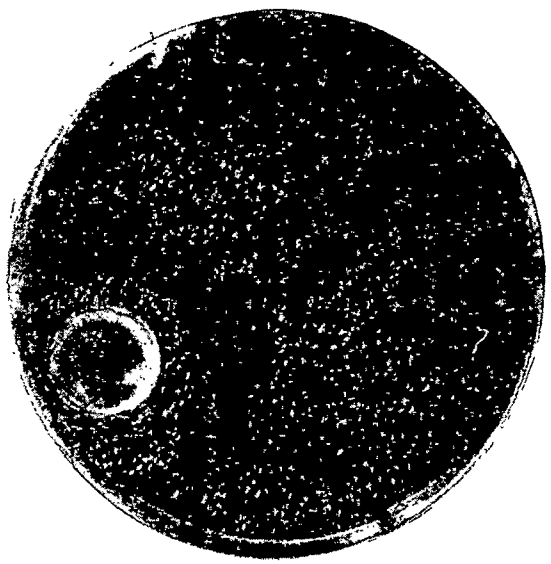

Fig. 2. The plate was seeded with *E. coli* and the cup on the left seeded with *L. acidophilus*. A pronounced zone of inhibition was produced after 24 h at 37° C. The 'ghost' cup on the right contained un-inoculated agar as a control, and has been overgrown by the *E. coli*

lactobacilli and therefore may, in part, account for the *in vivo* as well as the *in vitro* effect.

Reaction of Hydrogen Chloride Gas on RNA and its Component Nucleotides

The release of purines and characteristic sequences of pyrimidine oligonucleotides from DNA has been achieved by the use of diphenylamine and formic acid[1]. In RNA the phosphodiester bonds are extremely acid and alkali-sensitive due to the ease with which cyclic phosphate intermediates are formed involving the 2′ hydroxyl group. In order to limit the possibility of cyclization an attempt was made to carry out a depurination reaction with RNA in the solid phase.

Preliminary investigations have revealed that the degradation of RNA by boron trichloride (in which the RNA is insoluble) shows a measure of specificity and yields purines together with some pyrimidine oligonucleotides[2]. The mechanism of this reaction is thought to involve the production of hydrogen chloride by hydrolysis of the boron trichloride with the water present in intimate association with the RNA.

To test this hypothesis, hydrogen chloride gas has been reacted with RNA in the solid phase and found to be much more efficient than boron trichloride in releasing purines and pyrimidine oligonucleotides. Although water was again found to be necessary for complete reaction, there was no loss of ultra-violet absorbing material as found with boron trichloride.

The experiments were carried out on yeast microsomal RNA[3] which had been freeze-dried at a concentration of 5–10 mg/ml. The water content varied from 12–15 per cent, but could be reduced to 2 per cent by standing over phosphorus pentoxide *in vacuo* for several days. The reactions occurred in tubes into which hydrogen chloride gas was introduced at room temperature and pressure. The tubes were then sealed off and heated in a water bath for a range of times and temperatures. The reaction

product was taken up in buffer at *p*H 7, and estimations made of the adenine, the inorganic phosphorus and the end-group phosphorus liberated.

It was found that 100 per cent release of adenine could be achieved at a temperature of 85° C. The rate of the reaction was found to be dependent on the water content, but below 5 per cent, that is one molecule of water/nucleotide, the reaction only goes to completion when very long reaction times were used. It seems likely the role of water in the reaction is to allow the hydrogen chloride gas to ionize *in situ*. Since the RNA is in the solid phase the possibility of 2′(3′) cyclization and consequent phosphodiester breakage is eliminated. However, the hydrogen ions seem able to split the acid-sensitive purine-glycosidic bonds.

The phosphorus analyses show that after an initial lag, during which some 30 per cent of the purines are liberated, the release of inorganic phosphorus bears a linear relationship to that of the purines and reaches a maximum value of 25–30 per cent of the total phosphorus. The end-group phosphorus reaches a value of 70–75 per cent of the total phosphorus, which is close to the theoretical for a random sequence of bases, on the assumption that the remaining phosphorus lies between the pyrimidine nucleotides. The lag in the appearance of the inorganic phosphorus and its maximum value of 30 per cent support the view that only interpurine phosphorus is released and that two adjacent purines must be liberated before this can occur.

The reaction between hydrogen chloride gas and the component nucleotides of RNA has been studied. The following facts emerge:

(1) The rate of release of adenine and inorganic phosphorus was the same for the 5′ and 2′(3′) adenylic acids, indicating that degradation of the ribose was responsible for the release of the phosphate. This may be compared with the effect of aqueous mineral acids on the adenylic acids in which the 5′ compound is much more resistant to hydrolysis than the 2′(3′) compound[4].

(2) In the case of the pyrimidine mononucleotides two extra zones were found on chromatography in an isopropanol – ammonia – water system[5]. For the cytosine mononucleotide, the R_P value was 0·28 for 2′(3′) cytidine monophosphate and 0·1 and 0·44 for the two unknowns. The faster one was identified as the 2′ : 3′ cyclic phosphate, by its base : phosphorus ratio (1 : 1) and its sensitivity to 0·2 N hydrochloric acid. After 4 h at 37° C in 0·1 N hydrochloric acid, this compound reverted to 2′(3′) CMP. The slower zone gave a base/phosphorus ratio of 1 : 1 but treatment with phosphomonoesterase released only 50 per cent of the phosphorus. If this was followed by treatment with alkali, chromatography revealed zones corresponding to cytidine and cytidylic acid. This confirmed that the slower moving zone was a dimer of cytidylic acid. The faster zone amounted to only about 3 per cent of the total ultra-violet absorbing material but the slower one accounted for as much as 20 per cent.

The formation of dimers from the mononucleotides probably occurs as a result of dehydration of the phosphate group, followed by condensation preferentially with a primary hydroxyl group, that is, the 5′ hydroxyl group of an adjacent nucleotide. The cyclic 2′ : 3′ compound probably arises from condensation with a secondary hydroxyl group, that is, the 2′(3′) hydroxyl group of the same molecule.

The fact that pyrimidine dinucleotides are produced points to the stability of the interpyrimidine nucleotide phosphodiester bonds to hydrogen chloride gas, but invalidates the use of this reaction for quantitative studies.

PHYSIOLOGY

Sex Differences in the Serum Cholesterol Response to Stress in Monkeys

The investigation reported here was undertaken as an initial step in the assessment of central nervous system influences on the transport of serum lipids, with particular reference to their possible role in the pathogenesis of atherosclerosis. The experimental situation dictated that monkeys be moderately restrained for extended periods of time in order that the neural variables could be manipulated under controlled conditions. It became apparent, however, that such restraint itself was a significant variable affecting the level of cholesterol and other lipids in the serum, hence this study was designed to investigate this aspect of the problem in a detailed fashion.

Six male and 6 female rhesus monkeys weighing between 4 and 5 kg were examined. Initially the range of variation of cholesterol in the serum was determined under cage conditions. Blood samples (4 c.c.) were taken at varying intervals ranging from 1 day to 4 weeks. Aliquots from these samples were analysed in duplicate for total, free and esterified cholesterol using the method reported by Vahouney, Borja, Mayer and Treadwell[1] and modified by Goodman, Jarnigen, Meier and Shonley[2]. At least two such determinations were made during the control period before restraint was begun. When the level of serum cholesterol under cage conditions had been established, animals were stressed by confinement in a pillory-type primate chair for periods varying from 10 to 45 days. During this time blood samples were taken on an average of twice weekly. Following the period of restraint, animals were returned to their cages and the level of serum cholesterol determined for several weeks.

During the entire experimental period animals were kept on their normal diet of 3–4 'chimp crackers' (K. F. S. biscuits : protein, 21 per cent; fat, 4 per cent), plus one piece of fruit (apple, orange or banana) daily. Water was offered as desired. The weight of each animal was checked frequently before and after the period of restraint, and determinations of hæmoglobin were carried out at intervals to be certain that changes in these parameters were not significant.

The normal level of total cholesterol in the monkey under cage conditions was found to vary between 125 and 180 mg per cent. The mean value for 6 male monkeys was 159·6 mg per cent and in females was found to be 162·3 mg per cent. The difference between these two values was not statistically significant. Similar comparisons for free and esterified cholesterol fractions are shown in Table 1. These figures are similar to those obtained by other authors[3,4].

The serum-level of total, free and esterified cholesterol decreased under the stress of restraint in both sexes. Although there is considerable variation in the length of time for the maximal response to become manifest, initial indication of the decrease was usually apparent by the third day after the beginning of restraint. The maximum response was evident 5–10 days following the initiation of stress. In all 12 animals the serum-levels remained at this decreased value throughout the period of confinement. In Table 1 it can be seen that in male monkeys the mean total cholesterol value dropped from a level of 159·6 mg per cent to a mean value of 103 mg per cent. This amounted to a decrease of 35·5 per cent from the control period. Also in Table 1 it can be seen that the values for free and esterified fractions showed a proportionate decrease. The decrease in serum cholesterol in the 6 female monkeys was not so great (Table 1). The total cholesterol value for this group dropped from 162·3 to 132·0 mg per cent, which represented a 19·0 per cent fall in the cholesterol value during the period of restraint.

Table 1. Comparative Circulating Cholesterol Levels during Cage and Stress

		Cholesterol					
		Male monkeys			Female monkeys		
		I Total	II Free	III Ester	IV Total	V Free	VI Ester
A	No. of animals	6	6	6	6	6	6
	No. of test – pre-stress	11	11	11	9	9	9
	Mean	159·6 mg %	48 mg %	104 mg %	162.3 mg %	44 mg %	114 mg %
	S.D.	± 14·2	± 7·7	± 12·9	± 17·1	± 8·0	± 13·6
B	No. of animals	6	6	6	6	6	6
	No. of test – stress	68	68	68	67	66	67
	Mean	103 mg %	32 mg %	65 mg %	132 mg %	40 mg %	87 mg %
	S.D.	± 15·0	± 5·3	± 12·0	± 29·0	± 8·7	± 19·2
C	No. of animals	6	6	6	6	6	6
	No. of test – post-stress	20	20	18	20	20	19
	Mean	149·7 mg %	44 mg %	98 mg %	175 mg %	50 mg %	120 mg %
	S.D.	± 18·0	± 12·0	± 15·0	± 26·0	± 7·6	± 21·0

The statistical significance of these changes are summarized in Table 2. It can be seen that the decreases in the cholesterol-levels noted during stress are significant (P value less than 0·001) with the exception of the decrease in free cholesterol for the female group (P value 0·2). The differences in the total and esterified cholesterol response between the male and the female monkey also proved to be significant (P value less than 0·001) although the difference in the responses for free cholesterol was less significant (P value 0·05).

Table 2. Statistical Significance of Changes in Circulating Cholesterol

	t test	P
A I – B I	11·4	< 0·001
A II – B II	8 8	< 0·001
A III – B III	20·5	< 0·001
A I – C I	1·5	N.S.
A II – C II	0·9	N.S.
A III – C III	1·07	N.S.
A IV – B IV	3·0	0·01
A V – B V	1·29	N.S.
A VI – B VI	4·0	< 0·001
A IV – C IV	4·1	< 0·001
A V – C V	1·8	N.S.
A VI – C VI	0·07	N.S.
B I – B IV	7·2	< 0·001
B II – B V	2·0	< 0·05
B III – B VI	8·2	< 0·001

After animals were removed from the restraining chairs and returned to the cage environment their cholesterol-levels promptly increased. Four weeks after stress the male total cholesterol value was not significantly different from the pre-stressed level. In contrast, however, the mean total cholesterol value for female monkeys exceeded the control value by 13 mg per cent, which proved to be statistically significant.

This consistent response in the serum cholesterol-level to restraint is consistent with the findings of Mann and White, who applied other stressing agents to dogs and rats and found a similar decrease in the cholesterol-level, particularly in the esterified fraction[5]. Other investigators have noted a decrease in the serum cholesterol in human beings which could be correlated with the stress of surgery[2,6,7] and with myocardial infarction[8,9], while still others[10] have noted increases in serum cholesterol-levels in association with occupational stresses.

It is difficult as yet to delineate the intermediary mechanisms responsible for changes in the serum cholesterol fractions, or the sex differences noted in response to stress. Presumably such factors as altered rates of synthesis, utilization, excretion or deposition into bodily tissues are involved which must be identified in subsequent radioactively labelled tracer studies. Since in our experiments such factors as diet, weight and circulating hæmoglobin were kept constant, attention must be more sharply directed to the possibility that the psychological factors accompanying restraint played a major part in triggering the metabolic factors which led to alterations in the cholesterol-level. Although the neural and endocrine mechanisms which might subserve such function remain obscure, recent experimental evidence presented by Gunn, Friedman and Byers clearly indicates that the hypothalamic region of the brain may influence the level of circulating lipids and even the induction of arterial atherogenesis[11]. It seems likely that additional experimental evidence will rapidly accumulate to more clearly define the role of cerebral factors in the control of lipid metabolism and its possible relationship to the pathogenesis of atherosclerosis.

Blood Rheology in Cardio-vascular Diseases

The detection of impending thrombosis and initial atherosclerosis is one of the unsolved problems in medicine. In many cases[1,2] diagnosis is made *postmortem* because of lack of methods for the detection and assessment of the pathological states. However, thoughts were expressed recently that one of the factors involved in these states is blood rheology.

Wasilewski suggested[3] that blood has high viscosity in the cases of cardiac decompensation. Aksyantsev observed[4] an increase of blood viscosity in 33 per cent cases exhibiting transient interruption of the cerebral blood circulation. Guyton and Richardson believed[5] that it is logical to accept that viscous changes in blood could greatly influence the venous return to the heart and in this way also affect the cardiac output. Marin and Stefanini postulated[6] that a sudden coagulation of the blood within an apparently intact vascular channel may result from the

combined effect of stasis or slowing of the blood flow, and of a transient 'hypercoagulable' state.

I showed recently[7,8] that an examination of viscosity of blood, if carried out at very low rates of shear (0·001–1 sec^{-1}), renders it easily and readily to distinguish between the normal and abnormal blood. The effect of hæmatocrit value is minimal at low rates of shear, the main contributing phase to the blood viscosity being thixotropy caused by a reversible aggregation of red cells. I have observed that, in few cases examined, the thixotropy and viscosity of blood are up to ten-fold larger in patients suffering from thrombosis and coronary occlusion. These increases in the thixotropy and viscosity at low rates of shear are due to an enhancement of aggregation (flocculation) of the red cells. It appeared that an increased thixotropy and viscosity might indicate a precursor state of thrombosis.

A possible relation between the aggregation of red cells and thrombus formation was envisaged as early as in 1921 by Fahraeus[9].

While it is not the subject of this communication to discuss a relation between thrombosis and atherosclerosis, or the dilemma which of these is the primary and which the secondary event[10–13], it must be stated that if the viscosity of blood is to play a part in these phenomena, it should be capable of changing its value in the various areas or sites of circulation, and should permit the variability of rheological parameters to be quite pronounced at these various sites of circulation.

As the circulation time is very short, being of the order of 1 min or less[14], it might be difficult to see how any pronounced changes of blood viscosity may occur within such short time periods. Indeed, were blood a Newtonian fluid, only slight changes could have been expected in viscosity and attributed to variations in oxygen tension, concentration of the metabolic products, etc.

However, blood happens to be a thixotropic fluid[15]. Its viscosity is greatly affected by time and rate of shear. The complexity of blood rheology is due to the fact that the final viscosity is influenced by three thixotropic mechanisms: (*a*) reversible aggregation of red cells, which is responsible for the greater part of thixotropic properties; (*b*) thixotropy of the red cell (the effects of the interior and of the membrane are grouped together); (*c*) thixotropy of the plasma (most likely due to the hydrogen bondings).

This triple-thixotropic mechanism, each of which components shows a different response to the velocity gradient, is superimposed on the intrinsic properties of flow in circular vessels in which the profile of velocity gradient requires a zero rate of shear in the axis of the vessel. The profile is a function, also, of the visco-elasticity of the vessel wall, of the pressure gradient, of the pulse, of the smoothness of the endothelial lining, etc. Consequently, a great variability of the levels of thixotropy and viscosity can exist at various sites of circulation.

When blood is examined under equilibrium conditions, that is in a homogeneous field of velocity gradient, available in a cone-plate or a cone-cone rotational viscometer[7,16], the fundamental flow curve of the particular sample of blood can be plotted. The flow curve, if measured at low rates of shear and in the absence of anticoagulants, permits an appreciation of the degree of aggregation of red cells under any conditions which might occur in the living body.

The data obtained in an examination of a series of coronary occlusion, venous thrombosis and polycythæmia cases are plotted on a log–log scale as viscosity, in poises, against the rate of shear, in reciprocal seconds (Fig. 1). These blood samples have hæmatocrit of 30–77 per cent, the age of patients being 35–70 years. The control series (marked by open circles) contains hæmatocrits of 36–46 per cent, the age of donors varying from 19 to 55 years. The control series was made up of 10 persons, while the former series was composed of 12 cases. Blood viscosity was tested at 36° C, for a period of up to 4 min after the

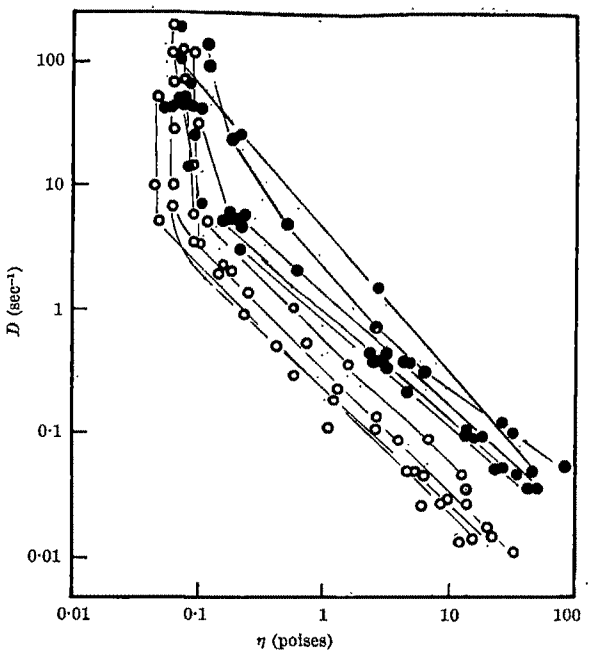

Fig. 1. Viscosity of blood obtained from 10 normal persons (circles) and 12 patients suffering from venous thrombosis, coronary occlusion, and polycythæmia (dots). The faint lines indicate the preponderant direction of the flow curves. Viscosity, in poises, is plotted against the rate of shear, in reciprocal seconds on a log–log scale. The viscosity determinations have been carried out in the absence of anticoagulants, at 36° C, by means of a rotational cone-in-cone viscometer (ref. 7). The clotting of blood occurred in about 4–6 min, and hence two or three samples of blood were required from each person in order to determine the viscosity of unclotted blood over the whole range of rates of shear. Viscosity changes due to clotting are not shown in this figure

extraction of blood. During this period no changes in viscosity of blood can be observed. Clotting starts after various time-periods, depending not only on the intrinsic properties of the particular blood sample, but also on the velocity gradient at which such clotting takes place. The micro-rheology of the clot formed depends on the velocity gradient.

It may be evident from Fig. 1 that a great difference exists between blood of healthy persons and blood of patients suffering from cardio-vascular disorders. It can be seen that an up to 10-fold difference exists in the viscosity—if compared at some constant rate of shear—and in the critical rate of shear. A statistical analysis indicates that the probability is less than 1 in 1,000,000 that such results are due to chance only.

It is feasible that red cells might contribute to thrombus formation through the two mechanisms: (*a*) At low rates of shear, the aggregation of red cells (as indicated by thixotropy) will lead to an intermittent and reversible intravascular sedimentation; this, in its turn, may lead to a formation of irreversible agglutinates and to sludging observed by Knisely[17]. An agglutinate may also plug an entrance to an arteriole or capillary, causing a more or less prolonged stasis. Stasis may follow also an abnormal plasma skimming[18], the degree of separation of plasma flow and red cell flow increasing with the increasing degree of aggregation of red cells. While the fluidity of the red cell interior[19] does not permit local hæmatocrit fluctuations to interfere greatly with circulation in the absence of a pronounced aggregation of red cells, that is not the case when the latter is enhanced by different causes (viruses, high level of fibrinogen, etc.). The degeneration of the red cell surfaces during sedimentation or stasis, due to hypoxia or anoxia, may induce contact activation of plasma clotting, or, alternatively, the red cells themselves might release factors initiating clotting[20]. It is relevant to note that Heilbrunn stated[21] that a clot can be formed by the aggregation of red cells solely.

(*b*) At high rates of shear, or under turbulent conditions, the rupture of red cells (such as mechanically-induced hæmolysis or breakage) may lead to a clot formation of a distinctly different type. This mechanism is now under consideration.

The present series of tests confirms the results obtained in the pilot series[7], and appears to confirm the hypothesis that the increased thixotropy and viscosity of blood (at low rates of shear) are symptomatic of the thrombotic condition. The work continues now on a larger scale in order to substantiate further all deductions and to test the applications of micro-rheological theories and techniques to some cardio-vascular problems.

Absorption of Chymotrypsin from the Intestinal Tract

THE primary objective of work reported here was to determine whether an intact enzyme can be absorbed from the gastro-intestinal tract of adult animals retaining its enzymatic activity.

Plasma enzyme-levels obtained after rectal and intestinal administration of chymotrypsin to healthy, adult, New Zealand White rabbits were compared to those obtained after intramuscular administration. The enzymatic activity appearing in the circulation following the administration of chymotrypsin was measured by the hydrolysis of *N*-acetyl-L-tyrosine ethyl ester (ATEE)[1]. Quantitation was accomplished by comparing the plasma activity with chymotrypsin standards dissolved in the plasma of the animal being studied. The plasma enzyme-levels shown in Fig. 1 represent mean values obtained from five rabbits receiving 10 mg/kg intramuscularly; five rabbits, 20 mg/kg intra-intestinally; and seven rabbits, 20 mg/kg rectally. In all cases the endogenous enzyme-level determined just prior to administration of chymotrypsin was less than 1·0 μg/10 ml. in terms of chymotrypsin activity, and in most cases it was less than 0·5 μg/10 ml.

It can be seen that a significant increase in enzymatic activity results after administration by all three routes. It remained to be shown, however, that this activity was that of chymotrypsin. When chymotrypsin is added to plasma or administered to rabbits, esterase activity against ATEE and benzoyl phenylalanine naphthol ester (BPNE) was obtained, but no activity against tosyl arginine methyl ester (TAME) or benzoyl arginine ethyl ester (BAEE) could be detected. The analytical procedure used for BPNE was a modification of that described by Ravin[2]. The procedures for TAME and BAEE were modifications of that used for ATEE[1]. The specificity obtained eliminates the possibility that the esterase found was plasmin, thrombin, urokinase, or the esterase derived from the first component of complement[3].

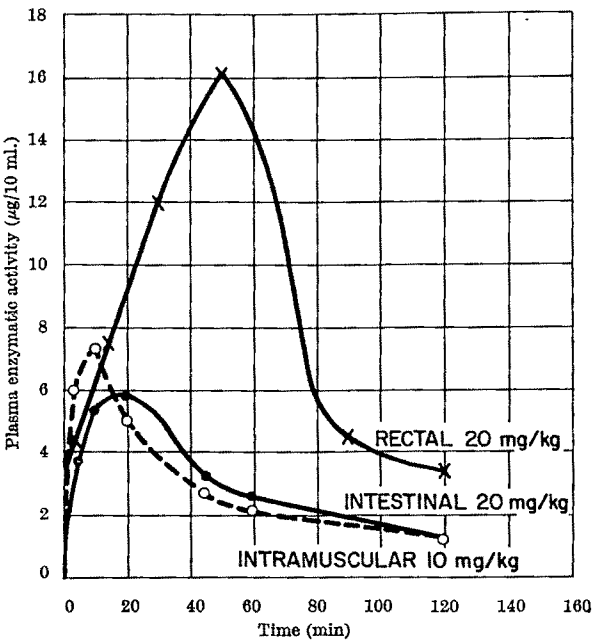

Fig. 1. Mean plasma levels after administration to rabbits

In order to characterize further the esterase appearing in the blood after chymotrypsin administration, we determined the hydrolytic activity of the plasma against two substrates, ATEE and BPNE, after rectal administration of the enzyme at several dosage-levels. The activity of aqueous solutions of chymotrypsin at several concentrations against the same two substrates was also determined. The *in vitro* activity ratio (ATEE/BPNE) was found to be $1{\cdot}82 \pm 0{\cdot}16$. After rectal administration the ratio was $1{\cdot}78 \pm 0{\cdot}49$. It appears, then, that chymotrypsin has been absorbed from the gastro-intestinal tract in an enzymatically active form.

Preliminary results with adult human subjects indicate that here, too, chymotrypsin is being absorbed from the gastro-intestinal tract.

Cæsium–Choline Interaction on Muscle Membrane

IT has been observed that the depolarizing effect of cæsium ions on membrane potential of frog muscle fibres increases when external sodium concentration is replaced by a so-called inert osmotic substitute, such as choline chloride[1]. This dependence on sodium choline of the depolarization of cæsium was in contrast to the independence of the sodium–choline observed on the potassium depolarization.

The purpose of the work recorded here is to determine whether variations in external sodium concentration produce this specific change in the depolarization of cæsium, or whether a cæsium–choline interaction on the muscle membrane mechanisms exists independent of the external sodium concentration. Sartorius muscles of frog were carefully dissected, so as to leave the lower side as free as possible from connective tissue. Muscles were mounted in a special holder to obtain 120 per cent of their resting length by means of a micrometer system. Forty pairs of muscles were used in each experimental solution. The average of membrane potential measurements on 220 muscle cells is represented in each point shown in Fig. 1.

Bathing solutions were made up by adding 10 mM cæsium or 10 mM potassium to standard Ringer's formula (112 mM sodium; 1·89 mM calcium; 2·5 mM disodium hydrogen phosphate; 0·5 mM sodium dihydrogen phosphate). Choline chloride or sucrose was substituted for part of the 112 mM sodium chloride to obtain osmotic equivalence, as indicated in Fig. 1.

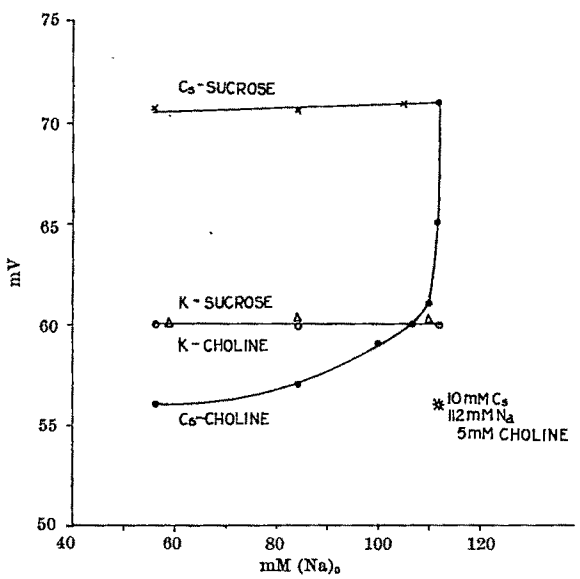

Fig. 1. Membrane potential obtained in 10 mM cæsium or 10 mM potassium at several external sodium concentrations. Osmolarity is adjusted with choline chloride or sucrose. ×, Cæsium sucrose; Δ, potassium sucrose: sodium is replaced by sucrose in order to maintain the osmolarity of the Ringer solution; ●, cæsium–choline; ○, potassium–choline: sodium is replaced by choline to maintain the osmolarity of the Ringer solution. 5 mM choline chloride was added to 10 mM cæsium–Ringer solution

All experiments were carried out at 25 ± 0·25° C and *p*H 7·2–7·3. Muscles were equilibrated for 60 min in 500 ml. of the experimental solution prior to microelectrode penetration. Membrane potentials were measured with glass micropipette electrodes filled with 3 M potassium chloride having a resistance between 10 and 12 megohms. Electrical measurements were made with conventional equipment for this work. Only potentials instantaneously developed with microelectrode penetration in the muscle cell were recorded and used in the data. The standard error of the mean is less than 1 mV.

The magnitude of the depolarization produced by 10 mM cæsium or 10 mM potassium as a function of the external sodium concentration when osmolarity was adjusted with choline chloride or sucrose is shown in Fig. 1. These results show that:

(1) Potassium depolarization is independent of external sodium concentration when osmolarity is adjusted with either choline chloride or sucrose.

(2) Cæsium depolarization is independent of external sodium concentration when osmolarity is adjusted with sucrose, but it is dependent on the external choline concentration.

(3) Cæsium depolarization at constant sodium concentration (112 mM sodium) is further increased when choline is added to the Ringer solution.

The specific change in the cæsium depolarization is produced by choline ions, and it is independent of the external sodium concentration.

The cæsium–choline effect is significantly dependent on choline from 1 to 15 mM and gradually decreases at higher concentrations of choline. The increase in depolarization of cæsium by choline is interpreted as due to a complex choline–cæsium interaction on muscle membrane mechanisms. It indicates that cæsium ions provoke 'activation' of specific membrane 'sites' to choline and, that the number of 'sites' activated must be related to the external concentration of choline ions.

Experiments in progress indicate that:

(*a*) The further increase of cæsium depolarization produced by addition of choline is not due to an increase of cæsium influx. Cæsium-137 was used to measure the uptake of cæsium by the muscle.

(*b*) The rate of penetration of choline labelled with carbon-14 (for example, rate of choline metabolism) in sartorius muscle increases with the presence of cæsium ions.

(*c*) The rate of oxygen consumption is 20–30 per cent higher in 10 mM cæsium than in 10 mM potassium.

These observations show that cæsium ions have far been implicated in enzyme activation in a pathway in which choline may be metabolized. The sequence of transformations associated with cæsium–choline depolarization and 'integration' of choline or acetylcholine system into the metabolic pathways of muscle cells is under investigation at present in this laboratory.

Facilitated Diffusion of Oxygen through Hæmerythrin Solutions

Hæmoglobin present in water solution facilitates the steady-state diffusion of oxygen through that solution[1,2]; the total oxygen flux is greater than the flux through an equivalent protein solution, for example, a solution of methæmoglobin. The hæmoglobin-mediated oxygen flux may be considered to be additive to the simple diffusion flux of oxygen. Fig. 1, which although obtained with the protein hæmerythrin is entirely typical of results obtained with hæmoglobin, reveals that the flux mediated by an oxygen-binding protein is constant in amount for a particular protein concentration and independent of the oxygen partial pressure difference across the solution at oxygen partial pressures sufficient to saturate largely the carrier. This property has the interesting consequence that at the low oxygen partial pressure presumably existing in tissue the hæmoglobin mediated flux would be expected to make up the largest part of the total oxygen flux. Quite possibly the facilitation of oxygen diffusion in the interior of muscle cells is a major function of myoglobin.

The mechanism of facilitated oxygen diffusion is not immediately apparent. The question arises whether some particular property of hæmoglobin is required or whether other substances that reversibly bind oxygen will facilitate

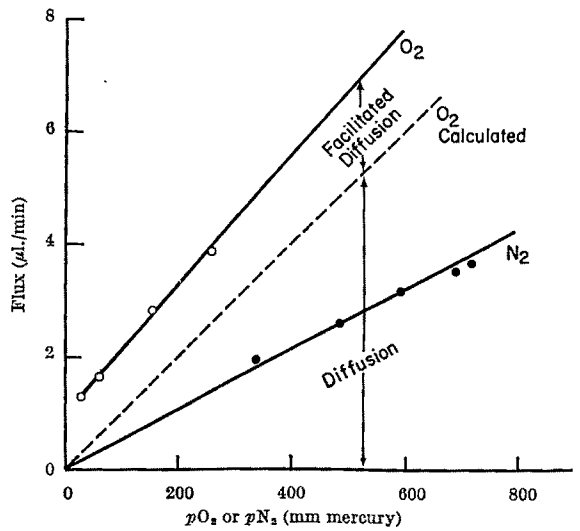

Fig. 1. Gas fluxes through a hæmerythrin solution. The solution is supported in a 'Millipore' filter (45 mm diameter) which separates two gas-filled chambers. The solid lines are the simultaneously measured fluxes of oxygen and nitrogen. The dashed line is the oxygen flux expected for simple diffusion

oxygen diffusion. The respiratory pigment hæmerythrin which occurs in the cœlomic corpuscles of certain marine worms offers an opportunity to test this question. Hæmerythrin (reviewed in refs. 3 and 4) is an iron-containing protein of molecular weight 105,000, which is thought to be made up of eight sub-units of molecular weight 14,000 (ref. 5). Each sub-unit contains two iron atoms and combines reversibly with one molecule of oxygen. No hæm group has been detected. The oxygen-combining capacity per weight of protein is approximately the same as in hæmoglobin.

A solution of hæmerythrin was prepared by lysis of washed cœlomic corpuscles from the sipunculid worm phascolosoma (*Golfingia gouldii*). The oxygen-combining capacity of this solution, estimated from the iron content ($2{\cdot}2 \times 10^{-2}$ g equiv. iron/l.), was 245 ml./l. The partial pressure of oxygen required for half-saturation of the hæmerythrin in this solution was estimated spectrophotometrically by the method of Wyman *et al.*[6] to be 2·2 mm mercury. The measurements described here were made at oxygen partial pressures greater than 25 mm mercury, which was sufficient to ensure full saturation of the hæmerythrin with oxygen.

A 'Millipore' filter (Type *HA*, Millipore Filter Corporation, Bedford, Mass.), wetted with the hæmerythrin solution, was clamped between two chambers, one of which contained thoroughly stirred mixtures of oxygen and nitrogen, saturated with water vapour. A rapid (80 ml./min) stream of water-saturated helium was passed through the second chamber. The helium stream was directed at the surface of the 'Millipore' filter to ensure rapid mixing with the oxygen and nitrogen passing through the hæmerythrin solution, and thus provide very low partial pressures of these gases at the 'Millipore' surface. The effluent helium stream passed to a gas sampling valve by means of which portions of the stream were introduced into a gas chromatograph for analysis. The flux of gases through the hæmerythrin solution is given by the product of the flow-rate and the fractions of oxygen and nitrogen in the effluent stream.

Fig. 1 presents the experimentally determined fluxes of oxygen and nitrogen as functions of the partial pressure of these gases in the mixtures exposed to the hæmerythrin-loaded membrane. The solid lines are drawn through the experimental points. The dashed line is the oxygen flux expected from simple diffusion. The latter can be established either by measurement in separate experiments or approximated from the determined nitrogen flux by the relation:

$$\text{Flux } O_2 = \text{Flux } N_2 \cdot \frac{\alpha O_2}{\alpha N_2} \times \frac{\sqrt{28}}{\sqrt{32}}$$

where α is the solubility coefficient in water, and 32 and 28 are the molecular weights of the gases. It will be noted that the determined oxygen flux is greater than the calculated diffusion flux by a constant amount. This difference is the hæmerythrin facilitated oxygen flux. It is of about the same magnitude as the oxygen flux facilitated by a hæmoglobin solution of equivalent oxygen-binding capacity.

It is concluded that the hæm group is not required for the facilitated diffusion of oxygen.

Metabolism of Endogenous Substrate in the Retina

THE use of radioactively labelled material has made possible a direct appraisal of the proportions of metabolic products derived from a particular substrate in an isolated tissue. Such *in vitro* metabolic studies on the young retina have shown that the respiratory carbon dioxide produced by the tissue during the oxidation of labelled exogenous glucose substrate does not correspond to the measured oxygen uptake. Cohen and Noell[1] found in the young, non-functional rabbit retina that about 65 per cent of the respiration appeared to be due to the oxidation of endogenous non-carbohydrate material, even when adequate glucose was available to the respiring tissue, whereas in the adult rabbit retina glucose oxidation accounted for the major proportion of respiration.

In the developing rat retina, Reading and Sorsby[2], using universally labelled ^{14}C-glucose, found in retinæ from 10-day-old animals (that is, where the retina had not become functional) that the quantity of glucose converted to carbon dioxide corresponded to only 25 per cent of the total oxygen uptake. At 21 and 60 days after birth, glucose to carbon dioxide conversion corresponded to 55 and 67 per cent, respectively, of the oxygen uptake.

These findings suggest that the retina oxidizes an endogenous substrate material and the proportion of this substrate contributing to the respiration is greater during the early stages of development than after the tissue has undergone full differentiation and assumed its full functional capacity.

It was decided to investigate the characteristics of the respiration of the retina in the absence of added substrate, in comparison with retina in the presence of adequate glucose. In addition, determinations of respiratory quotient values for retina at different stages of development, in the absence of added substrate, were carried out in an attempt to throw some light on the nature of the endogenous substrate being utilized. Material for the experiments was obtained from black-hooded (*PVG*) rats which were originally obtained from Glaxo Laboratories, Ltd., and from Dutch rabbits. In all experiments, litter mates were used. Rats were killed by cervical fracture, rabbits by injection of air into an ear vein. The eyes were excised and retinæ dissected out as rapidly as possible, the tissue being kept under ice-cold oxygenated saline during these operations. Retinæ were incubated at 37° C for periods of 1 h in Krebs–Ringer phosphate medium[3] in an atmosphere of oxygen, using a conventional Warburg

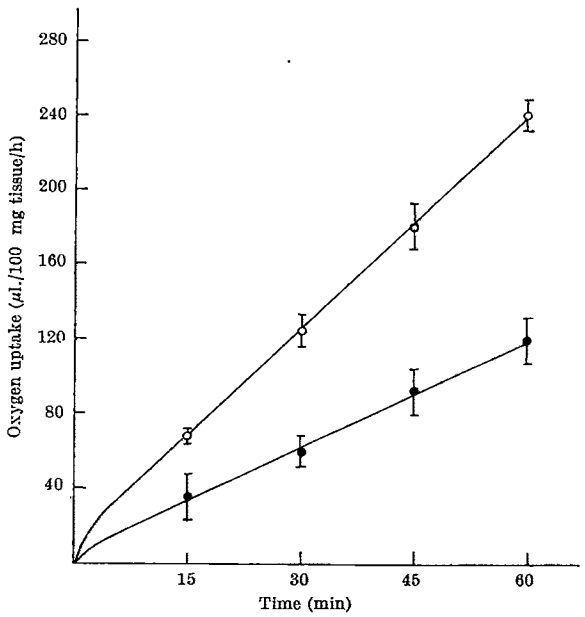

Fig. 1. Comparison of oxygen uptake by rat retina in the presence and absence of added glucose. Experimental details: Rats, black-hooded (*PVG*) litter mates, 40 days old. Four retinæ (wet weight approx. 40 mg) per flask, incubated in 1 ml. Krebs–Ringer phosphate medium at 37° C in an atmosphere of 100 per cent oxygen. ○, 0·1 per cent glucose in medium; ●, no glucose in medium. Horizontal lines show limits for each estimation

apparatus. Respiratory quotient determinations were made using the second method of Dickens and Simer[4]. This method requires two aliquots of relatively large weight of the tissue under examination and, in order to maintain homogeneity in the samples, rabbit rather than rat retina was chosen for respiratory quotient determinations. The time required for dissection and preparation of rabbit retina was much less than that for the rat, where a greater number of animals would have been required to produce a similar weight of tissue.

In the adult rat retina, without added carbohydrate substrate, oxygen uptake was linear over a period of at least 1 h. The rate of oxygen uptake was half that when glucose was available to the tissue, all other conditions being identical (Fig. 1). It would appear therefore, in the adult rat retina, that oxidation of endogenous material accounts for about 50 per cent of the measured oxygen uptake.

Table 1. Respiratory Quotients (R.Q.) and Qo_2 Values for Rabbit Retina in the Absence of Added Substrate

Age	R.Q.	Qo_2
15 days	0·75	−88·0
26 ,,	0·89	−94·0
70 ,,	1·02	−137·0

Qo_2 values expressed as mm³/100 mg wet weight tissue/h.

Respiratory quotient determinations carried out on retinæ taken from rabbits at ages 15, 27 and 70 days gave values of 0·75, 0·89 and 1·02 respectively (Table 1). These results are suggestive of a gradual change in the character of the endogenous substrate being oxidized, concomitant with development and functional maturation of the retina. In the young retina, where endogenous respiration is relatively high, the respiratory quotient value indicates an oxidation of material of a lipid nature. As development proceeds, the value of the respiratory quotient indicates a mixed carbohydrate–fat oxidation, and an entirely carbohydrate oxidation in adult tissue.

Futterman and Kinoshita[5] suggested lactate as the major endogenous substrate for retina, since aerobic lactic acid utilization by homogenates of cattle retina was unimpaired by the presence of sufficient iodoacetic acid to block glycolysis. This possibility seems to have been ruled out by the work of Cohen and Noell[1], who demonstrated, by the use of radioactive material, that glucose was the sole source of lactate carbon in the intact rabbit retina. This implies, of course, that in the absence of a source of carbohydrate lactate would not be available to the retina. In addition, there is the possibility that results obtained with retinal homogenates cannot be interpreted for the intact tissue, since it is well known that the metabolic characteristics of the retina are markedly changed by loss of integrity of the cells[6].

The classical researches of Warburg *et al.*[7] established the high rates of aerobic and anaerobic glycolysis in the retina, and, in consequence it has long been accepted that the mammalian retina depends almost entirely on glucose for its energy requirements. It seems likely, however, that the young developing retina to a large extent utilizes endogenous fatty material for oxidative purposes. The character of this substrate changes with increasing age, until at adult stages it is entirely of a carbohydrate nature. In addition, the capacity of the retina to utilize endogenous substrate of any nature decreases with increase in age.

Secretion of Magnesium and Calcium in Parotid Saliva of Sheep

With a conscious sheep, Kay[1] confirmed the findings of Coats and Wright[2], obtained with anæsthetized sheep, that the concentration of Na^+ and K^+ in parotid saliva showed a strong inverse correlation. However, neither author reported the saliva concentrations of Mg^{2+} and Ca^{2+}. McDougall[3] estimated the average magnesium concentration in parotid saliva of sheep as 0·6 m.equiv./l. and that of calcium as 0·4 m.equiv./l. Average values of 0·36 and 0·33 m.equiv./l. for saliva magnesium and calcium concentrations, respectively, were obtained here.

Saliva samples were obtained from a conscious Merino × Welsh Mountain ram after the left parotid duct had been cannulated some days earlier by the method described by Ash and Kay[4]. Secretion rates were measured for each sample and the saliva concentrations of magnesium estimated by atomic absorption flame photometry, those of calcium by high-temperature emission flame photometry and those of sodium and potassium by low-temperature emission flame photometry. The sheep was maintained sodium replete by the daily intraruminal administration of 50 g sodium bicarbonate.

Fig. 1 shows the relationship obtained between saliva magnesium concentration, x, and saliva secretion rate, y. This could be expressed in the form:

$$y = 8{\cdot}0\ e^{-5{\cdot}3x}$$

A similar exponential relationship was obtained between saliva potassium concentration and saliva secretion rate by Coats and Wright[2].

The saliva Ca^{++} concentration showed no significant correlation with changes in saliva secretion rate within the range studied, 0·11–2·39 g saliva/min. In accordance with the results of Kay[1] and Coats and Wright[2], an inverse correlation was noted between the concentration of Na^+ and K^+.

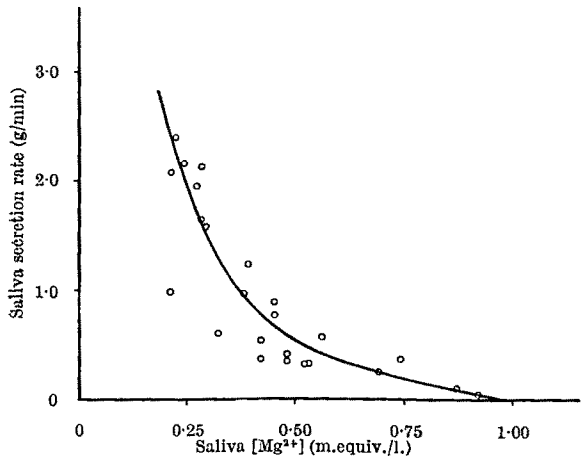

Fig. 1. Relationship between saliva magnesium concentration and saliva secretion-rate

The intravenous administration of 500 μg D-aldosterone was followed by a small fall in saliva Na^+ concentration, a marked rise in K^+ concentration and a small rise in Mg^{2+} concentration, after correction for the effect of variation in salivary secretion rate. There was no significant change in the saliva Ca^{2+} concentration. It thus seems likely that the re-absorption of Mg^{2+} from the salivary ducts is influenced in a manner similar to that of K^+ by the plasma concentration of aldosterone. This extends the similarity between the effects of mineralocorticoids on potassium and magnesium homeostasis already observed in the sheep by Care and Ross[5].

An increase in the plasma magnesium concentration to twice its normal value was associated with an increase in the saliva Mg^{2+} concentration, after correction for the effect of secretion rate, but there was no effect observed on the concentrations of Ca^{2+}, Na^+ or K^+.

No sudden increase was noted in the secretion rate of parotid saliva Mg^{2+} by a sheep, the diet of which was changed sharply from hay to heavily fertilized grass fed in the frozen state. A decrease in the efficiency of magnesium absorption is associated with the hypomagnesæmic response to such a dietary change[6]. Thus it is unlikely that an increase in the salivary secretion of Mg^{2+} is a contributory factor in the ætiology of this type of ruminant hypomagnesæmia.

HÆMATOLOGY

Demonstration of a Hæmolytically Active 11 *S* Component of Rabbit, Guinea Pig and Human Serum by means of Antigen – Antibody Precipitates

Taranta, Weiss and Franklin[1] and Müller-Eberhard and Kunkel[2] independently described a heat-labile substance in normal human serum which was capable of precipitating soluble aggregates of γ-globulin. The latter authors[2] isolated the factor from aggregated γ-globulin precipitated with normal human serum in the presence of ethylenediamine tetraacetic acid (EDTA). They showed that it was a euglobulin with an S^0_{20w} of 11 and further demonstrated that it constituted a component of hæmolytic complement distinct from the known components of the human system. They termed it the "11 *S* component". It will be shown that this same component is also present in guinea pig and rabbit serum and that it can be removed from these sera with immune precipitates in the presence of EDTA.

Pools of rabbit, guinea pig and human serum were adsorbed with preformed, washed egg albumin–rabbit anti-egg albumin precipitates prepared at equivalence. The adsorption of each serum was carried out at 4° C in the presence of 0·01 M EDTA using 1·0 mg of precipitate nitrogen per 1 ml. of serum. Guinea pig and rabbit serum required only 15 min incubation time with precipitate although on occasion it was necessary to incubate rabbit serum for as long as 30 min in order to remove the hæmolytic activity. With human serum, however, the time of incubation had to be extended to 24 h and even then an additional adsorption with 0·5 mg preformed precipitate nitrogen per ml. of serum for 3 h was needed before a suitable non-hæmolytic serum was obtained.

The supernatant serum after removal of the precipitate and the addition of 0·01 M Ca^{++} and Mg^{++} was termed the R_{11S} (ref. 2); that is, a serum deficient in the 11 *S* component. The 11 *S* component used to restore hæmolytic activity to the R_{11S} was prepared from normal human serum using soluble aggregates of human γ-globulin exactly as described[2].

Table 1. Restoration of Hæmolytic Activity of Rabbit, Human and Guinea Pig R_{11S} by Isolated Human 11 *S*

Species	Dilution	CH_{50}/ml.			Percentage restored
		Original serum	R_{11S}	R_{11S} + 11 *S*	
Rabbit	1/10	46	0	57	124
Human	1/50	166	0	122	75
Guinea pig	1/300	900	0	563	63

Fig. 1 shows the percentage of lysis obtained when untreated rabbit serum, R_{11S}, and R_{11S} with 11 *S* were added to sensitized sheep red blood cells using the complement assay system described by Kent *et al.*[3]. The 11 *S* component used was in a volume of 0·1 ml. containing 7 μg of total protein. Essentially the same results were obtained using the R_{11S} prepared from human and guinea pig serum. However, as Table 1 shows, the restoration of hæmolytic activity of human or guinea pig R_{11S} by the

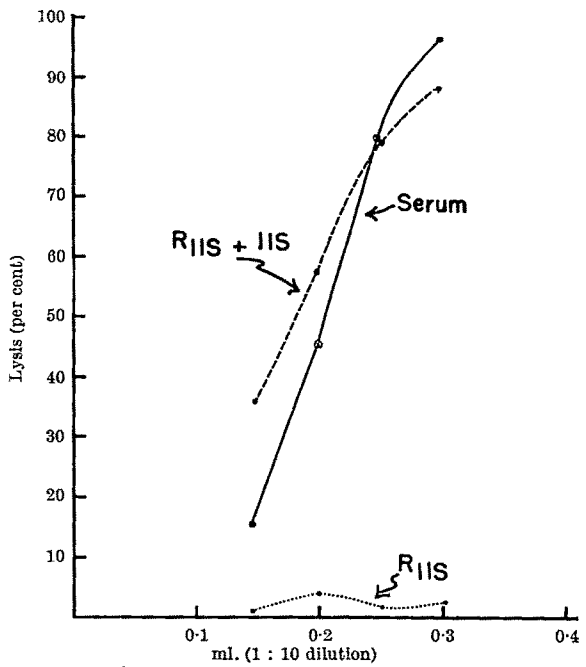

Fig. 1. Hæmolysis curves demonstrating loss of hæmolytic activity of rabbit serum by depletion of 11 *S* component (R_{11S}) and regaining of activity on addition of a preparation of isolated 11 *S*

human 11 S was not complete. In these experiments, there was 75 per cent restoration of the human and 63 per cent restoration of the guinea pig R_{11S}.

The 11 S component did not contain the first component of complement (C'1) and was inactivated by heating at 56° C for 30 min as described by Müller-Eberhard. It was also not inhibited by pre-incubation with 50 μg of soy bean trypsin inhibitor at room temperature for 15 min.

The lack of hæmolytic activity of the rabbit, human and guinea pig R_{11S} was not due to a lack of C'1. When tested with an $R1$ alone, hæmolysis was not obtained with any of the R_{11S}, but when tested with an $R1$ fortified with 11S the rabbit R_{11S} showed full C'1 activity, the human contained 77 per cent and the guinea pig showed 50 per cent of the C'1 activity of the original serum.

Whether there was an actual loss of C'1 activity in the preparation of the human and guinea pig R_{11S} or whether the foregoing results reflect the well-known inadequacy of the classical component reagents is not known.

HISTOCHEMISTRY

Thalamic Microneurones

In view of the recent deduction by experimental neurophysiologists[1] of the presence of 'interneurones' in the region of the somato-sensory relay (ventralis posterior) nucleus of the thalamus, it would seem timely to recollect that such neurones are almost certainly demonstrable under the light microscope (and generous to recall that the presence of such *Schaltzellen* was deduced sixty-seven years earlier, from brilliant experimental and pathoanatomical observations, by von Monakow[2]). It is rather surprising that the first histological report of thalamic 'microneurones' (to the 1949 International Neurological Congress[3]) has not been confirmed by anatomists outside Germany[4,5]. The explanation probably rests largely in the fact that in most of the commoner mammals used in neuro-anatomical research the somata of the microneurones are too similar in size and shape to those of astrocytes to be distinguished with confidence. From extensive surveys in the macaque (in celloidin-embedded, well-differentiated cresyl-violet preparations) I have ascertained that the microneurones tend to be proportional in size to the macroneurones in most of the sub-nuclei of the thalamus, and hence largest in nucleus ventralis posterior pars gigantocellularis. Unfortunately, again, the most commonly studied sub-primates do not possess a conspicuous pars gigantocellularis. In the dog, however, it is well developed, and its microneurones are as prominent as in the macaque. In both the dog and the rabbit, but not so far in the macaque, I have obtained occasional thalamic sections, impregnated by the silver sulphide method and counterstained by methylene blue[6], in which the display of heavy-metal granules is distinctly more condensed, and hence blacker, in the cytoplasm of the astroglia than in both orders of neurones.

In man the somata of the thalamic microneurones are, in a majority of the sub-nuclei, larger and less rounded than those of the astroglia, and hence can be confidently counted here, especially in paraffin-embedded cresyl-violet-stained sections. Their incidence ranges from about 1 microneurone to 3 macroneurones in nuclei ventralis posterolateralis, anterior and dorsomedialis, through about 1 microneurone to 6 macroneurones in the other main sub-nuclei, to about 1 microneurone to 12 or more macroneurones in the intralaminar group and reticularis. (They occur also in, for example, habenular and mammillary nuclei.) They seem as evenly distributed throughout their respective sub-nuclei as are the macroneurones, and in Nissl stains do not give the impression of being specially related topologically to particular macroneurones or groups of these. Golgi preparations show no obvious inter-relationship of processes, either, between the two neurone types; but, of course, the one-in-forty selectivity of Golgi impregnation provides an unsatisfactory tool for testing visually the synaptic validity of von Monakow's *Schaltzellentheorie*[2] and the closely similar schema of the Canberra workers[1].

The most clear-cut picture of microneurones is obtained, in my experience, in combined 'Luxol' fast blue and cresyl-violet preparations from multiple sclerosis brains with plaques affecting the thalamus: topology is optimal, any lipofuscin is conspicuous, background myelin is minimal, and astroglial nuclei are characteristically 'activated'. Next in clarity come those of the normal anterior nucleus with its richly staining neuronal cytoplasm and its paucity of myelinated fascicles. In diabetics the particularly deep-purple character of the lipofuscin in 'Luxol' preparations helps appreciably in distinguishing microneurone features from astroglial ones; and Lemieux[7] has described how clearly the still more conspicuous cytoplasmic lipoids in amaurotic family idiocy show up "small type thalamic neurones". If Turner's[8] "big spider cells" in the human thalamus stained by methylene blue and peroxide were in fact microneurones, then I can confirm his observation of their pathology in paretic dementia, in so far as the microneurones appear to be preferentially neuronophaged in the thalamic sections preserved in this laboratory from a series of congenital G.P.I. brains. I have been unable to discover any consistent microneurone pathology in any category of organic brain condition now commonly seen in a hospital for mental disorders; have satisfied myself that these small neuronal entities offer nothing obvious towards elucidation of the pathogenesis of the schizophrenic or the affective psychoses; but have not investigated them in mental defectives where the brain is otherwise microscopically normal. In an isolated case of ether-anæsthesia catastrophe with 50-h survival[9], I had the impression that the thalamic microneurones had been earlier overwhelmed by hypoxic ischæmia than the macroneurones. On that occasion I speculated on their conceivable role as step-function 'switches' (in ignorance of von Monakow's term), analogous to those in Ashby's cybernetic homeostats, concerned in an attention-focusing mechanism.

In my original report[3], based mainly on brains from leucotomized patients with up to 5 years' survival of the operation, I said that thalamic microneurones "do not appear to degenerate after cortical damage". I have since confirmed this in the anterior nuclei of macaques with 8–15 months' survival of cingulectomy, and in the dorsomedial nuclei of brains from further leucotomy patients with less than 10 years' survival. Some of the most impressive microscopic fields displaying only microneurones, apart from proliferated gliocytes, are to be seen in these preparations. In patients with 9, 9½, 11, 12, 14 and 16½ years' survival of the operation, the centres of the largest gliosed zones in dorsomedialis of the last four lack microneurones as well as macroneurones, and there is then an intermediate halo in which normal numbers of microneurones become visible before normal numbers of macroneurones. (The one short-survival case which showed neurone-free haloed zones similar to this was the only one where the patient had been given a course of insulin-coma therapy subsequent to the operation.)
